Preface

Every four years, as we plan the next edition of *Treatment of Skin Disease*, the editors ask ourselves these questions: Do we need another edition? Has enough changed in the practice of dermatology to justify all the work needed for another edition? Thanks to extraordinary advances in our specialty, the answer has always been an emphatic *yes*.

The last four years has seen dramatic changes in the treatment of common dermatologic conditions like psoriasis and atopic dermatitis. Anti-IL-17 antibodies were only investigational four years ago, and now two, secukinumab and ixekizumab, are approved and a third antibody to the IL-17 receptor, brodalumab, has also been approved and is about to enter the market for psoriasis. Pure anti-IL-23 antibodies were only in experimental stages based on the earlier success of ustekinumab which blocks both IL-23 and IL-12. Guselkumab has now been released and tildrakizumab has completed phase III trials and will hopefully be approved in the coming months. Another anti-IL-23 antibody, risankizumab, is already in phase III trials and has very promising results in phase II, and other anti-IL-23 antibodies are already in development for psoriasis. Dupilumab, an anti-IL-4/IL-13 antibody has just been approved for moderate to severe atopic dermatitis, and crisaborole, a topical phosphodiesterase 4 inhibitor has been introduced for the treatment of mild to moderate atopic dermatitis. Tofacitinib, a janus kinase inhibitor, has shown substantial efficacy in psoriasis and atopic dermatitis, though regulators have not allowed approval for those diseases thus far. Because the drug is available for rheumatoid arthritis in the US, it has been used to treat other inflammatory skin diseases like alopecia areata and vitiligo with striking success.

Treatment of less common conditions has advanced as well. Four years ago, we were just beginning to use the first hedgehog inhibitor for catastrophic basal cell carcinomas. We now have a second oral hedgehog inhibitor, sonidegib. We also have many new uses for drugs introduced earlier. The best example is the approval of adalimumab for the treatment of hidradenitis. Dermatologists were only starting to prescribe omalizumab for chronic idiopathic urticaria, and that treatment, first approved for asthma, is now well established for chronic urticaria.

Advances in the treatment of rare diseases have been extraordinary as well. Sildenafil is now commonly used for lymphatic malformations, and topical rapamycin is commonly used for facial angiofibromas. In some countries, afamelanotide has been approved for the treatment of erythropoietic protoporphyria.

Off label uses of many old therapies have also been tried for many dermatologic diseases and are covered well in the updated versions of our chapters. Many of the drugs approved for adults are also being studied in children, and hopefully we will see many new therapy approvals for pediatric indications.

The commercial successes of multiple biologic, oral and topical therapies for dermatologic indications, has sparked a tremendous amount of research and innovation in our field. As we send this edition to the printer, new oral agents are being studied for inflammatory skin diseases. Both topical and oral janus kinase inhibitors including ruxolitinib, baricitinib, and tofacitinib are being studied for alopecia areata, vitiligo, psoriasis, and atopic dermatitis. Investigation of phosphodiesterase inhibitors for itch and for other inflammatory skin conditions are underway. Creams that change the bacterial flora of conditions like atopic dermatitis are also in development, and numerous biologic therapies like nemolizumab for itch and anti-IL-13 antibodies like lebrikizumab and tralokinumab are being studied for atopic dermatitis.

Every chapter of this new edition has been carefully revised and updated with the latest innovations. As you read on, it will become clear how profoundly the rapid pace of progress is impacting on the benefits we can offer our patients - this is such an exciting time to be practising dermatology.

Acknowledgments

The editors want to acknowledge the constant, outstanding support they have received from Elsevier staff, particularly Trinity Hutton, Humayra Rahman Khan, Russell Gabbedy, Charlotta Kryhl, Joshua Mearns, and Srividhya Vidhyashankar. Many of the chapters were based on chapters written by authors of previous editions who created the excellent foundation on which our new chapters have been built. We must also thank our colleagues and residents who provided many of the clinical photos used in this edition and we offer a special thank you to Joe Bikowski, MD who gave us access to his spectacular collection of clinical photographs.

Dedication

We thank our spouses Madeleine Lebwohl, Rhonda Schnur, Rebecca Berth-Jones and Susan Christopher-Coulson for their unwavering support of this endeavor.

Evidence Levels

Each therapy covered has been assigned a letter from A (most evidence) to E (least evidence), signifying the amount of published evidence available to support its use. The following criteria were used in making this classification.

A: Double-Blind Study

At least one prospective randomized, double-blind, controlled trial without major design flaws (in the author's view).

B: Clinical Trial ≥ 20 Subjects

Prospective clinical trials with 20 or more subjects; trials lacking adequate controls or another key facet of design that would normally be considered desirable (in the author's opinion).

C: Clinical Trial < 20 Subjects

Small trials with fewer than 20 subjects with significant design limitations, very large numbers of case reports (at least 20 cases in the literature), or retrospective analyses of data.

D: Series ≥ 5 Subjects

Series of patients reported to respond (at least five cases in the literature).

E: Anecdotal Case Reports

Individual case reports amounting to published experience of fewer than five cases.

Acanthosis nigricans

Lawrence S. Feigenbaum, and Ponciano D. Cruz Jr.

Acanthosis nigricans is characterized by hyperpigmented, verrucous or velvety plaques that usually appear on flexural surfaces and in intertriginous regions. It is most commonly seen in individuals with insulin resistance states, especially obesity, and less frequently in association with other metabolic disorders, genetic syndromes, drugs, and malignancy. Although hyperinsulinemia, hyperandrogenemia, circulating antiinsulin receptor antibodies, and activating mutations

in fibroblast growth factor receptor (as found in both familial variants and syndromes associated with skeletal dysplasia such as Crouzon syndrome) have been implicated as causal factors, the precise pathogenesis is not yet known.

Management Strategy

The management of patients with acanthosis nigricans addresses the underlying cause, the identification of which requires a salient history, a targeted physical examination, focused diagnostic laboratory tests, and, occasionally, radiologic evaluation.

Relevant historical information includes age at onset, presence or absence of a family history, medications, transplant history, and presence or absence of symptoms related to hyperinsulinemia (with or without diabetes mellitus), hyperandrogenemia (with or without virilism), hypercortisolism, and internal malignancy (with or without weight loss).

Drugs reported in association with acanthosis nigricans include niacin, corticosteroids, estrogens, testosterone, insulin, aripiprazole, fusidic acid, protease inhibitors, triazinate, diethylstilbestrol, palifermin, and recombinant growth hormone. Acanthosis nigricans has also been associated with renal and lung transplantation.

Physical examination should document obesity, masculinization, lymphadenopathy, cushingoid features, and organomegaly. Initial laboratory screening should include fasting blood glucose and serum insulin tested concurrently to confirm or exclude insulin resistance (insulin value inappropriately high for the glucose level).

Because obesity is the most common cause of both insulin resistance and acanthosis nigricans, it is the likely cause of acanthosis nigricans in overweight patients with no historical suggestion of culprit drugs or evidence of malignancy.

Rare causes of insulin resistance and acanthosis nigricans include the type A and B syndromes, the former characterized by defective insulin receptors and manifesting typically in young girls with masculinized features, and the latter reported mostly in women with circulating antiinsulin receptor antibodies in association with autoimmune disorders such as lupus erythematosus. Other causes of insulin resistance and acanthosis nigricans are polycystic ovarian disease, HAIR-AN syndrome (hyperandrogenism, insulin resistance, and acanthosis nigricans), familial lipodystrophies, and various

endocrinopathies.

The most commonly associated malignancy is gastric adenocarcinoma. Less frequent associations are endocrine, genitourinary, lung, and gastrointestinal carcinomas, and, even more rarely, melanoma and cutaneous T-cell lymphomas/Sézary syndrome. Malignant acanthosis nigricans may coexist with other cutaneous markers of internal malignancy, such as tripe palms, the sign of Leser-Trélat, florid cutaneous papillomatosis, and hyperkeratosis of the palms and soles (tylosis). If malignancy-associated acanthosis nigricans is suspected, the initial laboratory screen may include a complete blood count, stool test for occult blood, and chest and gastrointestinal radiographs, as well as gastrointestinal endoscopy. Pelvic and rectal examinations, pelvic ultrasonography, and other screening may be warranted.

In the absence of objective evidence for a specific cause, the acanthosis nigricans may be labeled as idiopathic, which may or may not be familial. Treatment of the underlying cause, if identified, often leads to resolution of the acanthosis nigricans. Otherwise, most published treatment modalities are symptomatic and/or cosmetic, and testimony to their efficacy has been anecdotal.

Specific Investigations

- Document obesity based on ideal body weight, height/weight, body mass index (BMI).
- Determine fasting blood glucose and insulin levels in parallel. Also consider ordering HbA_{1c}, alanine aminotransferase (ALT), and fasting lipoprotein profile in obese patients.
- Depending on historical clues, screen for other endocrine diseases.
- Consider malignancy; if suspected refer to appropriate specialist for the best diagnostic procedure.
- Consider drugs as a cause.
- Consider transplantation as a cause.
- Consider familial/genetic disorders as a cause.

Acanthosis nigricans: a practical approach to evaluation and management

Higgins S, Freemark M, Prose N. Dermatol Online J 2008; 14(9): 2.

A review of the pathogenesis, clinical features, and management of

acanthosis nigricans.

An approach to acanthosis nigricans

Phiske M. Indian Dermatol Online J 2014; 5: 239.

A review of the prevalence, pathogenesis, types, and classifications of acanthosis nigricans. It also discusses the differential diagnosis, pertinent laboratory/radiologic investigations, and treatment options.

Prevalence and significance of acanthosis nigricans in an adult population

Hud J, Cohen J, Wagner J, Cruz P. Arch Dermatol 1992; 128: 941–4.

Up to 74% of obese adult patients seen at the Parkland Memorial Hospital Adult Obesity Clinic in Dallas, Texas, had acanthosis nigricans. The skin disorder predicted the existence of hyperinsulinemia.

Juvenile acanthosis nigricans

Sinha S, Schwartz RA. J Am Acad Dermatol 2007; 57: 502–8.

A review of the evaluation of children presenting with acanthosis nigricans.

Genes, growth factors and acanthosis nigricans

Torley D, Bellus G, Munro C. Br J Dermatol 2002; 147: 1096–101.

Craniosynostosis and skeletal dysplasia syndromes with acanthosis nigricans are associated with activating mutations in fibroblast growth factor receptors (FGR), particularly FGFR3.

Characterization of groups of hyperandrogenic women with acanthosis nigricans, impaired glucose tolerance and/or hyperinsulinemia

Dunaif A, Graf M, Mandeli J, Laumas V, Dobrjansky A. J Clin Endocrinol Metab 1987; 65: 499–507.

Among obese women with polycystic ovaries, 50% had acanthosis nigricans.

Malignant acanthosis nigricans: a review

Rigel D, Jacobe M. J Dermatol Surg Oncol 1980; 6: 923–7.

Gastric carcinoma was reported in 55% of 227 cases of acanthosis nigricans associated with an internal malignancy. Other intraabdominal malignancies accounted for 18% of cases, and the

remaining 27% had extraabdominal sites of malignancy.

First-Line Therapy

• Treat the underlying cause	D
------------------------------	----------

Acanthosis nigricans: a cutaneous marker of tissue resistant to insulin

Rendon M, Cruz P, Sontheimer R, Bergstresser P. J Am Acad Dermatol 1989; 21: 461–9.

In a woman with systemic lupus erythematosus and the type B syndrome of insulin resistance, the acanthosis nigricans cleared after treatment with oral corticosteroids and subcutaneous injection of insulin. Her circulating antiinsulin antibodies also disappeared with treatment of the autoimmune disease.

Clearance of acanthosis nigricans associated with the HAIR-AN syndrome after partial pancreatectomy: an 11-year follow up

Pfeifer SL, Wilson RM, Gawkrödger DJ. Postgrad Med J 1999; 75: 421–2.

An obese woman with HAIR-AN syndrome was diagnosed a year later with insulinoma. One year after resection of the tumor the patient's virilism resolved, and 9 years after the surgery the acanthosis nigricans was much improved.

Acanthosis nigricans in association with congenital adrenal hyperplasia: resolution after treatment

Kurtoglu S, Atabek ME, Keskin M, Canöz O. Turk J Pediatr 2005; 47: 183–7.

A 3-day-old girl with the salt-wasting type of 21-hydroxylase-deficient congenital adrenal hyperplasia presented with acanthosis nigricans of both axillae. After corticosteroid and mineralocorticoid therapy for disease, the acanthosis nigricans resolved.

Second-Line Therapies

• Topical trichloroacetic acid	C
• Topical adapalene	C
• Topical tretinoin +/- ammonium lactate	C
• Oral metformin	D
• Topical tazarotene	E
• Topical calcipotriol	E
• Topical glycolic acid	E

Using trichloroacetic acid in the treatment of acanthosis nigricans: a pilot study

Zayed A, Sobhi R, Abdel Halim D. J Dermatolog Treat 2012; 25: 223–5.

Topical 15% trichloroacetic acid as a superficial chemical peel weekly for 4 weeks led to less thickening and hyperpigmentation and improved overall appearance in six women studied.

The efficacy of topical 0.1% adapalene gel for use in the treatment of childhood acanthosis nigricans: a pilot study

Treesirichod A, Chaithirayanon S, Wongjitrat N, Wattanapan P. Indian J Dermatol 2015; 60: 103.

Topical 0.1% adapalene gel applied daily for 4 weeks led to less skin darkening in 16 patients with childhood acanthosis nigricans.

Topical therapy with tretinoin and ammonium lactate for acanthosis nigricans associated with obesity

Blobstein SH. Cutis 2003; 71: 33–4.

Five obese patients with acanthosis nigricans were successfully treated with 12% ammonium lactate cream twice daily and tretinoin 0.05% cream nightly to one side of the neck (the other side serving as control).

There was no mention of whether the obese patients lost weight

during the treatment period, which could have contributed to the improvement.

Therapeutic approach in insulin resistance with acanthosis nigricans

Tankova T, Koev D, Dakovska L, Kirilov G. *Int J Clin Pract* 2002; 56: 578–81.

Five obese patients (two children and three adults with diabetes mellitus) were treated with metformin daily for 6 months, resulting in significant reduction in plasma insulin, body weight, and body fat mass. Both children and one adult showed improvement of acanthosis nigricans.

Acanthosis nigricans associated with primary hypogonadism: successful treatment with topical calcipotriol

Gregoriou S, Anyfandakis V, Kontoleon P, Christofidou E, Rigopoulos D, Kontochristopoulos G. *J Dermatol Treat* 2008; 19: 373–5.

Topical calcipotriol ointment 50 mcg/g applied twice daily for 8 weeks completely cleared a man's acanthosis nigricans without relapse after 6 months of observation.

Effective treatment by glycolic acid peeling for cutaneous manifestation of familial generalized acanthosis nigricans caused by FGFR3 mutation

Ichiyama S, Funasaka Y, Otsuka Y, Takayama R, Kawana S, Saeki H, et al. *J Eur Acad Dermatol Venereol* 2016; 30: 442–5.

Glycolic acid 35% to 70% peel performed on two patients every 2 weeks led to less hyperpigmentation and keratinization. Continued peels every 2 to 5 months maintained improvement after 3 years.

Third-Line Therapies

• Oral isotretinoin	E
• Dietary fish oil	E
• Oral contraceptives	E
• Long-pulsed alexandrite laser	E
• Continuous wave carbon dioxide laser	E

Treatment of acanthosis nigricans with oral isotretinoin

Katz R. Arch Dermatol 1980; 116: 110–11.

An obese, hirsute, diabetic woman with acanthosis nigricans was treated with oral isotretinoin (2–3 mg/kg/day for 4 months), producing clearance of the skin problem, but long-term treatment was required to maintain clearance because the acanthosis nigricans recurred when the retinoid was discontinued. Side effects of isotretinoin may render long-term use impractical.

Acanthosis nigricans

Schwartz RA. J Am Acad Dermatol 1994; 31: 1.

A woman with lipodystrophic diabetes mellitus and acanthosis nigricans was treated with dietary fish oil supplementation, leading to improvement despite continued elevation of triglyceride levels.

Remission of acanthosis nigricans associated with polycystic ovarian disease and stromal luteoma

Andersen RN, Coleman SA, Fish SA. J Clin Endocrinol Metab 1974; 38: 347–55.

A girl with acanthosis nigricans and polycystic ovaries cleared completely after treatment with Ortho-Novum 2 mg/day.

Treatment of acanthosis nigricans of the axillae using a long-pulsed (5-msec) alexandrite laser

Rosenback A, Ram R. Dermatol Surg 2004; 30: 1158–60.

A woman with axillary acanthosis nigricans was treated with long-pulsed alexandrite laser (5 ms) on one axilla, with the other as an

untreated control. The treated axilla showed significant improvement.

Acne keloidalis nuchae

William Perkins

Courtesy of Neil Fernandes, MD.

Acne keloidalis nuchae (AKN) is an idiopathic chronic inflammatory process affecting the nape of the neck and the occipital scalp; it occurs predominantly in Afro-Caribbean males. Initial features consist of papules and pustules on the occiput and posterior

neck, which subsequently coalesce into plaques of dense scar tissue with central scarring alopecia. Although the etiology is unknown, the histology of early cases shows evidence of acute and chronic folliculitis, with ruptured follicles, perifolliculitis, and a foreign body granulomatous response. Later cases may show similar features, but additionally there may be hypertrophic scar formation. Close shaving of the hair has been postulated as a cause for AKN, but even during the 1960s and 1970s, with the fashion for longer hair, AKN was still seen. Physical trauma due to collars rubbing and picking by patients has been suggested as a precipitant, but this has not been investigated in any systematic way. Whether folliculitis leading to ruptured follicles and the subsequent foreign body reaction or the development of ingrowing hairs is the primary event, the term *acne keloidalis* is a misnomer. Keloids at other sites or a family history of keloids are not features of AKN, and excision of the area does not result in keloid formation. Pseudofolliculitis barbae was associated with AKN in five of six cases in one series, but clinical or histologic evidence of superficial hair penetration is lacking. Lesions resembling AKN have been reported in those receiving long-term ciclosporin, and sarcoid papules may occasionally mimic the condition.

Management Strategy

A clear diagnosis is a prerequisite for the management of AKN. The presence of inflammatory papules, pustules, and hypertrophic scar formation on the occipital scalp and posterior neck in a black male is pathognomonic, but cases have been described in Caucasians and occasionally in females. Biopsy of the area is not usually required, but concerns about keloidal scarring should not inhibit obtaining histologic confirmation. Folliculitis secondary to bacterial infections, particularly staphylococcal, needs to be excluded. In staphylococcal folliculitis the pustules and papules tend to be more widely distributed across the scalp, especially over the crown. Culture will yield heavy growths of staphylococci, and the condition usually responds well to treatment with oral antibiotics, but may recur and require long-term treatment.

In view of the suggested associations with close-cropped hair and picking, it may be worthwhile inquiring about these factors. If present, these practices should be avoided.

Treatment depends on the stage of presentation. Unfortunately, the

evidence base for many of the management recommendations is weak. Many patients will prefer no treatment or conservative treatment in the early stages of the disease. This is demonstrated by the fact that only 30% of patients identified in one survey had tried any treatment at all. Early disease with papules and pustules scattered across the posterior neck and occipital scalp may well be best managed by *topical antiseptics, antibiotics, or potent topical corticosteroids*.

With the development of hypertrophic scar formation, *topical or intralesional corticosteroids* may well be of benefit. Once scarring, alopecia, hypertrophic scars, and symptoms related to itch, pain, and discharging sinuses are present, treatment directed at the removal of the follicles from the affected area in their entirety is recommended.

Excisional surgery is the only treatment reported in any significant case series. The factors influencing the use of excision will be the severity of symptoms the patient is experiencing and the confidence the patient and surgeon have in the process of surgery. Scattered papules and pustules across the occipital scalp without confluent areas of hypertrophic scar formation and with only limited symptoms may lead patients to seek a more conservative treatment option.

Prioritization of the following treatments is not meant to be a strict hierarchy; for a well-developed case of AKN, the author's treatment of choice is excision. When this is not acceptable, some of the following nonsurgical approaches may be appropriate. Advice to *reduce the picking* (a consistently reported association) and *close cropping* of the hair is the first measure one should employ. This may be aided by the antiinflammatory effect of potent topical corticosteroids. In mild early cases, treatment with a topical antibiotic such as 1% *clindamycin* or *erythromycin* may be helpful. Oral antistaphylococcal antibiotics, such as *flucloxacillin*, may be helpful, but this is not a recommendation supported by trial evidence. A very good response to flucloxacillin or erythromycin in the early stages when no scarring is present may suggest staphylococcal folliculitis rather than AKN. Long-term oral *tetracycline* antibiotics may be of help in some cases of early disease. Limited hypertrophic scars may respond to intralesional *triamcinolone*. *Isotretinoin* has been used with success.

Specific Investigations

- Pustule swab
- Deep biopsy

Investigations are not particularly helpful in AKN, and even histology tends to be a by-product of excisional treatment. If the diagnosis is in doubt, a deep biopsy to below the level of the scar tissue and follicular bulbs will confirm the diagnosis. Folliculitis secondary to *Staphylococcus aureus* is worth excluding, largely based on clinical features such as the distribution and the lack of hypertrophic scar formation, but positive cultures from pustules may direct topical and systemic antibiotic therapy. Pustular lesions of AKN may well grow *S. aureus*, but the response to treatment in the context of a simple bacterial folliculitis will be much greater than that seen in AKN.

First-Line Therapies

• Dissuade from picking and close hair cutting	E
• Topical clindamycin 1% twice daily	E
• Oral antistaphylococcal antibiotic flucloxacillin 250 mg four times daily	E
• Oral tetracycline (lymecycline 408 mg once daily)	E
• Topical corticosteroids–propionate ointment once daily	B

Pseudofolliculitis barbae

Chu T. Practitioner 1989; 233: 307–9.

In a limited open study, 1% topical clindamycin was anecdotally found to be effective for pseudofolliculitis and acne keloidalis.

An open label study of clobetasol propionate 0.05% and betamethasone valerate 0.12% foams in the treatment of mild to moderate acne keloidalis

Callender VD, Young CM, Haverstock CL, Carroll CL, Feldman SR. Cutis 2005; 75: 317–21.

Acne keloidalis is a form of scarring alopecia

Sperling LC, Homoky C, Pratt L, Sau P. Arch Dermatol 2000; 136: 479–84.

Medical treatment for early papular lesions includes intralesional injections of corticosteroids, topical steroids, and topical or oral antibiotics (usually tetracycline).

Second-Line Therapies

• 13- <i>cis</i> -retinoic acid 0.5 to 1 mg per kg daily	E
• Intralesional triamcinolone 10 to 40 mg per mL every 2 months	E

Folliculitis nuchae scleroticans – successful treatment with 13-*cis*-retinoic acid (isotretinoin)

Stieler W, Senff H, Janner M. Hautarzt 1988; 39: 739–42.

Oral therapy with 13-*cis*-retinoic acid (isotretinoin) in a 23-year-old white man resulted in a remarkable improvement within a few weeks.

If antibiotic treatment fails, oral isotretinoin may be helpful in selected cases. Once hypertrophic scarring has developed, treatment with oral or topical antibiotics is less successful, and measures to control the formation of hypertrophic scar need to be employed. Potent topical corticosteroid creams may help, but intralesional injections of corticosteroids such as triamcinolone can reduce the bulk of the scar tissue. Despite these injections the process tends to continue and the treatment will need to be repeated at intervals.

Third-Line Therapies

• Excision to deep fat or fascia below follicles. Fusiform excision along posterior hairline where possible. Heal by second intention or primary closure as a staged procedure.	C
---	---

The surgical management of extensive cases of acne keloidalis nuchae

Gloster HM. Arch Dermatol 2000; 136: 1376–9.

Of 25 young African-Caribbean men with extensive AKN who underwent surgical excision of AKN, 20 underwent excision with layered closure in one stage. Four patients underwent two-stage

excisions with layered closure. One patient underwent excision with second-intention healing. All rated the cosmetic result of surgery as good to excellent. No patient experienced complete recurrence of acne keloidalis; 15 patients developed tiny pustules and papules within the surgical scar; 5 developed hypertrophic scars, all of which were successfully treated with high-potency topical and intralesional corticosteroids. Extremely large lesions should be excised in several stages.

Surgical excision of acne keloidalis nuchae with secondary intention healing

Bajaj V, Langtry JA. Clin Exp Dermatol 2008; 33: 53–5.

Anesthesia can be achieved simply with either 0.5% or 1% lidocaine plus epinephrine (adrenaline) 1:200,000 or even 0.1% with epinephrine 1:1,000,000. The advantage of the latter is that it gives excellent longer-term control of bleeding, which can be a problem with large scalp excisions. The use of electrosurgical excision can thus be avoided, as this is associated with increased levels of postoperative pain and an increased risk of wound dehiscence.

Acne vulgaris

Fragkiski Tsatsou, and Christos C. Zouboulis

Acne vulgaris is a chronic inflammatory disorder of the pilosebaceous unit with a multifactorial pathogenesis.

Management Strategy

Treatment depends on the type and severity of acne lesions. Combination therapy is often appropriate to address the multifactorial pathophysiology.

In mild forms of acne, *topical therapy* is most appropriate. Topical therapy is first indicated in comedonal acne and mild-to-moderate papulopustular acne without scarring. Topical therapeutic agents and oral regimens or procedural therapies are optimally administered simultaneously as combination therapy for treatment of more severe forms of acne. Topical regimens are also used as maintenance therapy to suppress formation of microcomedones, the precursor stage of acne lesions. Topical agents include retinoids, antimicrobial and antibacterial agents, hormonal agents, or herbal remedies. Four to 12 weeks should be allowed for most topical treatments to work before altering the regimen.

Treatment of choice for **comedonal acne** is monotherapy with *topical retinoids* as initiation therapy, due to its usually mild-to-moderate severity. After successful treatment, topical retinoids are suitable for maintenance therapy. Topical retinoids are comedolytic—they act against macrocomedones and microcomedones—and have direct antiinflammatory effects. Retinoids approved for topical acne treatment include tretinoin, isotretinoin, adapalene, and tazarotene. Retinaldehyde is used in cosmetic preparations. All topical retinoids are effective as single agents in mild-to-moderate acne, but they can differ in speed of efficacy and tolerability at an individual level. Local adverse events may occur, including erythema, dryness, itching, and stinging. They typically resolve within the first few weeks of use; alternate-day dosing may be preferred if irritation persists.

Treatment of choice for **mild and moderate papulopustular acne without scarring** is a combination of *benzoyl peroxide* (BPO) and *topical retinoids*, or BPO and *topical antibiotics*. Fixed-dose combination of BPO 2.5% with adapalene 0.1% or 0.3% and BPO 3% or 5% with clindamycin phosphate 1%, 1.2%, 3%, or 5% may increase the patient's adherence to treatment due to their once-daily-only application.

Topical antibiotics, mainly used for their role against *Propionibacterium acnes* (*P. acnes*), also have antiinflammatory properties. Commonly prescribed topical antibiotics include clindamycin and erythromycin. They are effective, but are not

recommended as monotherapy due to the possible induction of bacterial resistance. Instead, they should be combined with a topical retinoid or with BPO for faster lesion clearing and in order to reduce the likelihood of *P. acnes* resistance.

Azelaic acid 15% gel or 20% cream is a useful adjunctive topical acne treatment and can also be used in maintenance *therapy*, as well as to treat postinflammatory hyperpigmentation.

Topical dapsone 5% or 7.5% gel is recommended for inflammatory acne, particularly in adult females.

Topical adapalene, tretinoin, and benzoyl peroxide can be safely used in the management of preadolescent acne in children.

There is limited evidence to support recommendations for sulfur, nicotinamide, resorcinol, sodium sulfacetamide, aluminum chloride, and zinc in the treatment of acne.

For **moderate papulopustular acne with scarring** in males, *oral antibiotics* are the treatment of choice. They are also recommended in forms of inflammatory acne that are resistant to topical treatments. Although there is no correlation between the numbers of *P. acnes* and the severity of acne, the occurrence of antibiotic-resistant *P. acnes* correlates with poor clinical response. Second-generation tetracyclines (doxycycline, minocycline) have antiinflammatory properties, pharmacokinetic advantages over tetracycline, and are the agents of choice for papulopustular acne. Erythromycin use should be restricted due to increased risk of bacterial resistance. Although oral erythromycin and azithromycin can be effective in treating acne, their use should be limited to patients who cannot receive tetracyclines (i.e., pregnant women or children <8 years of age). Doxycycline is used at 100 or 200 mg daily in two equal doses. An initially higher dose of doxycycline or minocycline (4 weeks 100 mg daily, then 50 mg daily) is more effective than 50 mg daily over 12 weeks. Lower daily doses of bacterial subinhibitory concentrations of doxycycline are considered to promote bacterial resistance. Use of systemic antibiotics other than tetracyclines and macrolides is discouraged because there are limited data for their use. The administration of trimethoprim-sulfamethoxazole and trimethoprim alone should be restricted to patients who are unable to tolerate tetracyclines or in treatment-resistant patients.

Systemic antibiotic therapy of moderate papulopustular acne should be limited to the shortest possible duration. Concomitant topical therapy with BPO or a retinoid should be used to prevent

antibiotic resistance and for maintenance therapy. Concurrent use of oral and topical antibiotics should be avoided. In acne relapse, the same antibiotic can be used if previously effective. BPO for 5 to 7 days could also be administered between antibiotic courses to avoid *P. acnes* resistance.

In **nodulocystic or conglobate acne**, oral *isotretinoin* is the treatment of choice. Systemic isotretinoin is the most effective antiacne drug available, especially in severe recalcitrant nodulocystic acne and in the prevention of acne scarring. Oral isotretinoin is also appropriate for the treatment of moderate treatment-resistant acne.

Current guidelines recommend 0.5 mg/kg/d for at least 4 months, being extended in recalcitrant cases, especially with severe involvement of the chest and back. The widely proposed cumulative dose of isotretinoin with respect to relapse of acne is subject to controversy. Alternatively, isotretinoin can be initiated at a low dose of 10 mg/d and be gradually increased to the best tolerated dose. Intermittent dosing is not recommended for active treatment but can be administered during maintenance. Factors contributing to the need for longer treatment schedules include use of lower daily-dose regimens, presence of severe acne, extrafacial involvement, and prolonged history of the disease. In some patients only one course of oral isotretinoin leads to complete acne remission. Relapse is more likely in younger patients.

Isotretinoin treatment for acne can induce inflammatory flares of the disease during the first 3 to 4 weeks of treatment, occasionally leading to acne fulminans. Mild flares do not require modification of the oral dose and improve spontaneously. Severe episodes should be treated with addition of systemic *prednisolone* (30 mg/day), whereas dose reduction or discontinuation may only be required in individual cases.

The adverse event profile of oral isotretinoin includes characteristic dose-dependent mucocutaneous side effects (cheilitis, xerosis, dry mucosae, conjunctivitis, epistaxis), elevation of liver enzymes and/or serum lipids, arthralgia, myalgia, and rarely hyperostosis or extraskelatal calcification. Routine monitoring of liver function tests, serum cholesterol, and triglycerides at baseline and again until response to treatment is established is recommended. Low-dose long-term regimens (0.1–0.2 mg/kg daily) and a micronized isotretinoin formulation with similar efficacy are associated with a lower risk of adverse events.

The dose-independent teratogenic potential of isotretinoin with a high rate of spontaneous abortions and life-threatening congenital malformations demands the use of secure contraception when it is prescribed for females of fertile age. All patients treated with isotretinoin must adhere to the iPLEDGE risk management program. Contraception is recommended 1 month before initiation of treatment, during the entire period of drug administration, and over 3 months after regimen discontinuation. Oral isotretinoin is strictly contraindicated in pregnancy, during lactation, and in severe hepatic and renal dysfunction. Coadministration of vitamin A, tetracycline, and high doses of aspirin is contraindicated. Associated deterioration of preexisting depression, suicide, anxiety, bipolar disorder, psychosis, schizophrenia, and suicidal ideation have been reported during treatment and should be closely followed up, although a causal relationship has not been established.

Isotretinoin affects wound healing and could be associated with development of excessive tissue granulation after dermatologic procedures. It is suggested to delay elective surgical procedures, such as dermabrasion or laser resurfacing (e.g., with CO₂ or Er:YAG laser), for 6 to 12 months after treatment discontinuation. Tattoos, piercings, and epilation procedures should also be postponed.

For **acne fulminans**, a combination of an oral corticosteroid (e.g., prednisolone 30 mg/d for up to 4 weeks) and isotretinoin is indicated.

Infantile and **pediatric acne** may necessitate an alternative treatment. Topical adapalene, tretinoin, and BPO can be safely used in the management of acne in children of preadolescent age.

For **acne patients with adrenal hyperandrogenism**, a low-dose oral corticosteroid in combination with systemic retinoid is the treatment of choice.

Hormonal *antiandrogen* treatment of female acne is not a primary monotherapy and is largely reserved for female patients who present additional signs of peripheral hyperandrogenism or hyperandrogenemia. However, hormonal antiandrogens can be useful in females with acne tarda, in female patients with hormonally induced deterioration of acne (i.e., premenstrual flares), persistent acne recalcitrant to other treatments, an incidental need for contraception, and in order to provide contraceptive cover during systemic isotretinoin treatment.

Estrogen-containing combined oral contraceptives are effective and recommended in the treatment of inflammatory acne in females.

Combination oral contraceptive pills (COCs) contain both an estrogen and a progestin component, where the progestin can be one of drospirenone, cyproterone acetate, chlormadinone acetate, or dienogest (the latter three not registered in the United States). Also, selective aldosterone antagonists (e.g., spironolactone 50–200 mg daily) are useful in the treatment of acne in selected females. Spironolactone is well tolerated overall and its side effects are dose related, including hyperkalemia, diuresis, menstrual irregularities, breast tenderness, fatigue, headache, and dizziness. It is contraindicated in pregnancy, and concomitant use of a COC is recommended.

Specific Investigations

None are required routinely.

- Consider microbiology to exclude gram-positive or gram-negative folliculitis.
- Consider endocrine workup if hyperandrogenemia is suspected.

First-Line Therapies

Comedonal acne	
• Topical retinoids	B
• Dapsone gel with topical retinoid	B
Mild papulopustular acne	
• Benzoyl peroxide with topical retinoid	A
• Benzoyl peroxide with topical antibiotic	A
Moderate papulopustular acne without scarring	
• Benzoyl peroxide with topical retinoid	A
• Benzoyl peroxide with topical antibiotic	A
Moderate papulopustular acne with scarring	
• For males use oral antibiotics (tetracyclines, macrolides) with benzoyl peroxide or topical retinoid	A
• For females use an oral antiandrogen contraceptive with benzoyl peroxide and topical antibiotic	A
Nodulocystic and/or conglobate acne	
• Oral isotretinoin *	A
Acne fulminans	
• Oral isotretinoin * with low-dose oral corticosteroids	C

* In women only under application of secure contraception.

Guidelines of care for the management of acne vulgaris

Zaenglein AL, Pathy AL, Schlosser BJ, Alikhan A, Baldwin HE, Berson DS, et al. J Am Acad Dermatol 2016; 74: 945–73.

An evidence-based guideline reviewing grading, topical, and systemic management of acne.

Treatment of acne in pregnancy

Chien AK, Qi J, Rainer B, Sachs DL, Helfrich YR. J Am Board Fam Med 2016; 29: 254–62.

A review on the safety profiles of common therapies used in pregnancy. Topical azelaic acid or BPO can be recommended as baseline therapy. A combination of topical erythromycin or clindamycin with BPO is recommended for inflammatory acne. Oral erythromycin or cephalexin is considered safe for moderate-to-severe inflammatory acne when used for a few weeks. A short course of oral prednisolone may be useful for treating fulminant nodular cystic acne after the first trimester.

Topical retinoids in acne – an evidence-based overview

Thielitz A, Naser MB, Fluhr JW, Zouboulis CC, Gollnick H. J Dtsch Dermatol Ges 2010; 8 (Suppl 1): S15–23.

A review on retinoids approved for topical acne treatment, their differences in efficacy and tolerability, and their adverse effects, according to evidence-based medicine (EBM) levels.

Efficacy and safety of once-daily dapsons gel, 7.5% for treatment of adolescents and adults with acne vulgaris: first of two identically designed, large, multicenter, randomized, vehicle-controlled trials

Stein Gold LF, Jaratt MT, Bucko AD, Grekin SK, Berlin JM, Bukhalo M, et al. J Drugs Dermatol 2016; 15: 553–61.

A 12-week, randomized, double-blind, vehicle-controlled, multicenter clinical trial of patients ≥ 12 years with moderate inflammatory acne, where dapsons gel 7.5% applied topically once daily was shown to be an effective, safe, and well-tolerated regimen. *Dapsons is a sulfone with antiinflammatory and antimicrobial properties. Dapsons gel delivers clinically effective doses of dapsons with minimal systemic absorption.*

Two randomized, double-blind, split-face studies to compare the

irritation potential of two topical acne fixed combinations over a 21-day treatment period

Bhatia N, Bhatt V, Martin G, Pillai R. *J Drugs Dermatol* 2016; 15: 721–6.

Advances in formulation technology have provided new fixed combinations with higher concentrations of active ingredients and lower concentrations of potentially irritating ingredients without compromising efficacy. The tolerability of clindamycin–BPO 3.75% gel and adapalene 0.3%–BPO 2.5% gel was compared in healthy volunteers over 21 days, using a split-face methodology. Adverse events—stinging, erythema, dryness, scaling, burning, and itching—were twice as common with adapalene 0.3%–BPO 2.5% gel. Therefore clindamycin–BPO 3.75% gel is likely to be better tolerated than adapalene 0.3%–BP 2.5% gel in moderate-to-severe acne.

Effects of benzoyl peroxide 5% clindamycin combination gel versus adapalene 0.1% on quality of life in patients with mild to moderate acne vulgaris: a randomized single-blind study

Guerra-Tapia A. *J Drugs Dermatol* 2012; 11: 714–22.

The fixed-dose combination of BPO 5%/clindamycin 1% gel provided earlier improvement of quality of life than adapalene 0.1% gel. This could result from better efficacy and tolerability.

A randomized, single-blind comparison of topical clindamycin + benzoyl peroxide (Duac) and erythromycin + zinc acetate (Zineryt) in the treatment of mild to moderate facial acne vulgaris

Langner A, Sheehan-Dare R, Layton A. *J Eur Acad Dermatol Venereol* 2007; 21: 311–9.

Comparison of two combination treatments for facial acne: a ready-mixed, once-daily gel containing clindamycin phosphate (1%) plus benzoyl peroxide (5%) (CDP + BPO) and a twice-daily solution of erythromycin (4%) plus zinc acetate (1.2%) (ERY + Zn). Both regimens are effective, but CDP + BPO has an earlier onset of action that should improve compliance.

Study of the efficacy, tolerability, and safety of 2 fixed-dose combination gels in the management of acne vulgaris

Zouboulis CC, Fischer TC, Wohlrab J, Barnard J, Alió AB. *Cutis* 2009; 84: 223–9.

Comparison of clindamycin 1%/benzoyl peroxide 5% gel with

hydrating excipients (C/BPO HE) and adapalene 0.1%/BPO 2.5% gel. After 12 weeks of once-daily application, the treatments showed similar improvements of inflammatory and noninflammatory lesions, but C/BPO HE achieved better overall treatment success in less time with better tolerability and safety.

Clindamycin phosphate/tretinoin gel formulation in the treatment of acne vulgaris

Abdel-Naser MB, Zouboulis CC. Expert Opin Pharmacother 2008; 9: 2931–7.

Clindamycin phosphate 1.2% with tretinoin 0.025% fixed-dose combination gel is approved by the Food and Drug Administration (FDA) for treatment of acne in patients ≥ 12 years old. This formulation enhances effectiveness and minimizes irritation. The once-daily use, the rapid effect, and good tolerability have a positive impact on disease duration, compliance, and cost.

Making sense of the effects of the cumulative dose of isotretinoin in acne vulgaris

Rademaker M. Int J Dermatol 2016; 55: 518–23.

A study to determine the influence of daily and cumulative dosage on acne relapse. A chart review of 1453 patients, where daily and cumulative doses and duration were compared among patients who received one course and two or more courses, respectively. *Neither daily nor cumulative dosages influenced relapse of acne vulgaris in patients treated with varying doses of isotretinoin as long as treatment was continued for ≥ 2 months after the acne had completely resolved.*

Interrelationships between isotretinoin treatment and psychiatric disorders: depression, bipolar disorder, anxiety, psychosis and suicide risks

Ludot M, Mouchabac S, Ferreri F. World J Psychiatry 2015; 5: 222–7.

A literature review aiming to specify the link between isotretinoin and specific psychiatric disorders. *Many studies demonstrated an increased risk of depression, attempted suicide, and suicide. Several studies showed patients with bipolar disorder have an increased risk for symptom exacerbation. Few studies suggested a possible link between isotretinoin and psychosis.*

Hormonal antiandrogens in acne treatment

Zouboulis CC, Rabe T. J Dtsch Dermatol Ges 2010; 8 (Suppl 1): S60–74.

A review of the efficacy, classification, and mechanism of action of antiandrogens. Combinations of ethinyl estradiol with cyproterone acetate, chlormadinone acetate, dienogest, desogestrel, and drospirenone have shown the strongest antiacne activity. Gestagens or estrogens as monotherapy, spironolactone, flutamide, gonadotropin-releasing hormone agonists, and inhibitors of peripheral androgen metabolism are not recommended.

Efficacy and safety of 3 mg drospirenone/20 mcg ethinylestradiol oral contraceptive administered in 24/4 regimen in the treatment of acne vulgaris: a randomized, double-blind, placebo-controlled trial

Koltun W, Lucky AW, Thiboutot D, Niknian M, Sampson-Landers C, Korner P, et al. Contraception 2008; 77: 249–56.

This nonandrogenic progestin-containing contraceptive with strong antiandrogenic activity (drospirenone 3 mg) but reduced concentration of ethinyl estradiol (20 µg) has been shown to be effective and may replace the classic cyproterone acetate/ethinyl estradiol and chlormadinone acetate/ethinyl estradiol oral contraceptives due to an improved side effect profile.

Efficacy of a combined oral contraceptive containing 0.030 mg ethinylestradiol/2 mg dienogest for the treatment of papulopustular acne in comparison with placebo and 0.035 mg ethinylestradiol/2 mg cyproterone acetate

Palombo-Kinne E, Schellschmidt I, Schumacher U, Gräser T. Contraception 2009; 79: 282–9.

A combined oral contraceptive containing the antiandrogen dienogest with ethinylestradiol proved superior to placebo and not inferior to one containing the potent antiandrogen cyproterone acetate and ethinylestradiol.

Second-Line Therapies

Comedonal acne	
• Benzoyl peroxide (topical)	B
• Azelaic acid	B
• Superficial peels (lipohydroxy acid, salicylic acid)	B
Mild-to-moderate papulopustular acne	
• Azelaic acid	A
• Benzoyl peroxide (topical)	C
• Topical retinoid	A
• Azelaic acid with topical clindamycin	A
• Azelaic acid with topical erythromycin	A
• Dapsone gel	A
• Dapsone gel with topical retinoid	A
• Dapsone gel with benzoyl peroxide (topical)	A
• Systemic antibiotic with adapalene	C
• Topical erythromycin with topical retinoid	C
• Oral zinc	C
• Photodynamic therapy	B
• Intense pulsed light (IPL)	B
• Photodynamic therapy with IPL	B
• Blue light	B
• Blue/red light combinations	C
• Red low-level laser therapy (LLLT)	B
• 1450-nm diode laser	C
• Topical cyproterone acetate	A
• Zileuton	C
• Topical copaiba essential oil gel	A
• Topical 5% tea tree oil gel	A
• Glycolic acid oil-in-water emulsion	A
• Chemical peels (α -hydroxy acid, glycolic acid, β -hydroxy acid, salicylic acid)	B
• Microdermabrasion	C
Nodulocystic and/or conglobate acne	
• Oral antibiotic plus topical retinoid	C
• Oral antibiotic plus azelaic acid	C
• Oral antibiotic plus topical retinoid plus benzoyl peroxide	C

New and emerging treatments in dermatology: acne

Katsambas A, Dessinioti C. *Dermatol Ther* 2008; 21: 86–95.

An overview of the treatment of acne, including new therapies and future perspectives. Oral zinc sulfate and zinc gluconate have been used for the treatment of inflammatory acne vulgaris with conflicting results. Zinc acts via inhibition of polymorphonuclear cell chemotaxis and inhibition of growth of *P. acnes*. Its antiinflammatory activity could also be related to a decrease in tumor necrosis factor- α production, the modulation of the expression of integrins, and the inhibition of TLR2 surface expression by keratinocytes. Zinc salts have been used at a dosage of 30 to 150 mg of elemental zinc daily for 3 months. Zinc gluconate does not induce bacterial resistance, has a favorable safety profile, and can be administered to pregnant women.

A multicenter, randomized, single-blind, parallel-group study comparing the efficacy and tolerability of benzoyl peroxide 3%/clindamycin 1% with azelaic acid 20% in the topical treatment of mild-to-moderate acne vulgaris

Schaller M, Sebastian M, Röss C, Seidel D, Hennig M. *J Eur Acad Dermatol Venereol* 2016; 30: 966–73.

A randomized, single-blind, parallel-group, multicenter study over 12 weeks, where clindamycin 1% + BPO demonstrated greater efficacy than azelaic acid 20% in the treatment of mild-to-moderate acne.

Azelaic acid has a predominant antibacterial action and possesses a modest comedolytic effect. Burning upon application is common. Systemic side effects are not likely to occur, making it safe for acne treatment during pregnancy and lactation.

Zileuton, a new efficient and safe systemic antiacne drug

Zouboulis CC. *Dermato-Endocrinology* 2009; 1: 188–92.

In a multicenter study, zileuton, an oral 5-lipoxygenase inhibitor, showed a significant decrease in inflammatory lesions compared with placebo. Zileuton reduces the number of inflammatory lesions in moderate acne and inhibits the synthesis of sebaceous lipids. It appears to be safe and well tolerated.

Application of the essential oil from copaiba (*Copaifera langsdorfi* Desf.) for acne vulgaris: a double-blind, placebo-controlled clinical trial

Da Silva AG, Puziol Pde F, Leitao RN, Gomes TR, Scherer R, Martins

ML, et al. *Altern Med Rev* 2012; 17: 69–75.

Treatment with 1.0% copaiba oil significantly reduced the surface area affected with acne. Copaiba oil resin is widely used in traditional medicine due to its antiinflammatory, healing, and antiseptic activities.

The efficacy of 5% topical tea tree oil gel in mild to moderate acne vulgaris: a randomized, double-blind placebo-controlled study

Enshaieh S, Jooya A, Siadat AH, Iraj F. *Indian J Dermatol Venereol Leprol* 2007; 73: 22–5.

This was found to be effective.

Nutritional clinical studies in dermatology

Liakou AI, Theodorakis MJ, Melnik BC, Pappas A, Zouboulis CC. *J Drugs Dermatol* 2013; 12: 1104–9.

The relationship between acne and diet, predominantly the role of high-glycemic-load diets and dairy consumption, has recently gained increased interest. The data on the relationship between nutrition and skin are until now controversial, and much more work is needed to be done to clarify possible etiologic correlations.

A 10% glycolic acid containing oil-in-water emulsion improves mild acne: a randomized double-blind placebo-controlled trial

Abels C, Kaszuba A, Michalak I, Werdier D, Knie U, Kaszuba A. *J Cosmet Dermatol* 2011; 10: 202–9.

Treatment was applied once daily in the evening in 120 patients with mild acne over 90 days and improved mild acne significantly after 45 days with good tolerability. α -Hydroxy acids exhibit comedolytic and antimicrobial properties.

Clinical evaluation of glycolic acid chemical peeling in patients with acne vulgaris: a randomized, double-blind, placebo-controlled, split-face comparative study

Kaminaka C, Uede M, Matsunaka H, Furukawa F, Yamamoto Y. *Dermatol Surg* 2014; 40: 314–22.

A prospective, randomized, double-blind, placebo-controlled, split-face clinical trial of 26 patients with moderate acne who were treated with 40% glycolic acid (pH 2.0) on half the face and placebo on the other half five times at 2-week intervals showed significant

improvement of moderate acne in Asians.

Randomized trial comparing a chemical peel containing a lipophilic hydroxy acid derivative of salicylic acid with a salicylic acid peel in subjects with comedonal acne

Levesque A, Hamzavi I, Seite S, Rougier A, Bissonnette R. J Cosmet Dermatol 2011; 10: 174–82.

A split-face study. Twenty subjects received a total of six peels at 2-week intervals. There was no significant difference in response. Lipohydroxy acid is a lipophilic derivative of salicylic acid with comedolytic properties.

Photodynamic therapy for the treatment of different severity of acne: a systematic review

Keyal U, Bhatta AK, Wang XL. Photodiagnosis Photodyn Ther 2016; 14: 191–9.

Thirty-six clinical trials were selected, among which 24 trials were performed to see the effect of photodynamic therapy (PDT) in acne, whereas 12 trials compared the effect of PDT with light- or laser-alone therapy. Among 24 trials that used PDT only, 3 were clinical trials with control, 14 were clinical trials without control, 6 were randomized controlled trials (RCTs), and 1 was a retrospective study. PDT has been extensively studied and found to be safe and effective in acne. PDT can control inflammatory and noninflammatory acne lesions and can improve all acne lesions, ranging from mild to severe. More RCTs are needed to establish standard guidelines regarding concentrations and the incubation period of photosensitizers and optimal parameters of light sources.

Daylight photodynamic therapy with 1.5% 3-butenyl 5-aminolevulinate gel as a convenient, effective and safe therapy in acne treatment: a double-blind randomized controlled trial

Kwon HH, Moon KR, Park SY, Yoon JY, Suh DH, Lee JB. J Dermatol 2016; 43: 515–21. A study on the efficacy and safety of daylight PDT in acne treatment. The novel variant of 5-aminolevulinate (ALA)-ester, 1.5% 3-butenyl ALA-bu gel, was applied using daylight only as the potential visible light source. Forty-six acne patients were randomly assigned to either ALA-bu or vehicle application group in a double-blind fashion. Both groups applied the allocated gel to facial acne lesions every other day for 12 weeks. Daylight-PDT was effective,

very well tolerated, and convenient for treating inflammatory acne lesions.

A randomized controlled study for the treatment of acne vulgaris using high-intensity 414 nm solid state diode arrays

Ash C, Harrison A, Drew S, Whittall R. J Cosmet Laser Ther 2015; 17: 170–6.

A randomized controlled study quantifying the efficacy of a blue light device as a self-treatment regimen. Forty-one adults with mild-to-moderate facial inflammatory acne achieved a reduction of inflammatory lesions after 12 weeks. Treatment was free of pain and side effects. *Blue light phototherapy using a narrowband light-emitting diode (LED) appears to be a safe and effective additional therapy for mild-to-moderate acne.*

Comparison of red and infrared low-level laser therapy in the treatment of acne vulgaris

Aziz-Jalali MH, Tabaie SM, Djavid GE. Indian J Dermatol 2012; 57: 128–30.

In this single-blind randomized study, two different wavelengths of LLLT (630 and 890 nm) were evaluated. Twenty-eight patients with mild-to-moderate acne vulgaris were treated with red LLLT (630 nm) and infrared LLLT (890 nm) on the right and left sides of the face, respectively, twice a week for 12 sessions. There was significant clinical improvement with 630 nm but not with 890 nm.

Treating acne scars in patients with Fitzpatrick skin types IV to VI using the 1450-nm diode laser

Semchyshyn N, Prodanovic E, Varade R. Cutis 2013; 92: 49–53.

A study assessing the efficacy and side effect profile of a 1450-nm diode laser for the treatment of acne scars in participants with Fitzpatrick skin types IV to VI. Findings show the nonablative 1450-nm diode laser is safe and effective in improving the appearance of atrophic acne scars in darker skin types. Postinflammatory hyperpigmentation was a common occurrence.

Combined autologous platelet-rich plasma with microneedling versus microneedling with distilled water in the treatment of atrophic acne scars: a concurrent split-face study

Asif M, Kanodia S, Singh K. J Cosmet Dermatol 2016; 15: 434–43.

Microneedling was performed on both face halves of 50 patients with atrophic acne scars. Intradermal injections plus platelet-rich plasma (PRP) was administered on the right face half, intradermal administration of distilled water on the left half. Three treatment sessions were given at a 1-month interval. PRP showed efficacy in the management of atrophic acne scars. It can be combined with microneedling to enhance the final clinical outcomes in comparison with microneedling alone.

The efficacy of topical cyproterone acetate alcohol lotion versus placebo in the treatment of the mild to moderate acne vulgaris: a double blind study

Iraji F, Momeni A, Naji SM, Siadat AH. Dermatol Online J 2006; 12: 26.

A trial with 86 female patients with mild-to-moderate acne vulgaris. The use of cyproterone acetate alcohol lotion is suggested as one of the main treatments for mild-to-moderate acne in female patients and as an adjuvant treatment for moderate-to-severe acne vulgaris.

Superficial chemical peels and microdermabrasion for acne vulgaris

Kempiak SJ, Uebelhoer N. Semin Cutan Med Surg 2008; 27: 212–20.

A description of the procedure steps and the complications in the office setting. The evaluation of patients before the procedure is discussed, as well as postpeel regimens. Comparative studies between the two most commonly used superficial peeling agents, glycolic and salicylic acid, are discussed.

Third-Line Therapies

Mild-to-moderate acne	
• Chemical peels (α -hydroxy acid, glycolic acid, β -hydroxy acid, salicylic acid)	B
• Microdermabrasion	B
Acne sinuses and scars	
• Intralesional steroids	C
• Medium-depth chemical peels (Jessner solution/trichloroacetic acid (TCA), TCA, phenol)	B
• Dermabrasion $\pm$ platelet-rich plasma	B
• Radiofrequency	C
• Fractional laser resurfacing (ablative, nonablative)	B
• Surgical scar revision	C
• Injectable fillers	C

Trichloroacetic acid versus salicylic acid in the treatment of acne vulgaris in dark-skinned patients

Abdel Meguid AM, Elaziz Ahmed Attallah DA, Omar H. *Dermatol Surg* 2015; 41: 1398–404.

Comparison of efficacy of TCA 25% peels with salicylic acid 30% in 25 patients with acne vulgaris. Twenty-five percent TCA was applied to the right half of the face and 30% salicylic acid to the left half at 2-week intervals for 2 months. TCA is superior in treating comedonal lesions, whereas salicylic acid is better at treating inflammatory lesions with no statistical difference between the results.

Comparison of fractional microneedling radiofrequency and bipolar radiofrequency on acne and acne scar and investigation of mechanism: comparative randomized controlled clinical trial

Min S, Park SY, Yoon JY, Suh DH. *Arch Dermatol Res* 2015; 307: 897–904.

Fractional microneedling radiofrequency (FMR) is one of the promising methods in acne treatment. Moreover, bipolar radiofrequency (BR) generates heat, inducing neocollagenesis. Twenty subjects with mild-to-moderate acne and acne scars were treated in a split-face manner with FMR and BR in a prospective single-blind, randomized clinical trial over 12 weeks, receiving two treatment sessions 4 weeks apart. Both treatments showed no severe adverse events other than erythema. FMR showed superior efficacy in acne and acne scars compared with BR.

Treatment of acne scars by fractional bipolar radiofrequency

energy

Gold MH, Biron JA. Cosmet Laser Ther 2012; 14: 172–8.

Fifteen patients with mild-to-moderate acne scars received three monthly treatments with a fractional bipolar RF device. Physician-assessed acne scar severity was significantly reduced at 1 month and 3 months. Adverse events were limited to transient erythema. Dryness, bruising, and crusting erosion were limited. Subject-assessed fine lines and wrinkles, brightness, tightness, acne scar texture, and pigmentation improved significantly.

Deep peeling using phenol versus percutaneous collagen induction combined with trichloroacetic acid 20% in atrophic postacne scars: a randomized controlled trial

Leheta TM, Abdel Hay RM, El Garem YF. J Dermatolog Treat 2014; 25: 130–6.

Deep peeling using phenol and percutaneous collagen induction (PCI) with TCA 20% were both effective in treating postacne atrophic scars. Comparison of the degree of improvement in different types of scars within the same group after treatment revealed very highly significant improvement in the rolling scar type.

Treatment of acne vulgaris with salicylic acid chemical peel and pulsed dye laser: a split face, rater-blinded, randomized controlled trial

Lekakh O, Mahoney AM, Novice K, Kamalpour J, Sadeghian A, Mondo D, et al. J Lasers Med Sci 2015; 6: 167–70.

An evaluation of the safety and efficacy of concurrent use of salicylic acid peels with pulsed dye laser (PDL) versus salicylic acid peels alone in 19 patients with moderate-to-severe acne vulgaris. The adjunctive utilization of PDL to salicylic acid peel therapy can lead to better outcomes in acne management.

Comparison of two kinds of lasers in the treatment of acne scars

Reinholz M, Schwaiger H, Heppt MV, Poetschke J, Tietze J, Eppler A, et al. Facial Plast Surg 2015; 31: 523–31.

A pilot study comparing the results of acne scars treated either with a fractional Er:YAG (erbium-doped yttrium-aluminum-garnet [Er:Y3Al5O11]) or a carbon dioxide (CO₂) laser at different wavelengths. Fourteen patients with severe scars on both cheeks were

treated four times in a random split-face approach: on one side with Er:YAG laser and on the contralateral side with CO₂ laser following a standardized protocol. Treatment results displayed a higher efficacy of the fractional CO₂ laser compared with the Er:YAG laser.

Acne scars in ethnic skin treated with both nonablative fractional 1550 nm and ablative fractional CO₂ lasers: comparative retrospective analysis with recommended guidelines

Alajlan AM, Alsuwaidan SN. Lasers Surg Med 2011; 43: 787–91.

Eighty-two patients with skin phototype III–V were included; 45 were treated with nonablative fractional (NAF) 1550 nm laser and 37 with ablative fractional (AF) CO₂ laser. Both lasers were effective in treating acne scars with good patient satisfaction rate and high safety profiles. Transient postinflammatory hyperpigmentation was noted in both groups, but decreased with routine use of bleaching creams.

Acrodermatitis enteropathica

Joanna E. Gach

Acrodermatitis enteropathica (AE) OMIM 201100 is a rare, autosomal-

recessive, inherited disorder of zinc deficiency. It is caused by mutations in the *SLC39A* gene located on 8q24.3, which encodes for ZIP4 intestinal zinc transporter expressed in enterocytes that absorb dietary zinc from the small intestine. The estimated prevalence is 1 in 500,000 children worldwide, without apparent predilection for race or gender. AE manifests itself shortly after birth in a bottle-fed infant and sometime soon after weaning in a breast-fed infant. Zinc within breast milk is more bioavailable to infants than within bovine milk due to binding to a low-molecular-weight ligand secreted by the pancreas. Characteristic clinical signs are lesions in acral and periorificial sites; the first signs are eczematous, pink, scaly plaques that can become vesicular, bullous, pustular, or desquamative. They can resemble the severe diaper dermatitis of infancy. Angular cheilitis and paronychia can also be seen early. If left untreated, AE usually causes diarrhea, irritability, and alopecia, and skin lesions become secondarily infected with bacteria and *Candida albicans*. Impaired physical and mental development is seen in advanced disease. Appropriate supplementation of zinc in the infant's diet results in a rapid improvement.

The diagnosis of AE is applied only to *inherited* zinc deficiency; noninherited zinc deficiency is called *acquired zinc deficiency*. Transient neonatal zinc deficiency OMIM 608118, caused by mutations of the ZnT2/SLC30A2 in mothers, occurs in breast-fed, full-term infants due to low zinc concentrations in the mother's breast milk. Clinical symptoms identical to AE are alleviated with zinc supplementation to the infant, but not to the mother. Long-term therapy and management of zinc deficiency vary depending on the severity of the disorder.

Management Strategy

Chronic dermatitis in periorificial and acral areas should suggest the possibility of zinc deficiency, but establishing the diagnosis of AE may be difficult. The first step is laboratory determination of blood plasma or serum zinc levels. A blood sample needs to be drawn into a trace element-free bottle with a stainless steel needle. Avoid contact with rubber stoppers, as they contain zinc, avoid hemolysis, use zinc-free anticoagulants, and separate plasma or serum from cells within 45 minutes. Zinc levels will decrease in states of hypoalbuminemia because zinc binds albumin in the circulation. If the diagnosis of zinc deficiency has been confirmed, management becomes relatively

simple: *oral zinc supplementation* produces dramatic resolution of the problem. High-dose supplementation will allow for increased paracellular zinc absorption despite the absence of a functional *ZIP4* zinc transporter.

The patient or his or her family must understand the need for lifelong management of the disorder in terms of zinc supplementation and medical supervision. Discuss *foods rich in zinc, such as shellfish, nuts, and green leafy vegetables*. Bioavailability of zinc can be reduced by phytates, which naturally occur in plant fibers, and also with regular iron supplementation. With age and a more varied diet, the dose of daily zinc supplementation may be reduced. Zinc therapy should be monitored periodically with morning fasting specimen, full blood count, serum copper level, and stool examination for occult blood. Zinc supplementation has a theoretical risk of reducing copper absorption, leading to refractory microcytic anemia that will not respond to iron therapy until the serum copper level is normalized.

Specific Investigations

- Morning fasting blood plasma or serum zinc levels
- Urine zinc excretion
- Serum albumin and alkaline phosphatase
- Serum copper levels
- Genetic studies

The normal plasma zinc level is 70 to 110 µg/dL and in serum 80 to 120 µg/dL. Urinary zinc can be measured but is not definitive for diagnosis.

Homozygosity mapping places the acrodermatitis enteropathica gene on chromosomal regions 8q24.3

First-Line Therapy

• Oral zinc supplementation	A
-----------------------------	---

In most cases, oral supplementation with two to three times the recommended daily allowance of zinc salts in doses of 30 to 55 mg of elemental Zn^{2+} will be sufficient to restore normal zinc status within days to a few weeks, depending on the degree of depletion. The dose of elemental zinc must be determined by the patient's blood or plasma zinc levels and by body weight. In AE, zinc replacement should begin at 2 to 3 mg/kg/day of elemental zinc. Serum or plasma zinc should be checked every 3 to 6 months, adjusting the zinc dosage accordingly. In patients with acquired or dietary zinc deficiency, treatment should begin at 0.5 to 1 mg/kg/day. Available forms of zinc supplementation include zinc sulfate, zinc acetate, zinc gluconate, and zinc propionate. *Dosage must be based on the amount of elemental zinc present in the preparation, which varies between compounds. For example, a standard 220-mg capsule of a commercial zinc preparation contains approximately 55 mg Zn^{2+} , which is an adequate daily dose for most deficient individuals. A commonly used preparation is Zincate, which is $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$.*

A significant side effect of zinc supplementation is gastric irritation with nausea, vomiting, and gastric hemorrhage. Large accidental overdoses of zinc may cause fatal multisystem organ failure.

Zinc deficiency in acrodermatitis enteropathica: multiple dietary intolerance treated with synthetic diet

Barnes PM, Moynahan EJ. Proc Roy Soc Med 1973; 66: 327–9.

In 1973 Barnes and Moynahan were treating children with chronic, unresponsive AE-type acral dermatoses and having poor results. They then tried different medications, one of which was oral zinc. To their surprise, the patients receiving the zinc supplements cleared rapidly and completely.

Acrodermatitis enteropathica and an overview of zinc metabolism

We acknowledge Dr. Kenneth H. Neldner for his contribution to this chapter.

Actinic keratoses

Sherrif F. Ibrahim, and Marc D. Brown

Actinic keratoses (AKs) are ill-defined, pink-to-skin-colored, scaly papules found on chronically sun-exposed areas in light-skinned individuals. They most frequently appear on the face, ears, balding scalp, extensor forearms, and dorsal hands. AKs are a strong predictor for the development of squamous cell carcinoma (SCC) and, to a lesser extent, basal cell carcinoma. Australians have the highest reported prevalence, which approaches 60%, and in the United States AKs are the second most common reason for visits to the dermatologist.

Management Strategy

Actinic keratoses are common dysplastic intraepidermal lesions that are considered precursors to SCC. Reports have varied as to the rates of progression to invasive SCC, from 0.025% to over 25% per year, and AKs are commonly located adjacent to SCC histologically. For these reasons, most practitioners advocate the treatment of AKs, because considerable morbidity and potential mortality can be associated with invasive disease. However, no randomized controlled studies have demonstrated a reduction in the frequency of SCC with treatment of AKs.

The diagnosis of AK is primarily clinical, and because of their superficial nature, a variety of effective management approaches exist. Biopsy of suspected AKs is typically not warranted; however, in patients with a history of multiple skin cancers, immunosuppressed patients, and lesions in high-risk areas such as the lip or ear, clinicians should have a low threshold for biopsy to rule out invasive SCC. Indications for biopsy include tenderness, rapid growth or thickening of lesions, bleeding, hyperkeratosis, and failure to respond to treatment.

Prevention of AKs through sun avoidance and diligent use of broad-spectrum sunscreens and blocking agents is an important aspect of management. This has been shown to prevent the development of new AKs and reduce the incidence of nonmelanoma skin cancers.

With cumulative sun exposure and advancing age, rates of AK development increase, necessitating either *ablative* or *topical treatment*. *Cryotherapy* with liquid nitrogen is by far the most commonly employed therapeutic modality because it can be performed quickly and effectively in the office setting. However, given the common appearance of AKs on a background of diffuse actinic damage, individual lesions may be poorly defined and involve large, confluent areas requiring field treatment with topical agents such as 5-*fluorouracil* (5-FU) and *imiquimod*. The latter has recently been shown to have high rates of treatment success with durable results and has become an accepted first-line therapy with a newer 3.75% formulation recently introduced. The most recently approved topical agent, *ingenol mebutate*, is derived from the *Euphorbia peplus* plant and has efficacy for the field treatment of AKs. The advantages of topical approaches are that they are patient administered, noninvasive, carry little risk of scarring or pigmentary change, and can be used for anatomically difficult or cosmetically sensitive areas. However, these agents require adequate patient compliance and are often

accompanied by prolonged erythema lasting several weeks. *Photodynamic therapy* (PDT) with aminolevulinic acid (ALA) or methyl aminolevulinate (MAL) has continued to become more widespread, given its proven therapeutic results and excellent cosmetic outcome. PDT offers a physician-administered approach to field treatment with shorter periods of inflammation and erythema than several topical agents, and thus many studies indicate higher patient satisfaction. Variations in the light dose, light source (including ambient daylight), sensitizing agent and its application time, and frequency of treatments may improve efficacy. Head-to-head trials of different treatment approaches are difficult to perform, as variations in treatment protocols make direct comparisons challenging. Recently there has been a continuing trend toward *combination therapy*, such as topical agents either before or after cryotherapy, or sequential use of multiple topical modalities with varying mechanisms of action. Other approaches such as *laser resurfacing*, *chemical peels*, and *dermabrasion* may be considered in certain situations when lesions have failed the aforementioned treatments or if severe photodamage is present. Finally, for recalcitrant or hyperkeratotic lesions, *curettage* or *excision* may be appropriate.

Specific Investigation

In selected cases:

- Biopsy

Actinic keratoses and the incidence of occult squamous cell carcinoma: a clinical–histopathologic correlation

Ehrig T, Cockerell C, Piacquadio D, Dromgoole S. *Dermatol Surg* 2006; 32: 1261–5.

A total of 271 clinically diagnosed AKs were biopsied. Clinical diagnosis was in agreement with histology 91% of the time, with about 1 in 25 lesions revealing invasive SCC.

Clinical recognition of actinic keratoses in a high-risk population: how good are we?

Venna SS, Lee D, Stadecker MJ, Rogers GS. *Arch Dermatol* 2005; 141: 507–9.

Seventeen of 23 lesions (74%) with classic features of AK in patients

with a history of previous skin cancer were confirmed histologically. Five lesions (22%) were shown to be SCC.

Actinic keratoses are typically diagnosed clinically. However, there should be a low threshold to biopsy tender, hyperkeratotic, large, or recalcitrant lesions to exclude malignancy.

First-Line Therapies

• Sunscreens	A
• Cryosurgery	B
• Topical 5-FU	A
• Imiquimod	A
• Photodynamic therapy	A

A randomized controlled trial to assess sunscreen application and beta carotene supplementation in the prevention of solar keratoses

Darlington S, Williams G, Neale R, Frost C, Green A. Arch Dermatol 2003; 139: 451–5.

In this Australian study, 1621 adults were randomized to either daily use of sunscreen or application at their usual discretionary rate. There was a 24% reduction in AKs in the daily-use group.

Reduction of solar keratoses by regular sunscreen use

Thompson SC, Jolley D, Marks R. N Engl J Med 1993; 14: 1147–51.

In a 6-month randomized, placebo-controlled trial of 588 patients in Australia, SPF 17 sunscreen applied daily was found to both reduce the development of new AKs and increase the remission of existing

AKs compared with a vehicle cream.

A prospective study of the use of cryosurgery for the treatment of actinic keratoses

Thai K, Fergin P, Freeman M, Vinciullo C, Francis D, Spelman L, et al. *Int J Dermatol* 2004; 43: 687–92.

In this prospective multicenter study, 90 patients with 421 AKs on the face and scalp were treated with cryotherapy with a single freeze–thaw cycle using different freeze times. The patients were reviewed 3 months later. Overall, the complete response (CR) rate was 67.2%, varying from 39% for freeze times less than 5 seconds to 83% for times longer than 20 seconds. The authors also found that hypopigmentation was present in 29% of CR lesions. Patients rated cosmetic outcomes as good to excellent for 94% of CR lesions.

Effect of a 1 week treatment with 0.5% topical fluorouracil on occurrence of actinic keratosis after cryosurgery

Jorizzo J, Weiss J, Furst K, VandePol C, Levy SF. *Arch Dermatol* 2004; 140: 813–16.

This study demonstrates that there is a role for the combination of therapeutic modalities in the treatment of AKs. In this prospective, double-blind, randomized controlled trial, 144 patients, each with at least five AKs on the face, were randomized to receive 1 week of treatment with 0.5% 5-FU cream daily for 7 days or placebo cream. Patients were then treated with single freeze–thaw cycle cryotherapy using liquid nitrogen, with a freeze time of 10 seconds. These patients were then followed up at 4 weeks and 6 months. The authors found that at 4 weeks, 16.7% of patients in the 5-FU group were completely clear of lesions, compared with 0% in the vehicle group ($p < 0.001$). At 6 months posttreatment, 30% of patients in the 5-FU group were clear of lesions, compared with 7.7% of patients in the vehicle group ($p < 0.001$).

Imiquimod 5% cream for the treatment of actinic keratosis: results from two phase III, randomized, double-blind, parallel group, vehicle-controlled trials

Lebwohl M, Dinehart S, Whiting D, Lee PK, Tawfik N, Jorizzo J, et al. *J Am Acad Dermatol* 2004; 50: 714–21.

In this report of two phase III double-blind, vehicle-controlled studies, 436 subjects at 24 centers in the United States were

randomized to either 5% imiquimod or vehicle applied once daily, 2 days per week, for 16 weeks. The complete clearance rate for the treated arm was 45%, as opposed to 3.2% for the vehicle group. The median percent reduction in AK lesions was 83% for the treated group and 0% for the vehicle group, indicating that a reduced frequency of imiquimod application is quite effective.

Imiquimod 2.5% and 3.75% for the treatment of actinic keratoses: results of two placebo-controlled studies of daily application to the face and balding scalp for two 3-week cycles

Hanke CW, Beer KR, Stockfleth E, Wu J, Rosen T, Levy S. J Am Acad Dermatol 2010; 62: 573–81.

Imiquimod 2.5% and 3.75% for the treatment of actinic keratoses: results of two placebo-controlled studies of daily application to the face and balding scalp for two 2-week cycles

Swanson N, Abramovits A, Berman B, Kulp J, Rigel DS, Levy S. J Am Acad Dermatol 2010; 62: 582–90.

These two back-to-back reports demonstrate the efficacy and tolerability of lower-concentration formulations of imiquimod, as well as alternate dosing schedules. Interestingly, the results were essentially identical for two 3-week cycles as they were for two 2-week cycles, with the 3.75% strength imiquimod proving superior to the 2.5% in both studies and slightly less efficacious than previous studies that have investigated 5% imiquimod used twice weekly for 16 weeks.

A randomised study of topical 5% imiquimod vs. topical 5-fluorouracil vs. cryosurgery in immunocompetent patients with actinic keratoses: a comparison of clinical and histologic outcomes including 1-year follow-up

Krawtchenko N, Roewert-Huber J, Ulrich M, Mann I, Sterry W, Stockfleth E. Br J Dermatol 2007; 157 (Suppl 2): 34–40.

This study compared the baseline and 1-year follow-up rates of clinical clearance, histologic clearance, and cosmetic outcomes of imiquimod, 5-FU, and cryosurgery for the treatment of AKs. Patients were randomized to one of the three treatment groups. Clinical clearance was achieved in 68% of those treated with cryosurgery, 96% with 5-FU, and 85% with imiquimod. Histologic clearance rate was 32% for cryosurgery, 67% for 5-FU, and 73% for imiquimod. The 1-

year sustained clearance rate was 28% for cryosurgery, 54% for 5-FU, and 73% for imiquimod. The patients treated with imiquimod were also judged to have superior cosmetic outcomes.

Guidelines on the use of photodynamic therapy for nonmelanoma skin cancer: an international consensus

Braathen LR, Szeimies R, Basset-Seguin N, Bissonnette R, Foley P, Pariser D, et al. *J Am Acad Dermatol* 2007; 56: 125–43.

This is a comprehensive evidence-based review and treatment recommendations for the use of PDT to treat nonmelanoma skin cancers, including AKs. The authors review each of the main clinical trials using PDT to treat AKs and conclude that PDT with MAL and ALA is highly effective, offering excellent cosmetic results, and should be considered as first-line therapy.

Intraindividual, right–left comparison of topical methyl aminolaevulinate–photodynamic therapy and cryotherapy in subjects with actinic keratoses: a multicentre, randomized controlled study

Morton C, Campbell S, Gupta G, Keohane S, Lear J, Zaki I, et al. *Br J Dermatol* 2006; 155: 1029–36.

In this 24-week study subjects received one treatment session of PDT to one side of their face and two cycles of freeze–thaw cryosurgery to the other. Of the 1501 lesions treated, PDT resulted in a higher rate of cure (87% vs. 76% reduction from baseline). Both subjects and investigators preferred PDT and also felt it had a better cosmetic outcome. Both treatment regimens were deemed safe and well tolerated.

Multicentre intraindividual randomized trial of topical methyl aminolaevulinate–photodynamic therapy vs. cryotherapy for multiple actinic keratoses on the extremities

Kaufmann R, Spelman L, Weightman W, Reifenberger J, Szeimies RM, Verhaeghe E, et al. *Br J Dermatol* 2008; 158: 994–9.

This was another intraindividual trial that treated one side of the body (nonface/scalp) with a single course of PDT and the other with cryotherapy. For the 1343 lesions treated, both treatment modalities had high efficacy rates at 24 weeks, although cryosurgery performed better (78% for PDT and 88% for cryosurgery). Investigator and patient assessment of cosmetic outcome was much higher for PDT

than for cryosurgery (79% vs. 56% of lesions having “excellent cosmetic outcome” based on investigator evaluation, 50% vs. 22% based on patient evaluation).

Photodynamic therapy with aminolevulinic acid topical solution and visible blue light in the treatment of multiple actinic keratoses of the face and scalp: investigator-blinded, phase 3, multicenter trials

Piacquadio DJ, Chen DM, Farber HF, Fowler JF Jr, Glazer SD, Goodman JJ, et al. *Arch Dermatol* 2004; 140: 41–6.

In this randomized, placebo-controlled study 243 patients were randomized to receive vehicle or ALA followed by PDT within 14 to 18 hours. Clinical response rate was based on complete clearing of 75% of lesions measured at weeks 8 and 12. Of the PDT-treated group, 77% had a complete response by week 8 and 89% by week 12. This compared with 18% and 13% for the placebo group. Most patients experienced erythema and edema at the treated sites, which improved within 4 weeks of therapy. Stinging, burning, or pain occurred during the treatments, but resolved within 24 hours.

Results of an investigator-initiated single-blind split-face comparison of photodynamic therapy and 5% imiquimod cream for the treatment of actinic keratoses

Hadley J, Tristani-Firouzi P, Hull C, Florell S, Cotter M, Hadley M. *Dermatol Surg* 2012; 38: 722–7.

In this split-faced trial, 61 patients received 5% imiquimod twice weekly to half the face and two sessions of ALA-PDT to the other side of the face. No significant difference was noted with respect to partial or total clearance rate; however, ALA-PDT was superior when mean lesion reduction rate was evaluated.

Daylight photodynamic therapy with MAL cream for large-scale photodamaged skin based on the concept of ‘actinic field damage’: recommendations of an international expert group

Philipp-Dormston WG, Sanclemente G, Torezan L, Tretti Clementoni M, Le Pillouer-Prost A, Cartier H, et al. *J Eur Acad Dermatol Venereol* 2016; 30: 8–15.

A review of daylight PDT in both European and Australasian trials. Daylight MAL-PDT had a similar efficacy to conventional light source PDT at 3-month (lesion complete response rate of 89% vs. 93% in the

Australian study and 70% vs. 74% in the European study, respectively) and 6-month follow-ups (97% maintenance of complete lesion response) in the treatment of AKs. Daylight PDT is not only efficacious, but also nearly pain free and easy to perform, and therefore results in high patient acceptance, especially for the treatment of areas of actinic field damage.

Network meta-analysis of the outcome ‘participant complete clearance’ in nonimmunosuppressed participants of eight interventions for actinic keratosis: a follow-up on a Cochrane review

Gupta AK, Paquet M. Br J Derm 2013; 169: 250–9.

In this thorough meta-analysis of eight common treatments for AKs, the authors conclude that 5% 5-FU was superior in achieving complete clearance. They comment on the inherent difficulty in comparing studies.

Second-Line Therapies

• Topical adapalene	A
• Topical diclofenac	A
• Topical ingenol mebutate	A

Assessment of adapalene gel for the treatment of actinic keratoses and lentigines: a randomized trial

Kang S, Goldfarb MT, Weiss JS, Metz RD, Hamilton TA, Voorhees JJ, et al. J Am Acad Dermatol 2003; 49: 83–90.

In this prospective randomized, vehicle-controlled study 90 patients received either 0.1% adapalene gel, 0.3% adapalene gel, or vehicle gel, initially daily for 4 weeks, then twice daily for up to 9 months. Overall, 62% ($p < 0.01$) of those who received 0.1% adapalene gel and 66% ($p < 0.01$) of those who received 0.3% adapalene gel

showed at least a moderate improvement of their AKs, compared with 34% of patients receiving a vehicle cream. Adapalene gel recipients reported a higher level of mild erythema, peeling, and dryness compared with control groups.

Three percent diclofenac in 2.5% hyaluronan gel in the treatment of actinic keratoses: a meta-analysis of the recent studies

Pirard D, Vereecken P, Melot C, Heenen M. Arch Dermatol Res 2005; 297: 185–9.

This meta-analysis pooled 364 patients from three studies that compared diclofenac with hyaluronan vehicle gel. Overall, patients treated with diclofenac had a significantly higher rate of complete clearance of lesions. They concluded that complete response rates were 39% with a mean treatment duration of 75 ± 21 days. Mild-to-moderate skin irritation was the major side effect of the treatment group.

Diclofenac sodium 3% gel for the management of actinic keratosis: 10+ years of cumulative evidence of efficacy and safety

Martin GM, Stockfleth E. J Drugs Dermatol 2012; 11: 600–8.

This comprehensive review draws from 17 publications beyond the initial phase III clinical trials that led to the approval of diclofenac sodium for the treatment of AKs. It discusses the data with regard to treatment efficacy, tolerability, and performance compared with other topical field agents, as well as its use in combination treatment strategies.

Ingenol mebutate gel for actinic keratosis

Lebwohl M, Swanson N, Anderson LL, Melgaard A, Xu Z, Berman B. N Engl J Med 2012; 366: 1010–19.

This multicenter, randomized, double-blind report investigated the use of 0.015% ingenol mebutate (IM) used once daily for 3 consecutive days for AKs on the face and scalp, as well as 0.05% IM used once daily for 2 consecutive days for AKs on the trunk and extremities. All analyses were conducted at day 57. The rate of complete clearance was 42% for the face/scalp group and 34% for the trunk/extremities group. Local skin reactions peaked between day 3 and day 8 and were mild to moderate in nature. Hypertrophic or hyperkeratotic lesions were excluded from the study.

Randomized, double-blind, double-dummy, vehicle-controlled study of ingenol mebutate gel 0.025% and 0.05% for actinic keratosis

Anderson L, Schmieder GJ, Werschler WP, Tschien EH, Ling MR, Stough DB, et al. J Am Acad Dermatol 2009; 60: 934–43.

A total of 222 patients from 22 U.S. centers with nonfacial AKs were randomized to receive vehicle for 3 days, 0.025% ingenol mebutate (IM) gel for 3 days, vehicle for 1 day followed by 0.05% IM gel for 2 days, or 0.05% IM gel for 3 days. Partial clearance rate (>75% reduction in baseline AKs), as well as complete clearance rate, was statistically significantly higher in all three treatment groups over baseline, and these results were dose dependent. Partial and complete clearance rates were 28%/20% for the 0.025% × 3 days group, 34%/24% for the 0.05% × 2 days group, and 43%/31% for the 0.05% × 3 days cohort. The most common local skin responses seen in all groups included erythema, scaling, crusting, swelling, erosion/ulceration, vesiculation, and pigmentary changes and were largely resolved by day 15. Patient satisfaction was high.

Third-Line Therapies

• Curettage	E
• Excision	E
• Laser resurfacing	B
• Chemical peels	D
• Dermabrasion	D

Full face laser resurfacing: therapy and prophylaxis for actinic keratoses and nonmelanoma skin cancer

Iyer S, Friedli A, Bowes L, Kricorian G, Fitzpatrick RE. *Lasers Surg Med* 2004; 34: 114–19.

In this retrospective study of 24 patients with over 30 AKs on the face treated with full-face ultrapulse CO₂ laser or erbium (Er):YAG laser resurfacing, the authors found that 21 patients remained lesion free for at least 1 year.

Recurrence rates and long-term follow-up after laser resurfacing as a treatment for widespread actinic keratoses on the face and scalp

Ostertag JU, Quaedvlieg PJ, Neumann MH, Krekels GA. *Dermatol Surg* 2006; 32: 261–7.

A retrospective case-control study of 25 patients who underwent laser resurfacing for widespread AKs on the scalp and/or face. Forty-four percent had no recurrence in an average follow-up period of 39 months (range 7–70 months).

Nonablative fractional photothermolysis for facial actinic keratoses: 6-month follow-up with histologic evaluation

Katz TM, Goldberg LH, Marquez D, Kimyai-Asadi A, Polder KD, Landau JM, et al. *J Am Acad Dermatol* 2011; 65: 349–56.

In this study, 14 patients underwent five treatments of nonablative fractional resurfacing with 32% to 40% surface area coverage at 2- to 4-week intervals. Clinical images and biopsies were evaluated. Although clinical images had a reduced number of AKs, virtually all histologic specimens were positive for features of AK and/or SCC. It was concluded that fractional nonablative resurfacing was not adequate therapy for AKs.

A clinical comparison and long-term follow-up of topical 5-fluorouracil versus laser resurfacing in the treatment of widespread actinic keratoses

Ostertag JU, Quaedvlieg PJ, van der Geer S, Nelemans P, Christianen ME, Neumann MH, et al. *Lasers Surg Med* 2006; 38: 731–9.

A prospective randomized trial of 55 patients comparing 5-FU with Er:YAG laser resurfacing. At 3, 6, and 12 months there were significantly fewer recurrences in the laser group than in the 5-FU

group. Side effects were more common in the group treated with laser resurfacing and included erythema and hypopigmentation.

Long-term efficacy and safety of Jessner's solution and 35% trichloroacetic acid vs. 5% fluorouracil in the treatment of widespread facial actinic keratoses

Witheiler DD, Lawrence N, Cox SE, Cruz C, Cockerell CJ, Freeman RG. *Dermatol Surg* 1997; 23: 191–6.

In this prospective study, 15 patients with severe facial AKs were treated on one side of the face with a single application of Jessner solution—a medium-depth chemical peel—and the other side with twice-daily applications of topical 5-FU 5% for 3 weeks. The authors found that both treatments resulted in a similar reduction of AKs at 12 months, with an increase in the number of AKs in both groups from 12 to 32 months. The authors concluded that both treatments were similarly efficacious in the treatment of AK and that retreatment for recurrences might be necessary after 12 months.

Dermabrasion for prophylaxis and treatment of actinic keratoses

Coleman WP, Yardborough JM, Mandy SH. *Dermatol Surg* 1996; 22: 17–21.

In this retrospective study, 23 patients who had undergone dermabrasion for facial AKs were followed for 2 to 5 years. The authors found that the benefits of dermabrasion diminished with time: 1 year postdermabrasion, 22 patients remained clear of AKs. Of 13 patients who were followed up for 5 years, 7 remained clear. The authors concluded that dermabrasion provided long-term clearance of AKs in some patients.

Recalcitrant treatment-resistant AKs may be treated with physically destructive approaches that include curettage and surgical excision. Both techniques enable tissue to be obtained for histologic analysis. Surgical excision is particularly useful in lesions suspected of being SCC because this technique enables the clinician to treat the lesion and establish the diagnosis. Widespread, extensive AKs may benefit from field treatments of a destructive nature. These include ablative laser resurfacing, dermabrasion, and chemical peels.

Actinic prurigo

Robert S. Dawe, and Martha C. Valbuena

(*Synonyms:* hereditary polymorphic light eruption of American Indians, Hutchinson summer prurigo, photodermatitis in North American Indians)

Actinic prurigo (AP) is a distinct photodermatosis, diagnosed on the basis of characteristic clinical features. It has a perennial nature, although it is worse in the sunnier months in countries with seasonal variation in sunlight exposure. Morphologically, it presents as a

papular or mixed papular and vesicular (in Latin America, vesicles usually being a feature of eczematization or secondary infection) eruption during acute flares, persistent eroded nodules, and/or dermatitic patches (sometimes affecting covered sites), scarring, dorsal nose involvement, cheilitis, and conjunctivitis. Abnormal photosensitivity (to ultraviolet A [UVA], ultraviolet B [UVB]) is frequently severe, but when onset has been in childhood, the condition generally gradually improves (probably largely by learning to live with the condition), especially when presenting before the usual age of 10 years.

Management Strategy

Diagnosis is normally straightforward, but the differential diagnosis can include severe polymorphic light eruption and photoaggravated atopic dermatitis. Although differences between European and Amerindian forms of AP have been described, these are either closely related conditions or the same disease with some differences affected by population and environment. Phototesting and human leukocyte antigen (HLA) typing may sometimes be helpful in cases of diagnostic uncertainty. Possible coexisting conditions such as sunscreen allergic contact dermatitis or photocontact reactions should be considered, as their presence will affect the recommended treatments.

Once the diagnosis is established, initial treatment consists of advice on *sunlight avoidance* measures (behavioral, clothing, and topical sunscreen) and the use of potent or very potent *topical corticosteroids*. *Topical tacrolimus* can also be used, especially if prolonged treatment to the face is required. This approach alone is often insufficient, and many patients require the addition of a springtime course of narrowband (TL-01) UVB or psoralen-ultraviolet A (PUVA). When *phototherapy* is administered for this indication, only normally sunlight-exposed sites should be treated. It is helpful to apply a potent topical steroid to the treated areas immediately after each exposure to reduce the risk of AP flares.

In Scotland, systemic treatment is rarely required; it is more often necessary where the availability of phototherapy is limited and in countries with more intense year-round sunlight exposure. *Antimalarials* and β -carotene are sometimes tried, but it remains uncertain whether they are truly of value. *Thalidomide* is useful, but its

value is restricted by teratogenicity and the risk of irreversible peripheral neuropathy. *Pentoxifylline* has anti-tumor necrosis factor (TNF)- α effects and, although listed as a third-line therapy here, may sometimes be worth considering before thalidomide because of its more attractive safety profile.

Specific Investigations

- Phototesting
- HLA typing
- Histopathology of cheilitis

Actinic prurigo—a specific photodermatosis?

Addo HA, Frain-Bell W. Photodermatology 1984; 1: 119–28.

This study showed that almost 60% of AP patients have abnormal delayed erythema on monochromator phototesting.

Phototest abnormalities tend to be more severe in AP than in polymorphic light eruption.

Actinic prurigo among the Chimila Indians in Colombia: HLA studies

Bernal JE, Duran de Rueda MM, Ordonez CP, Duran C, de Brigard D. J Am Acad Dermatol 1990; 22: 1049–51.

In this population, the HLA class I antigen Cw4 was more frequent in AP patients than in controls.

HLA-DR4 may determine expression of actinic prurigo in British patients

Menage H du P, Vaughan RW, Baker CS, Page G, Proby CM, Breathnach SM, et al. J Invest Dermatol 1996; 106: 362–7.

Actinic prurigo and HLA-DR4

Dawe RS, Collins P, O'Sullivan A, Ferguson J. J Invest Dermatol 1997; 108: 233–4.

An even stronger association with the HLA class II antigen HLA-DR4 was shown and, more specifically, with HLA-DRB1*0407.

Association of HLA subtype DRB10407 in Colombian patients with actinic prurigo

Suárez A, Valbuena MC, Rey M, de Porras Quintana L.
Photodermatol Photoimmunol Photomed 2006; 22: 55–8.

These associations are not a feature of polymorphic light eruption. The absence of HLA-DR4 can help to rule out the diagnosis of AP, whereas the presence of HLA-DRB1*0407 helps to rule in the diagnosis.

Actinic prurigo: clinical features and HLA associations in a Canadian Inuit population

Wiseman MC, Orr PH, MacDonald SM, Schroeder ML, Toole JW. J Am Acad Dermatol 2001; 44: 952–6.

No statistically significant association of AP with HLA-DR4 (frequent in the studied population) or HLA-DRB1*0407 was detected, and another HLA type (DRB1*14) was found more commonly than expected, although it was only present in 19 of 37 AP subjects. The authors acknowledge the possibility that they were studying a different condition from AP in other populations.

Actinic prurigo in Singaporean Chinese: a positive association with HLA-DRB1*03:01

Chen Q, Shen M, Heng YK, Theng TS, Tey HL, Ren EC, et al. Photochem Photobiol 2016; 92: 355–9.

In this population the strongest association was with HLA-DRB1*03:01, although it should be noted that although a strong association was compared with controls, only 6 of these 14 Chinese Singaporean patients diagnosed with AP had this HLA allele.

These findings suggest we should be cautious in attempting to use HLA typing as a diagnostic test, especially in populations in which strong HLA associations have not been confirmed. The diagnosis should still be based on the characteristic constellation of clinical features.

Actinic prurigo of the lower lip – review of the literature and report of five cases

Mounsdon T, Kratochvil F, Auclair P, Neale J, Lee L. Oral Surg Oral Med Oral Pathol 1988; 65: 327–32.

Follicular cheilitis – a distinctive histopathologic finding in actinic prurigo

Herrera-Geopfert R, Magana M. Am J Dermatopathol 1995; 17: 357–

Actinic prurigo cheilitis: clinicopathologic analysis and therapeutic results in 116 cases

Vega-Memije ME, Mosqueda-Taylor A, Irigoyen-Camacho ME, Hojyo-Tomoka MT, Dominguez-Soto L. Oral Surg Oral Med Oral Pathol Oral Radiol Endod 2002; 94: 83–91.

A “follicular cheilitis” has been reported to be characteristic of AP. Thirty-two of 116 patients attending a dermatology clinic in Mexico City had cheilitis as their sole manifestation of disease.

Lip histopathology may be helpful diagnostically, especially in patients presenting with cheilitis without cutaneous features at presentation. Where other typical features (skin, eyes) are present, it is arguable how much lip histopathology will contribute to diagnosis.

First-Line Therapies

• Sunlight avoidance – environmental, behavioral, clothing, topical sunscreen	C
• Potent/very potent topical corticosteroids	C
• Topical tacrolimus	E
• Narrowband (TL-01 lamp) UVB phototherapy	C

Topical photoprotection for hereditary polymorphic light eruption of American Indians

Fusaro RM, Johnson JA. J Am Acad Dermatol 1991; 24: 744–6.

The authors of this open study found 18 of 30 patients with hereditary polymorphic light eruption of American Indians (with described features indistinguishable from AP) to show “good to excellent results” with use of a broad-spectrum sunscreen.

Although broad-spectrum sunscreens are useful, advice on other sunlight avoidance measures, including appropriate clothing and behavioral avoidance, is equally important.

Actinic prurigo deterioration due to degradation of DermaGard window film

Kerr AC, Ferguson J. Br J Dermatol 2007; 157: 619–20.

Window films that reduce the transmission of UV rays can be used

as a method of environmental photoprotection. This case report describes an exacerbation of AP explained by increased transmission through such a window film as it aged. Because the technology of such window films has matured, such degradation now might be less likely, but the possibility of it should be considered.

Treatment of actinic prurigo with intermittent short-course topical 0.05% clobetasol 17-propionate: a preliminary report

Lane PR, Moreland AA, Hogan DJ. Arch Dermatol 1990; 126: 1211–3.

Seven out of eight patients treated with intermittent 3- to 14-day courses of topical 0.05% clobetasol 17-propionate cream or ointment cleared or markedly improved. All had previously found less potent topical steroids ineffective.

Narrow-band UVB (TL-01) phototherapy: an effective preventative treatment for the photodermatoses

Collins P, Ferguson J. Br J Dermatol 1995; 132: 956–63.

Six patients with AP were included in this open study. All reported at least a sixfold increase in tolerable duration of sunlight exposure, which was sustained 4 months after treatment. In one patient whose phototesting (severely abnormal before treatment) was repeated after treatment, the test results normalized.

Actinic prurigo: treatment with tacrolimus. Favorable response in two pediatric patients

Vivoda JL, Mantero N, Jaime LJ, Rueda ML, Grees SA. Rev Arg Derm 2015; 96: 30–4.

These two girls showed a good response by 10 days of treatment with tacrolimus ointment.

Treatment of actinic prurigo with tacrolimus 0.1%

Gonzalez-Carrascosa Ballesteros M, De la Cueva DP, Hernanz Hermosa JM, Chavarria E. Med Cutan Ibero Lat Am 2006; 34: 233–6.

A 13-year-old boy with only facial involvement with AP was reported to respond rapidly to 0.1% tacrolimus ointment after topical corticosteroids (uncertain what strengths) had not worked.

Tacrolimus ointment can be helpful in treating facial AP, especially when there are concerns about topical corticosteroid adverse effects.

The quality of life of 790 patients with photodermatoses

Jong CT, Finlay AY, Pearse AD, Kerr AC, Ferguson J, Benton EC, et al. Br J Dermatol 2008; 159: 192–7.

Of the photodermatoses assessed in the British tertiary referral photodermatology centers participating in this study, AP was associated with the greatest health-related quality of life impairment. We do not know whether measuring health-related quality of life is useful in the day-to-day management of these patients, but important effects of AP on quality of life should be considered when planning treatments.

Second-Line Therapies

• Psoralen–UVA photochemotherapy	C
• Thalidomide	C

Treatment of actinic prurigo with PUVA: mechanism of action

Farr PM, Diffey BL. Br J Dermatol 1989; 120: 411–8.

Five patients were treated in this open study. Clinical improvement was accompanied by an increase of UVA minimal erythema doses to within the normal range on phototesting. Corroboration that PUVA worked through a local effect was provided by before and after phototesting of areas kept covered during treatment. The UVA minimal erythema dose did not increase in these areas.

In the absence of any controlled study comparisons of PUVA and TL-01 phototherapy for this condition, PUVA should generally be reserved for those who fail to benefit from TL-01.

Thalidomide in the treatment of actinic prurigo

Londoño F. Int J Dermatol 1973; 12: 326–8.

Thirty-four patients were treated, with a starting dose of 300 mg thalidomide daily, gradually reducing to a minimum of 15 mg; 32 had good results while on the drug, but relapsed on stopping.

Thalidomide in actinic prurigo

Lovell CR, Hawk JL, Calnan CD, Magnus IA. Br J Dermatol 1983; 108:

467–71.

Of 14 patients treated with thalidomide (adult starting dose 100–200 mg daily), 13 (one could not tolerate the drug due to dizziness) reported improvement. This benefit was sustained in 11, of whom 8 required maintenance doses of between 50 mg weekly and 100 mg daily.

Includes a review of earlier open studies reporting the use of thalidomide in AP.

Third-Line Therapies

• β -Carotene	C
• Pentoxifylline	C
• Tetracycline and vitamin E	C
• Oral corticosteroids	E
• Azathioprine	E
• Chloroquine	E
• Ciclosporin eye drops	E

Hereditary polymorphic light eruption in American Indians: photoprotection and prevention of streptococcal pyoderma and glomerulonephritis

Fusaro RM, Johnson JA. JAMA 1980; 244: 1456–9.

Seventeen of 54 patients who participated in this open study were reported to have achieved complete photoprotection, and 16 “marked improvement.” The plasma carotene level tended to be higher in those who benefited. The authors also comment on their use of

dihydroxyacetone and lawsone cream, with apparent benefit.

The clinical features of the study patients were not reported, but the authors' introductory description of hereditary polymorphic light eruption suggests that they probably included AP.

Pentoxifylline in the treatment of actinic prurigo: a preliminary report of 10 patients

Torres-Alvarez B, Castanedo-Cazares JP, Moncada B. *Dermatology* 2004; 208: 198–201.

Clinical improvement was reported in all 10 participants in this 6-month open-label uncontrolled study.

Treatment of actinic prurigo in Chimila Indians

Duran MM, Ordonez CP, Prieto JC, Bernal J. *Int J Dermatol* 1996; 35: 413–16.

One group of eight patients was treated with tetracycline (1.5 g daily), and another eight with vitamin E (100 IU daily). On follow-up analysis comparing signs and itch, no difference was found between the groups. Both treatments were considered promising and the possibility of using a tetracycline–vitamin E combination therapy raised.

These treatments need further investigation, but may be worth considering if first-line therapies are inadequate and thalidomide is contraindicated or not tolerated.

The clinical features and management of actinic prurigo: a retrospective study

Lestarini D, Khoo LS, Goh CL. *Photodermatol Photoimmunol Photomed* 1999; 15: 183–7.

This is a review of the features and clinical course of 11 patients. Of three treated with systemic corticosteroids, one improved slightly. Intralesional steroids helped one. Three patients were treated with azathioprine: two appeared to benefit.

Actinic prurigo: clinico-pathologic correlation

Hojyo-Tomoka MT, Dominguez-Soto L, Vargasocamp F. *Int J Dermatol* 1978; 17: 706–10.

In this review, the authors comment that chloroquine “seems to give temporary relief” and also suggest that antihistamines and tranquilizers may be of some benefit.

Use of topical ciclosporin for conjunctival manifestations of actinic prurigo

McCoombes JA, Hirst LW, Green WR. Am J Ophthalmol 2000; 130: 830–1.

Topical ciclosporin in the treatment of ocular actinic prurigo

Ortiz-Castillo JV, Boto-De-Los-Bueis A, De-Lucas-Laguna R, Pastor-Nieto B, Peláez-Restrepo N, Fonseca-Sandomingo A. Arch Soc Esp Oftalmol 2006; 81: 661–4.

In these two case reports topical 2% ciclosporin eye drops were associated with improvement in chronic AP conjunctivitis.

Actinomycosis

Jonathan E. Blume, and Daniel Caplivski

Actinomycosis is an indolent infection that may be difficult to recognize initially and is caused by an anaerobic, gram-positive rod that is a normal human commensal. Infections are usually the result of introduction of bacteria into a normally sterile space from the oropharynx, gastrointestinal tract, or vaginal tract. The organism may be difficult to recover in the microbiology laboratory because it grows slowly and is ideally cultured under anaerobic conditions. Microscopically, it has a similar appearance to *Nocardia* spp.; however, it does not retain the modified acid-fast stain, and the

colonies may have a molar tooth appearance. Infections of the cervical region are typified by the slow induration of the skin at the angle of the jaw that progresses over several weeks or months. A mass may be palpable and, due to the slow progression and absence of systemic inflammatory symptoms, the infection can often be confused with other conditions such as malignancies. Patients may notice the discharge of small yellow grains known as *sulfur granules*. These are macroscopic colonies of the organism that may be cultured for confirmation, but their absence should not exclude the diagnosis from consideration.

Management Strategy

Actinomyces spp. are universally susceptible to penicillin. The severity of the illness will dictate whether the patient requires intravenous or oral formulations of the antibiotic, but the general principle is that prolonged treatments for 6 months or more are often required for cure. In patients who are penicillin allergic, the tetracycline class of antibiotics is a useful substitute. Surgical removal of the abscess may also be required in order to ensure complete resolution. Treatment failures are rare, but may be due to coinfecting organisms from the oropharynx. In order to treat these organisms, the combination of a β -lactam antibiotic with a β -lactamase inhibitor may be sufficient. Carbapenems such as imipenem, meropenem, or ertapenem are also effective.

Clinical review: actinomycosis

Wong VK, Turmezei TD, Weston VC. BMJ 2011; 343: d6099.

Susceptibility of pathogenic actinomycetes to antimicrobial compounds

Lerner PI. Antimicrob Agents Chemother 1974; 5: 302–9.

SPECIFIC INVESTIGATIONS

Diagnostic methods for human actinomycosis

Holmberg K. Microbiol Sci 1987; 4: 72–8.

An excellent review of the diagnosis of actinomycosis.

The most accurate way to diagnose actinomycosis is by culture—usually a difficult task—which requires thioglycolate or brain–heart–enriched agar at 37°C under anaerobic or microaerophilic conditions. “Molar-tooth” and “breadcrumb” colonies may take up to 3 weeks to grow. Unfortunately, definitive identification cannot be based on colony morphology and requires the measurement of physiologic and biochemical characteristics (e.g., sensitivity to oxygen, presence of preformed enzymes).

Because cultures of *Actinomyces* spp. are often unsuccessful, observation of “sulfur granules” on a peripheral smear or histology often helps make the diagnosis. The granules are bacterial colonies, which on hematoxylin and eosin staining have a basophilic central area surrounded by a zone of eosinophilic “clubs.” Other typical histologic findings include extensive fibrosis, chronic granulation tissue, sinus tracts, and scattered microabscesses.

Immunofluorescent staining of *Actinomyces* spp. is available and can be used on clinical material, granules, and formalin-fixed tissues. The direct immunoperoxidase technique can specifically show *Actinomyces* spp. in formalin-fixed sections via light microscopy. These techniques, as well as gene sequencing (see later), are promising diagnostic modalities given the difficulty of culture and histologic identification.

Cervicofacial actinomycosis: diagnosis and management

Oostman O, Smego RA. *Curr Infect Dis Resp* 2005; 7: 170–4.

Culture isolation of *Actinomyces* spp. and microscopic visualization of gram-positive, nonacid-fast, thin, branching filaments remain the best methods of diagnosing cervicofacial actinomycosis.

Diagnosis of pelvic actinomycosis by 16S ribosomal RNA gene sequencing and its clinical significance

Woo PCY, Fung AMY, Lau SKP, Hon E, Yuen KY. *Diagn Microbiol Infect Dis* 2002; 43: 113–8.

Actinomyces odontolyticus was identified by rRNA gene sequencing. Because the 16 S ribosomal RNA gene is conserved within a species, it can be used to identify a specific species of bacteria.

Cervicofacial actinomycosis: CT and MR imaging findings in 7 patients

Park JK, Lee HK, Ha HK, Choi HY, Choi CG. *AJNR Am J Neuroradiol*

2003; 24: 331–3.

Findings on computed tomography (CT) and magnetic resonance imaging (MRI) may be helpful in distinguishing cervicofacial actinomycosis from malignant neoplasms, tuberculosis, and fungal infections.

First-Line Therapy

• Penicillin	C
--------------	---

Antimicrobial susceptibility testing of *Actinomyces* species with 12 antimicrobial agents

Smith AJ, Hall V, Thakker B, Gemmell CG. J Antimicrob Chemother 2005; 56: 407–9.

The authors tested the susceptibility of 87 strains of *Actinomyces* to 12 different antimicrobial agents. All isolates were susceptible to penicillin and amoxicillin.

Actinomycosis

Smego RA, Foglia G. Clin Infect Dis 1998; 26: 1255–63.

The authors recommend 2 months of oral penicillin V (2–4 g/day divided every 6 hours) or a tetracycline (e.g., oral doxycycline 100 mg twice daily) for mild cervicofacial disease. For more complicated infections, parenteral penicillin G (10–20 million U/day divided every 6 hours) for 4 to 6 weeks followed by 6 to 12 months of oral penicillin V (2–4 g/day divided every 6 hours) is suggested. Tetracycline, erythromycin, clindamycin, or cephalosporins are advocated for patients allergic to penicillin.

Actinomycosis and nocardiosis. A review of basic differences in therapy

Peabody JW, Seabury JH. Am J Med 1960; 28: 99–115.

The authors review the treatment of actinomycosis and state that penicillin is the drug of choice.

Second-Line Therapies

• Amoxicillin	C
• Ceftriaxone	D
• Clindamycin	C
• Doxycycline	D
• Erythromycin	D
• Imipenem	C
• Minocycline	C
• Tetracycline	D

The use of oral amoxicillin for the treatment of actinomycosis: a clinical and in vitro study

Martin MV. Br Dent J 1984; 156: 252–4.

Ten patients with cervicofacial actinomycosis were cured in less

than 6 weeks with a combination of amoxicillin (500 mg four times daily) and surgery.

Actinomycosis abscess of the thyroid gland

Cevera JJ, Butehorn HF, Shapiro J, Setzen G. Laryngoscope 2003; 113: 2108–11.

A 39-year-old woman who developed actinomycosis of the thyroid gland after tooth extraction was cured with thyroidectomy and 6 months of ceftriaxone (1 g intravenously every 12 hours).

Successful treatment of thoracic actinomycosis with ceftriaxone

Skoutelis A, Petrochilos J, Bassaris H. Clin Infect Dis 1994; 19: 161–2.

A 38-year-old patient with pulmonary actinomycosis was successfully treated with a 3-week course of daily ceftriaxone (2 g intravenously), followed by 3 months of daily oral ampicillin (no dose listed but typically given 500 mg orally every 6 hours).

Mandibular actinomycosis treated with oral clindamycin

Badgett JT, Adams G. Pediatr Infect Dis J 1987; 6: 221–2.

Clindamycin in the treatment of cervicofacial actinomycosis

deVries J, Bentley KC. Int J Clin Pharmacol 1974; 9: 46–8.

A 60-year-old man with cervicofacial actinomycosis that was resistant to penicillin and tetracycline responded fully to a 1-month course of clindamycin (150 mg four times a day).

Clindamycin in the treatment of serious anaerobic infections

Fass RJ, Scholand JF, Hodges GR, Saslaw S. Ann Intern Med 1973; 78: 853–9.

Four patients with cervicofacial actinomycosis and one with thoracic actinomycosis were successfully treated with a combination of intravenous (1.8–2.7 g/day) and oral (0.9–1.2 g/day) clindamycin.

Primary actinomycosis of the hand: a case report and literature review

Mert A, Bilir M, Bahar H, Torun M, Tabak F, Ozturk R, et al. Int J Infect Dis 2001; 5: 112–4.

A 35-year-old man with primary actinomycosis of the hand was cured with 1 month of intravenous ampicillin (12 g/day), followed by 11 months of oral doxycycline (200 mg/day).

Actinomycosis of the prostate

de Souza E, Katz DA, Dworzack DL, Longo G. J Urol 1985; 133: 290–1.

A case of acute prostatitis due to *Actinomyces* spp. was cured with long-term erythromycin (500 mg intravenously every 6 hours followed by 500 mg orally every 6 hours), chosen because of its excellent penetration into prostatic secretions.

Actinomycosis of the temporomandibular joint

Bradley P. Br J Oral Surg 1971; 9: 54–6.

A 58-year-old man with actinomycosis of the temporomandibular joint was cured with a 12-week course of erythromycin (500 mg six times a day).

Use of imipenem in the treatment of thoracic actinomycosis

Yew WW, Wong PC, Wong CF, Chau CH. Clin Infect Dis 1994; 19: 983–4.

Report of eight cases of pulmonary actinomycosis and their treatment with imipenem–cilastatin

Yew WW, Wong PC, Lee J, Fung SL, Wong CF, Chan CY. Monaldi Arch Chest Dis 1994; 54: 126–9.

Seven of eight patients with pulmonary actinomycosis were successfully treated with a 4-week course of parenteral imipenem–cilastatin (500 mg intravenously every 8 hours).

Cutaneous disseminated actinomycosis in a patient with acute lymphocytic leukemia

Takeda H, Mitsuhashi Y, Kondo S. J Dermatol 1998; 25: 37–40.

A patient with primary cutaneous disseminated actinomycosis was cured with a 3-month course of intravenous minocycline (2 mg/kg/day).

Antibiotic treatment of cervicofacial actinomycosis for patients allergic to penicillin: a clinical and in vitro study

Martin MV. Br J Oral Maxillofac Surg 1985; 23: 428–34.

Six patients with cervicofacial actinomycosis were cured with 8 to 16 weeks of oral minocycline (250 mg four times a day). There were no recurrences after 1 year.

Primary actinomycosis of the quadriceps

Langlosh JT, Lauerman WC. J Pediatr Orthop 1987; 7: 222–3.

Surgical drainage followed by a 6-week course of oral tetracycline (500 mg orally every 6 hours) cured a case of actinomycosis of the quadriceps.

Comparative in vitro susceptibilities of 396 unusual anaerobic strains to tigecycline and eight other antimicrobial agents

Goldstein EJ, Citron DM, Merriam CV, Warren YA, Tyrrell KL, Fernandez HT. Antimicrob Agents Chemother 2006; 50: 3507–13.

Tigecycline (50 mg intravenously every 12 hours, with a 100-mg loading dose) had good in vitro activity against isolates of *Actinomyces* spp.

Third-Line Therapies

• Ciprofloxacin	E
• Levofloxacin	E
• Rifampicin	E
• Hyperbaric oxygen	E

Treatment of recalcitrant actinomycosis with ciprofloxacin

Macfarlane DJ, Tucker LG, Kemp RJ. J Infect 1993; 27: 177–80.

Treatment of pulmonary actinomycosis with levofloxacin

Ferreira D de F, Amado J, Neves S, Taveira N, Carvalho A, Nogueira R. J Bras Pneumol 2008; 34: 245–8.

Treatment of pulmonary actinomycosis with rifampin

Morrone N, De Castro Pereira CA, Saito M, Dourado AM, Pereira Da

Silva Mendes ES. G Ital Chemioter 1982; 29: 121–4.

Pulmonary actinomycosis. Rapid improvement with isoniazid and rifampin

King JW, White MC. Arch Intern Med 1981; 141: 1234–5.

Adjunctive hyperbaric oxygen therapy for actinomycotic lacrimal canaliculitis

Shauly Y, Nachum Z, Gdal-On M, Melamed Y, Miller B. Graefes Arch Clin Exp Ophthalmol 1993; 231: 429–31.

A 52-year-old patient with treatment-resistant lacrimal canaliculitis due to *A. israelii* was cured with hyperbaric oxygen.

Hyperbaric oxygen in the treatment of actinomycosis

Manheim SD, Voleti C, Ludwig A, Jacobson JH. J Am Med Assoc 1969; 210: 552–3.

After failing to respond to surgery and intravenous penicillin, a 63-year-old patient with perirectal actinomycosis was cured with hyperbaric oxygen.

Acute generalized exanthematous pustulosis

Aysha Javed, and Ian H. Coulson

Acute generalized exanthematous pustulosis (AGEP) is characterized

by the acute onset of numerous small, nonfollicular, sterile pustules arising on a diffuse erythematous base in a febrile patient with an accompanying blood neutrophilia. The majority of cases occurs in the context of drug ingestion (commonly within 24 hours). Rapid resolution after drug withdrawal is the usual outcome.

Management Strategy

Treatment of AGEP involves establishing the correct diagnosis coupled with the *withdrawal of any implicated medication* ([Table 8.1](#)). Pustular psoriasis is its main differential diagnosis. A comprehensive drug history and a personal or family history of psoriasis are therefore required.

Intraepidermal or subcorneal pustules in conjunction with a leukocytoclastic vasculitis, focal necrosis of keratinocytes, marked edema of the papillary dermis, and an infiltrate of eosinophils are histologic features that help distinguish AGEP from pustular psoriasis; biopsy is thus an integral facet of management.

Differentiation of AGEP from other inflammatory, toxic, or infectious conditions, such as Sneddon–Wilkinson disease (subcorneal pustular dermatosis) or, in severe cases, toxic epidermal necrolysis, is often readily apparent both clinically and histologically. The clinician should, however, be aware that erythema multiforme–like targetoid lesions, mucous membrane involvement, facial edema, purpura, and vesiculobullous lesions have all been documented in the context of AGEP.

Antibiotics (primarily penicillin or macrolide based) are the most frequently implicated medications. Numerous case reports have cited various other causative agents, including calcium channel blockers, nonsteroidal antiinflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, and anticonvulsants ([Table 8.1](#)). Acute enterovirus infection, mycoplasma pneumonia, cytomegalovirus, parvovirus B19, spider bites, Chinese herbal compounds (ginkgo biloba), contrast media, and mercury exposure have also been reported as possible causes.

There is no specific therapy for AGEP. A skin swab establishes the sterile nature of the pustules, and drug withdrawal, if feasible, results in rapid spontaneous resolution. *Supportive therapy* is all that is required. A superficial desquamation often occurs during this time and may be treated with *simple emollients*. Several case reports cite the

use of patch testing to confirm the causative medication. Only a single case report supports the use of *systemic corticosteroids* for this self-limiting condition.

Specific Investigations

- Detailed history
- Hematology
- Skin swab of pustule
- Microscopy, culture, Gram stain
- Skin biopsy

First-Line Therapy

- | | |
|-------------------|---|
| • Drug withdrawal | E |
|-------------------|---|

Risk factors for acute generalized exanthematous pustulosis (AGEP) – results of a multinational case-control study (EuroSCAR)

Sidoroff A, Dunant A, Viboud C. Br J Dermatol 2007; 157: 6.

A multinational case-control study (97 cases of AGEP and 1009 controls) that assessed the risk for different drugs causing severe cutaneous adverse reactions.

The most frequently implicated drugs were pristinamycin (a macrolide marketed in France), ampicillin/amoxicillin, quinolones, (hydroxy)chloroquine, anti-infective sulfonamides, terbinafine, and diltiazem. Infections and a personal or family history of psoriasis were not deemed to be significant risk factors for developing AGEP. Of note, the median treatment duration was 1 day for antibiotics and 11 days for all other associated drugs.

Acute generalized exanthematous pustulosis. Analysis of 63 cases

Roujeau JC, Bioulac-Sage P, Bourseau C, Guillaume JC, Bernard P, Lok C, et al. Arch Dermatol 1991; 127: 1333–8.

A thorough retrospective review of cases of AGEF. Almost 90% of cases were attributable to drugs, with 50% of reactions occurring within 24 hours of ingestion.

AGEF is distinct from pustular psoriasis based on histologic differences, drug induction in most cases, a more acute course of fever and pustulosis, blood neutrophilia, and rapid spontaneous healing (within 15 days).

Acute generalized exanthematous pustulosis

Manders SM, Heymann WR. *Cutis* 1994; 54: 194–6.

Two of the three cases reported in this series were attributable to penicillin. This succinct overview of AGEF also provides the reader with useful clinicopathologic features that may help distinguish AGEF from pustular psoriasis.

Table 8.1

Drugs and other substances reported to have caused AGEF

Drugs

Antibiotics

Penicillins: amoxicillin, ampicillin, bacampicillin, piperimidic acid, piperacillin, propicillin, tazobactam, meropenem

Macrolides: azithromycin, erythromycin

Quinolones: ciprofloxacin, norfloxacin, ofloxacin

Tetracyclines: doxycycline, minocycline

Cephalosporins: cefaclor, cefazolin, cefuroxime, cephalexin, cephhradine

Aminoglycosides: gentamicin, isepamicin sulfate, streptomycin

Other antibiotics: chloramphenicol, clindamycin, cotrimoxazole, imipenem/cilastatin, lincomycin, metronidazole, nifuroxazide, sulfamethoxazole, teicoplanin, vancomycin, daptomycin, telavancin

NSAIDs

Celecoxib, etoricoxib, ibuprofen, naproxen, nimesulide, valdecoxib

ACE inhibitors

Captopril, enalapril

Calcium channel blockers

Nifedipine, nimodipine, diltiazem

Anticonvulsants

Carbamazepine, phenobarbital, phenytoin

Analgesia (opioid/nonopioid)

Acetaminophen, paracetamol, morphine, codeine, dextropropoxyphene

Antiplatelets

Aspirin, ticlopidine, clopidogrel

Benzodiazepines

Clobazam, nitrazepam, tetrazepam

Antimalarials

Chloroquine, hydroxychloroquine, proguanil, pyrimethamine

Antipsychotics

Clozapine, chlorpromazine

Antifungals

Amphotericin, fluconazole, itraconazole, nystatin, terbinafine

Antivirals

Lamivudine, lopinavir, ritonavir, zidovudine

Antituberculosis drugs

Isoniazid, rifampicin

Proton pump inhibitors

Lansoprazole, omeprazole

Immunosuppressants

Azathioprine

Antidepressants

Amoxapine, sertraline

Antihistamines

Clemastine, hydroxyzine

Beta agonists

Buphenine, fenoterol, nadolol

H2 receptor antagonists

Cimetidine, famotidine, ranitidine

Cholesterol-lowering medications

Simvastatin, pitavastatin, fenofibrate

Corticosteroids

Dexamethasone, methylprednisolone, prednisolone

Diuretics

Furosemide, hydrochlorothiazide

Antineoplastic drugs

Gefitinib, imatinib, vemurafenib

Other drugs

Acetazolamide, allopurinol, bleomycin, carbimazole, cytarabine, disulfiram, eperisone hydrochloride, eprazinone, fluindione, icodextrin, interferon, metamizole, pentoxifylline, piperazine, bamifylline, propafenone, alprostadil, pseudoephedrine, psoralen + UVA, quinidine, sulbutiamine, senna, sulfasalazine, terazosin, thalidomide, cadralazine, progestogens, dalteparin, carbutamide, bupropion hydrochloride, ranolazine

Other substances

Chromium picolinate

Diphenyl sulfone

Contrast agents iohexol and iopamidol

Mercury

Pneumococcal vaccine

Essential oil

Andrographis paniculata

Pustular eruption after drug exposure: is it pustular psoriasis or a pustular drug eruption?

Spencer JM, Silvers DN, Grossman ME. Br J Dermatol 1994; 130: 514–9.

Another series highlighting the diagnostic challenge when confronted with a patient with pustulosis and fever. One of the four cases of AGEP occurred in a patient with known psoriasis who was given trimethoprim for a urinary tract infection. An awareness of the condition, eosinophils in the biopsy, and rapid resolution after drug withdrawal prevented unnecessary treatment for pustular psoriasis.

Generalized pustular psoriasis or drug-induced toxic pustuloderma? The use of patch testing

Whittam LR, Wakelin SH, Barker JNWN. Clin Exp Dermatol 2000; 25: 122–4.

Patch testing to a 1% and 5% amoxicillin preparation confirmed a type 4 hypersensitivity reaction in a patient with long-standing plaque psoriasis who developed a generalized pustular eruption when treated with amoxicillin for an episode of epididymo-orchitis.

A systemic reaction to patch testing for the evaluation of acute generalized exanthematous pustulosis

Mashiah J, Brenner S. Arch Dermatol 2003; 139: 1181–3.

The authors report a generalized AGEP-like reaction caused by patch tests carried out to determine the drug eliciting AGEP. Interestingly, negative results were obtained with the drug in question.

Second-Line Therapies

• Corticosteroids	E
• Cyclosporin	E

Acute generalised exanthematous pustulosis

Criton S, Sofia B. Indian J Dermatol Venereol Leprol 2001; 67: 93–5.

A case report in which the authors claim that parenteral corticosteroids hastened the resolution of AGEF presumptively caused by benzyl penicillin.

Successful treatment of hydroxychloroquine-induced recalcitrant acute generalized exanthematous pustulosis with ciclosporin: case report and literature review

Yalcin B, Cakmak S, Yidirim B. Ann Dermatol. 2015; 27: 431–4.

A case report of a 67-year-old rheumatoid arthritis patient with recalcitrant AGEF secondary to hydroxychloroquine responding successfully to cyclosporin 4 mg/kg/day tapered over 2 months.

Allergic contact dermatitis and photoallergy

Harini Rajgopal Bala, Claire L. Higgins, and Rosemary L. Nixon

Allergic contact dermatitis (ACD) is a delayed or type IV hypersensitivity reaction, which generally manifests 24 to 48 hours after contact with an allergen to which the individual has previously been sensitized. The rash of acute ACD is characterized by pruritic papules and vesicles on an erythematous base. Lichenified plaques may occur in chronic disease. The rash is initially localized to the site of contact with the causative allergen, but may spread to other areas. This may occur due to a so-called *id reaction* (autoeczematization) or from transfer of the allergen, commonly from the hands to the face. Spread of the rash beyond the primary site is characteristic of ACD and may help to differentiate it clinically from irritant contact dermatitis.

The primary site may point toward the causative allergen: for example, involvement of the ears and neck in cases of ACD caused by nickel in earrings or necklaces; the hands in ACD caused by rubber glove accelerators; and the scalp, neck, and hairline in ACD caused by para-phenylenediamine or other intermediates in permanent hair dye. Infrequently, systemic contact dermatitis may occur when a previously sensitized individual is exposed to an allergen via the oral, intravenous, intramuscular, intraarticular, or inhalation route.

Determinants of whether sensitization will occur include the size and chemical nature of the allergen involved, the duration and concentration of skin contact with the allergen, and individual susceptibility, including skin integrity and likely genetic factors. Once an individual has been sensitized, ACD may be elicited through reexposure with only minute amounts of allergen.

Photoallergic contact dermatitis (PACD), or photoallergy, requires a substance to be activated by ultraviolet A (UVA) light (wavelength 320–400 nm) in order to become allergenic. The severity of the reaction does not correlate with the dose of photoallergen or UV. The two most common causes of PACD currently are organic UV absorbers in sunscreens, particularly octocrylene and benzophenone-3, and topical nonsteroidal antiinflammatory drugs (NSAIDs), such as ketoprofen and etofenamate. Other causes include antibiotics, such as fluoroquinolones and sulfonamide antibacterials, fragrances, and phenothiazines such as chlorpromazine and promethazine. Previously, halogenated salicylanilides in deodorant soaps, musk ambrette, and 6-methylcoumarin in fragrances, quinidine, and some pesticides have been identified as important photoallergens.

Chronic actinic dermatitis (CAD) is a rare condition whereby individuals continue to develop dermatitis after removal of the photoallergen and may present with recurrent transient or persistent light reactions. CAD may occur after chronic ACD to sesquiterpene lactones, found in the *Compositae* group of plants, as well as fragrances, lichens, and NSAIDs, coupled with chronic UV radiation.

Management strategy

The principal management strategy for both ACD and photoallergy is *identification* and *avoidance* of offending allergens and cross-reacting agents, education, and treatment. *Patch testing* is the gold standard for identifying skin allergens. From a public health perspective, ACD, and particularly occupational-related disease, represents a significant clinical, social, and economic burden. Allergen avoidance is therefore a priority and may occur at the manufacturing, workplace, or individual level—in some cases governed by legislation. For example, the European Nickel Directive restricts the nickel content of metal objects such as jewelry that contacts the skin. The addition of ferrous sulfate to cement in the European Union effectively reduces the available chromate through chemical reduction. Substitution of strong sensitizers in products by manufacturers is also important: the preservative methylisothiazolinone in baby wipes and toiletries is currently causing a major epidemic of ACD.

In the workplace, measures to reduce exposure to known allergens include substitution of common allergens, changing design processes to limit physical contact with chemicals, installation of appropriate ventilation to reduce airborne exposure to substances, and the use of personal protective equipment (PPE).

Gloves are a crucial part of PPE and must be appropriate for handling a particular chemical; for example, double nitrile gloves when working with acrylates. Cotton gloves may be worn underneath rubber or leather gloves to help prevent contact with rubber accelerators or chromate in cement, for example. This is particularly important when working in hot environments, where sweating and leaching of allergens may occur.

The initial treatment of ACD involves the general principles of eczema therapy, including avoidance of skin irritants such as wet work, soap, heat, and sweating. *Topical corticosteroids*, together with emollients, remain the most effective treatment to control an acute

flare. The *topical calcineurin inhibitors tacrolimus and pimecrolimus* have also been shown to be effective. The use of *barrier creams* to prevent dermatitis has had limited success. Short courses of *oral corticosteroids*, such as prednisolone 25 to 50 mg daily for 1 week, are effective treatment in severe cases. *Oral antibiotics*, such as cephalosporins, erythromycin, flucloxacillin, or clindamycin, may be required if the dermatitis becomes secondarily infected. *Topical antibiotics* such as mupirocin or fusidic acid may be helpful, particularly for the treatment of persistently cracked or fissured skin that becomes infected.

Once the cause of ACD has been identified, long-term treatments other than avoidance of the allergen(s) are usually not required, although recurrence may occur from inadvertent allergen exposure. In some cases, severe episodes of ACD may precipitate a recurring eczematous condition, termed *persistent postoccupational dermatitis*. It is believed that the longer an individual has severe ACD, the longer it will take for the condition to resolve once the cause is identified.

In adult patients with chronic ACD refractory to first-line treatment, short-term ultraviolet light therapy in the form of narrowband ultraviolet B (UVB) or psoralen plus UVA (PUVA) is suggested. *Alitretinoin* has a strong evidence base for treatment of chronic hand eczema, although not all patients studied had ACD. In fact many studies regarding the treatment of chronic hand eczema do not specify whether ACD was present. There is moderate evidence for efficacy of the *systemic immunosuppressant* cyclosporine. Azathioprine and methotrexate have less supporting evidence but traditionally have been considered helpful. *Acitretin* may be considered, particularly for hyperkeratotic palmar involvement.

In photoallergy, identification and avoidance of the photoallergen is the major treatment goal. If avoiding the causative allergen is not possible, sun-protective clothing and sunscreen are required. In the case of allergy to a chemical sunscreen agent, avoidance of the allergen or substitution with physical UV blockers such as zinc oxide or titanium dioxide is recommended.

Specific Investigations

- Patch testing to appropriately diluted allergens.
- Repeat open application test (ROAT) to determine whether a

reaction is significant in individuals who develop weak (1+) positive reactions to an allergen.

- Photopatch testing if PACD is suspected: duplicate sets of allergens are applied, and after 48 hours one set is exposed to 5 J/cm² UVA; results are read after a further 48 hours.
- Phototesting (e.g., via monochromator) if CAD is suspected.

Allergic contact dermatitis

Paz Castanedo-Tardan M, Zug KA. In: Goldsmith L, Katz S, Gilchrest B, Paller A, Leffell D, Fitzpatrick T, et al, eds. Fitzpatrick's Dermatology in General Medicine. New York: McGraw Hill Medical, 2012; [Chapter 13](#).

This chapter from a major dermatology text is an excellent place to start.

First-Line Therapies

Allergic contact dermatitis

• Allergen avoidance and substitution	C
• Skin care education	B
• Personal protective equipment	D
• Topical corticosteroids	B
• Emollients and soap substitutes	C
• Barrier creams	B
• Calcineurin inhibitors (tacrolimus, pimecrolimus)	B
• Prednisolone	D
• Antibiotics – topical and systemic	D
• Alitretinoin	A

Photoallergy

• Allergen avoidance and substitution	C
• Photoprotection	C
• Sunscreens – physical UV blockers	E

Skin care education and individual counseling versus treatment as usual in healthcare workers with hand eczema: randomised clinical trial

Ibler KS, Jemec GBE, Diepgen TL, Glud C, Hansen JL, Winkel P, et al. BMJ 2012; 345: e7822.

Two hundred and fifty-five health care workers with hand eczema were randomized to either an intervention group, comprising education in skin care, individual counseling based on patch and prick testing, and assessment of occupational and domestic exposures, or a control group. At the 5-month follow-up, hand eczema was significantly improved in the intervention group compared with the control group as measured both objectively and subjectively.

Determinants of epoxy allergy in the construction industry: a case–control study

Spee T, Timmerman JG, Rühl R, Kersting K, Heederik DJJ, Smit LAM. Contact Dermatitis 2016; 74: 259–66.

A case-control study compared 179 German epoxy workers with diagnosed ACD to epoxy (cases) with 151 epoxy workers without such an allergy (controls). ACD to epoxies was found to be associated with unusually high levels of exposure to the chemicals (OR 2.13) and with poor compliance with personal protection, including wearing short sleeves and trousers (OR 2.38), and incorrect glove use (OR 2.12).

The effect of a corticosteroid cream and a barrier-strengthening moisturizer in hand eczema. A double-blind, randomized, prospective, parallel group clinical trial

Lodén M, Wirén K, Smerud KT, Meland N, Hønnås H, Mørk G, et al. J Eur Acad Dermatol Venereol 2012; 26: 597–601.

Forty-four patients were randomized to either betamethasone 0.1% once daily with the use of a urea moisturizer in the evening or the use of betamethasone 0.1% twice daily. The trial concluded that twice-daily application of topical betamethasone was not superior to once-daily treatment and that once-daily treatment with an effective barrier cream had a greater response in patients with moderate eczema.

Tacrolimus 0.1% vs. mometasone furoate topical treatment in allergic contact hand eczema: a prospective randomized clinical study

Katsarou A, Makris M, Papagiannaki K, Lagogianni E, Tagka A, Kalogeromitros D. Eur J Dermatol 2012; 22: 192–6.

Thirty adults with chronic hand eczema and positive patch test reactions were randomized to either tacrolimus 0.1% ointment or mometasone furoate 0.1%. A significant difference was observed in both groups in all parameters between baseline and day 90 results. The results suggest tacrolimus is a favorable alternative therapy to topical corticosteroids with similar outcomes.

A phase 3, randomized, double-blind, placebo controlled study evaluating the efficacy and safety of alitretinoin (BAL4079) in the treatment of severe chronic hand eczema refractory to potent topical corticosteroid therapy

Fowler JF, Graff O, Hamedani AG. J Drugs Dermatol 2014; 13: 1198–204.

Five hundred and ninety-six participants were randomized to either a treatment arm, which administered 30 mg of alitretinoin, or placebo for 24 weeks. Patients were assessed every 4 weeks, with the primary end point being clear or almost clear of eczema at the end of the trial. Alitretinoin was shown to significantly improve severe chronic hand eczema.

New sunscreens confer improved protection for photosensitive patients in the blue light region

Moseley H, Cameron H, Macleod T, Clark C, Dawe R, Ferguson J. Br J Dermatol 2001; 145: 789–94.

Seven patients with known photosensitivity extending into the visible (blue) region at 430 ± 30 nm were tested with new reflectant sunscreens incorporating larger particle size zinc oxide and pigmentary-grade titanium dioxide as active ingredients. The mean

photo protection factors at this wavelength were determined. The new sunscreens were found to provide protection for patients with sensitivity to visible light (blue light region), for example, those with CAD, compared with sunscreens using chemical UV absorbers and microfine particles, which scatter radiation.

Second-Line Therapies

Allergic contact dermatitis

• Ultraviolet light (PUVA, UVB)	B
• Azathioprine	C
• Cyclosporine	D
• Methotrexate	D
• Acitretin	E
• Low-nickel diet for nickel dermatitis	C

Local narrowband UVB phototherapy vs. local PUVA in the treatment of chronic hand eczema

Sezer E, Etikan I. Photodermatol Photoimmunol Photomed 2007; 23: 10–4.

Fifteen participants with chronic hand eczema of dry and dyshidrotic types were administered local narrowband UVB irradiation on one arm starting with 150 mJ/cm² with a 20% increase per session until a final dose of 2000 mJ/cm² was reached and local paint-PUVA using 0.1% 8-methoxypsoralen gel on the other hand three times a week over a 9-week period. The study found localized narrowband UVB therapy as effective as paint PUVA in patients with chronic hand eczema.

Azathioprine versus betamethasone for the treatment of Parthenium dermatitis: a randomized controlled study

Verma KK, Mahesh R, Srivastava P, Ranam M, Mukhopadhyaya AK. Indian J Dermatol Venereol Leprol 2008; 74: 453–7.

Fifty-five patients with contact dermatitis caused by airborne *Parthenium* were randomly assigned to azathioprine 100 mg daily or betamethasone 2 mg daily for 6 months in a double-blinded manner. Treatment effects appeared equal in each group; however, the group randomized to betamethasone appeared to have more adverse effects.

Oral cyclosporine inhibits the expression of contact hypersensitivity in man

Higgins EM, McLelland J, Friedmann PS, Matthews JN, Shuster S. J Dermatol Sci 1991; 2: 79–83.

The expression of delayed contact hypersensitivity was studied in six patients with chronic contact dermatitis treated with cyclosporine 5 mg/kg/day. Quantitative patch test reactions were diminished in all six; responses were reduced over the whole range of allergen concentrations. In addition, the clinical manifestations of ACD underwent complete resolution within 2 to 3 weeks of cyclosporine therapy.

Treatment of Parthenium dermatitis with methotrexate

Sharma VK, Bhat R, Sethuraman G, Manchanda Y. Contact Dermatitis 2007; 57: 118–9.

Sixteen patients with Parthenium dermatitis unresponsive to topical treatment were treated with methotrexate, topical corticosteroids, and sunscreen. Some improvement was observed, suggesting a role for methotrexate in this condition.

Open-label exploratory study of acitretin for the treatment of severe chronic hand dermatitis

Tan J, Maari C, Nigen S, Bolduc C, Bissonnette R. J Dermatolog Treat 2015; 26: 373–5.

In a pilot study, nine participants with severe chronic hand dermatitis were treated with 10 to 30 mg of acitretin daily for up to 24 weeks. Three patients withdrew from the study. In the remaining patients 33.3% achieved clear or almost clear on physician global assessment.

Systemic nickel allergy: oral desensitization and possible role of cytokines interleukins 2 and 10

Ricciardi L, Carni A, Loschiavo G, Gangemi S, Tigano V, Arena E, et al. *Int J Immunopathol Pharmacol* 2013; 26: 251–7.

Twenty-two participants with known systemic nickel allergy syndrome (SNAS) were initiated on an oral desensitization therapy associated with a low-nickel diet for 3 months. Patients' tolerability to nickel improved significantly, and 18 of 22 participants had a negative nickel oral challenge at the end of the treatment.

Third-Line Therapy

Allergic contact dermatitis

• Pentoxifylline	E
------------------	---

The effect of the topical application of different pentoxifylline concentrations on the patch test results of nickel-sensitive patients

Saricaoglu H, Baskan EB, Tunalı S. *Int J Dermatol* 2004; 43: 315–6.

Twenty-two volunteers with nickel-induced contact dermatitis were pretreated with three concentrations of pentoxifylline and then patch tested to nickel. Though there was some evidence of suppressed patch test results, the decrease in patch test reactions was statistically insignificant.

Alopecia areata

John Berth-Jones

Alopecia areata (AA) is a T-lymphocyte-mediated autoimmune disease of the hair follicle. It is characterized by patchy hair loss developing in otherwise normal skin, with “exclamation mark” hairs around margins of expanding areas. Most cases are limited to one or more coin-sized patches, but in severe cases there may be complete baldness of the scalp (alopecia totalis, AT) or of the entire body (alopecia universalis, AU). The alopecia is noncicatrizing.

Management Strategy

Leaving AA untreated is a reasonable option for many patients. Spontaneous remission usually occurs within a few months, and no treatment has been shown to alter the long-term prognosis. Treatment can be time consuming, uncomfortable, and potentially toxic, and relapse after treatment may be difficult to cope with. Many patients are distressed, so psychologic support can be helpful, and careful “management of expectations” from treatment is important. Contact with other sufferers and support groups may also help.

The treatments listed as first line are the most consistently effective and safe; however, the response to any treatment is variable and depends largely on the extent and duration of the alopecia. This is one reason why the results of trials are often conflicting. Trials involving recent-onset patchy alopecia may have a high rate of spontaneous remission, whereas trials limited to severe long-standing disease that is resistant to treatment do not exclude efficacy in mild alopecia.

Intralesional corticosteroid injections are considered first-line treatment for adult patients when only one or two small patches of alopecia are present, but can be used on larger areas if patients can tolerate the discomfort. The author most frequently uses triamcinolone acetonide aqueous suspension (2.5–10 mg/mL) injected intradermally in multiple 0.05- to 0.1-mL doses and does not inject more than 20 mg in total at one visit. Treatment is repeated at intervals of 4 to 12 weeks. A concentration of 2.5 mg/mL can be used on the eyebrow area. The main side effect is pitting atrophy, which is usually transient.

Topical immunotherapy is the induction of contact allergy on the scalp. Contact sensitizers include dinitrochlorobenzene (DNCB; now considered potentially carcinogenic and therefore no longer used), squaric acid dibutyl ester (SADBE; this has limited stability), and *diphencyprone* (DPCP, diphenylcyclopropenone). The latter compound combines efficacy and safety with a practical shelf life and has become the most widely used. Diphencyprone can initially be applied as 2% lotion to a small area (2–4 cm²) of scalp until the site of application becomes pruritic and erythematous. Treatment is then continued over a larger area with weekly applications of lower concentrations, typically ranging from 0.001% to 0.1%. The lowest concentration that maintains mild erythema or pruritus should be used. My patients usually have half of their scalp treated initially until a favorable result means treatment can then be extended to the contralateral scalp. This is one of the best-documented therapies for AA, and is the one most

likely to be effective in extensive long-standing disease. However, the timing of the response is quite unpredictable, so the author treats patients for as long as they wish to continue. Relapse rates may be high. Side effects include regional lymphadenopathy and, rarely, generalized eczema or even an eruption resembling erythema multiforme. Vitiligo may develop, although this is usually confined to the treated areas. For this reason, sensitization therapy is best avoided in patients with pigmented skin types.

Topical corticosteroids have demonstrated efficacy in some studies of patchy AA, particularly those using potent steroids with occlusion. They are inexpensive and practical to use, and the main side effect is transient folliculitis. Results are variable, however, and they do not appear to be very effective in AT or AU.

Topical prostaglandin analogs have been reported as effective in treating the eyelashes of patients affected with AU.

Irritants, including *anthralin (dithranol)* and *retinoic acid*, are safe and practical to use, although the evidence for their efficacy is limited. For patients with dark hair, anthralin has the advantage of camouflaging a pale area of scalp by staining it brown. Application needs to be frequent and at a fairly high concentration, with the purpose of inducing significant irritation to be effective. Retinoic acid is more practical for use in patients with fair hair.

Topical minoxidil is a safe treatment, but most studies have failed to demonstrate a response of cosmetic value in most patients.

Systemic corticosteroids are effective in some cases if high doses are used. However, AT, AU, and ophiasiform AA do not respond well, and high relapse rates make this toxic treatment hard to justify. Given the level of emotional disturbance associated with alopecia, there is clearly a risk of encountering serious difficulty in withdrawing treatment. It is difficult to justify the use of potentially harmful modalities.

Less conventional treatments from which benefit has been reported are listed next as third line. Many patients find wigs an acceptable *camouflage*. Tattooing (dermatography) of the eyebrows may lead to a more socially acceptable image for some patients. Most recently, anecdotal reports of the oral Janus kinase (JAK) inhibitor, *tofacitinib*, have led to its off-label use for AT, AU, and ophiasiform AA.

The wide variety of treatments that have been investigated attest to the tantalizing nature of this disease, which can resolve spontaneously even after many years, yet currently continues to

represent a therapeutic challenge.

Specific Investigations

No investigation is routinely required. However, in patients with symptoms or a family history of autoimmune disease, investigation may be indicated.

- Consider full blood count, thyroid function tests, serum B₁₂, and autoantibodies.

First-Line Therapies

• Intralesional steroids	A
• Topical clobetasol propionate	A
• Topical immunotherapy	B

Benefit of different concentrations of triamcinolone acetonide in alopecia areata: an intrasubject pilot study

Chu TW, Aljasser M, Albarbi A, Abahussein O, McElwee K, Shapiro J. J Am Acad Dermatol 2015; 73: 338–40.

Four patients each received six injections of saline and triamcinolone acetonide (TCA) 2.5, 5, and 10 mg/mL at 6-week intervals. All three concentrations yielded similar responses, and all were superior to the placebo.

Intralesional treatment of alopecia areata with triamcinolone acetonide by jet injector

Abell E, Munro DD. Br J Dermatol 1973; 88: 55–9.

A report of 84 patients treated with 0.1-mL needleless injections of triamcinolone acetonide 5 mg/mL and normal saline controls. After 6 weeks, regrowth was observed in 86% of patients treated with triamcinolone and 7% of controls. Mild transient atrophy was

frequently observed.

Intralesional triamcinolone acetonide versus topical betamethasone valerate (BV) in management of localized alopecia areata

Devi M, Rashid A, Ghafoor R. J Coll Physicians Surg Pak 2015; 25: 860–2.

Two randomized groups of 113 patients received twice-daily 0.1% BV or injection, at baseline, of TCA 10 mg/mL. Regrowth was seen at 12 weeks in 74% of the intralesional group, versus 47% of the topical group ($p < 0.001$).

Clobetasol propionate, 0.05%, vs. hydrocortisone, 1%, for alopecia areata in children

Lenane P, Macarthur C, Parkin PC, Krafchik B, DeGroot J, Khambalia A, et al. JAMA Dermatol 2014; 150: 47–50.

A double-blinded study in a relatively responsive population. Creams were applied twice daily for two 6-week cycles (6 weeks on, 6 weeks off) over 24 weeks. Clobetasol yielded a significantly greater response.

Clobetasol propionate 0.05% under occlusion in the treatment of alopecia totalis/universalis

Tosti A, Piraccini B, Pazzaglia M, Vincenzi C. J Am Acad Dermatol 2003; 49: 96–8.

A refractory group of 28 patients with AT/AU of 3 to 12 years' duration who had not responded to immunotherapy were treated on half of their scalp with 2.5 g of clobetasol propionate ointment under plastic film on 6 nights per week for 6 months. Regrowth started at 6 to 14 weeks, and eight patients (28.5%) achieved >75% regrowth, which was then extended to the other side of the scalp. Eleven patients developed painful folliculitis, including five of the six who withdrew from the study. After a further 6 months' follow-up 18% of the 28 patients retained complete regrowth.

Diphencyprone in the treatment of alopecia areata

Happle R, Hausen BM, Weisner-Menzel L. Acta Derm Venereol 1983; 63: 49–52.

This study nicely illustrated the unilateral response observed when one side of the scalp is treated, which so convincingly establishes the

efficacy of this treatment.

Topical immunotherapy with diphenylcyclopropenone in the treatment of chronic extensive alopecia areata

Sotiriadis D, Patsatsi A, Lazaridou E, Kastanis A, Vakirlis E, Chrysomallis F. Clin Exp Dermatol 2007; 32: 48–51.

In this prospective open clinical trial, 17 patients had either AT or AU and 24 had severe alopecia (>50% scalp involvement). After sensitization with DPCP 2% in acetone, progressively higher concentrations (from 0.001%–0.1%) were applied once a week for a period of 6 to 12 months. Of the 41 patients, 38 (16 with AT or AU and 22 with extensive AA) completed therapy. Significant hair regrowth was observed in five patients with AT or AU (31.25%) and ten patients with extensive alopecia (45.4%). These results were sustained in 66.6% of patients for a 12-month follow-up period.

Second-Line Therapies

• Anthralin/dithranol	B
• Retinoic acid	B
• Topical minoxidil	B
• Bimatoprost/latanoprost eye drops	B

Treatment of alopecia areata by anthralin-induced dermatitis

Plewig G, Braun-Falco O. Arch Dermatol 1979; 115: 1254–5.

In this study using 0.5% and 1.0% concentrations of anthralin, the mean time to response was 11 weeks and the mean time to cosmetic response was 23 weeks (range 8–60 weeks). Cosmetic response was achieved in 29% (11/38) of patients with <75% scalp hair loss and in 20% (6/30) of patients with >75% scalp hair loss. Approximately 75% of responders maintained adequate hair growth with continued treatment.

Topical tretinoin as an adjunctive therapy with intralesional triamcinolone acetonide for alopecia areata. Clinical experience in northern Saudi Arabia

Kubeyinje EP, C'Mathur M. *Int J Dermatol* 1997; 36: 320.

In this open study 58 patients with mainly patchy alopecia were treated with monthly triamcinolone injections; 28 patients also had daily application of 0.05% tretinoin cream. More than 90% regrowth was achieved in 66.7% of patients with triamcinolone alone and in 85.7% of patients with both treatments, which was statistically significant.

Comparative assessment of topical steroids, topical tretinoin (0.05%) and dithranol paste in alopecia areata

Das S, Ghorami RC, Chatterjee T, Banerjee G. *Indian J Dermatol* 2010; 55: 148–9.

This prospective study of 80 patients with AA concluded that there was a good response in 55% of patients treated with topical tretinoin, in comparison with 70% of patients treated with topical steroids and 35% of patients treated with dithranol.

Topical minoxidil solution (1% and 5%) in the treatment of alopecia areata

Fiedler-Weiss VC. *J Am Acad Dermatol* 1987; 16: 745–8.

Sixty-six patients with >75% scalp hair loss applied the treatments twice daily. Even in the high-dose group only 6% showed a cosmetically acceptable response. Occlusion of the treated area with white petrolatum at night was necessary to achieve maximum results.

Bimatoprost in the treatment of eyelash universalis alopecia areata

Vila OT, Camacho Martinez FM. *Int J Trichology* 2010; 2: 86–8.

In this retrospective study of 41 patients, 0.03% bimatoprost eye drops were applied to the eyelid margins once a day for 1 year. Complete regrowth of the eyelashes was noted in 24.3% of patients and moderate regrowth in 18.9% of subjects.

Latanoprost in the treatment of eyelash alopecia in alopecia areata universalis

Coronel-Perez IM, Rodriguez-Rey EM, Camacho-Martinez FM. *J Eur Acad Dermatol Venereol* 2010; 24: 481–5.

A 2-year prospective, nonblinded, nonrandomized, controlled study of 54 subjects with AAU and eyelash alopecia. The control group comprised 10 subjects who received injections of 0.5 mg/cm² of triamcinolone acetonide (TAC) in their eyebrows and 1 mg/cm² of TAC injections in affected scalp. The treatment group included 44 subjects who received the same treatment as the control group in scalp and eyebrows, but they also applied a drop of latanoprost 0.005% (50 µg/mL) ophthalmic solution to their eyelid margins every night. In the treatment group, there was complete regrowth in 17.5%, moderate regrowth in 27.5%, slight regrowth in 30%, and no response in 25%. No patients had cosmetically acceptable eyelash regrowth in the control group.

Lack of efficacy of topical latanoprost and bimatoprost ophthalmic solutions in promoting eyelash growth in patients with alopecia areata

Roseborough I, Lee H, Chwalek J, Stamper RL, Price VH. J Am Acad Dermatol 2009; 60: 705–6.

A controlled trial of 16 weeks' duration with 11 patients did not confirm any response.

Another small trial of similar design has also shown the same negative result.

Bimatoprost versus mometasone furoate in the treatment of scalp alopecia areata: a pilot study

Zaher H, Gawdat HI, Hegazy RA, Hassan M. Dermatology 2015; 230: 308–13.

A study on patchy AA of the scalp in which 30 adult subjects applied each treatment to separate patches of AA. The prostaglandin analog yielded superior regrowth.

Use of these prostaglandin (PGF_{2α}) analogs has occasionally been associated with increased pigmentation of the iris and eyelid.

Bimatoprost (Latisse) is licensed in the United States as a “cosmetic” product used to thicken normal eyelash growth, an effect that may also be beneficial for patients with AA.

Third-Line Therapies

• PUVA	B
• Systemic corticosteroids	B
• Systemic cyclosporine	C
• Intralesional autologous platelet rich plasma	B
• Oral minoxidil	B
• Sulfasalazine	B
• Methotrexate	C
• Azathioprine	C
• Tofacitinib	E
• Inosiplex (inosine pranobex)	B
• Nitrogen mustard	C
• Dermatography	B
• Cryotherapy	B
• Pulsed infrared diode laser	C
• Excimer laser	C
• Topical bexarotene	C
• Topical azelaic acid	C
• Combination treatment of simvastatin and ezetimibe	C
• Diphenacyclone with imiquimod	C
• Hydroxychloroquine	E
• Adalimumab	E
• Phenol	C
• Aromatherapy	B
• Onion juice	B
• Garlic gel with betamethasone valerate	B

Treatment of alopecia areata with three different PUVA modalities

Lassus A, Eskelinen A, Johansson E. Photodermatology 1984; 1: 141–4.

Seventy-six patients with severe AA were treated with local or oral 8-methoxypsoralen and local or whole-body UVA irradiation. In 43 cases (57%) a good-to-excellent result was obtained, with 20 to 40 treatments being sufficient in most cases. No particular treatment method was significantly superior. Patients with circumscribed or ophiasic alopecia responded better than patients with AT or AU. Disease duration, onset before the age of 20 years, and atopy were poor prognostic factors. During a follow-up period of 6 to 68 months, 22 patients had a relapse.

High-dose pulse corticosteroid therapy in the treatment of severe alopecia areata

Seiter S, Ugurel S, Tilgen W, Reinhold U. Dermatology 2001; 202: 230–4.

In this prospective open study 30 patients with >30% hair loss were treated with three courses of IV methylprednisolone (8 mg/kg) on 3 consecutive days at 4-week intervals. Twelve of 18 AA patients achieved >50% regrowth. None of the four patients with AT, five with AU, or three with ophiasic AA responded. Ten patients who responded retained the growth at 10 months.

Placebo-controlled oral pulse prednisolone therapy in alopecia areata

Kar BR, Handa S, Dogra S, Kumar B. J Am Acad Dermatol 2005; 53: 1100–1.

Forty-three patients were randomized to receive oral prednisolone 200 mg weekly (23) or placebo (20) for 3 months. All patients had more than 40% scalp hair loss, or more than 10 patches of AA, for more than 9 months. Eight of 23 in the treatment group showed more than 30% regrowth, compared with none in the placebo group. More than 60% regrowth occurred in only two patients, both within the treatment group. Side effects occurred in 55% of the treatment group, compared with 11% in the placebo group, although all were temporary.

Numerous reports of using systemic corticoids over the last 60 years in various doses and regimens indicate that high doses can be effective while treatment is continued. There is no convincing evidence of any change to the

natural course of the disease when treatment is stopped.

Oral cyclosporine for the treatment of alopecia areata

Gupta AK, Ellis CN, Cooper KD, Nickoloff BJ, Ho VC, Chan LS, et al. J Am Acad Dermatol 1990; 22: 242–50.

Six patients with alopecia (two AA, one AT, and three AU) were treated with oral cyclosporine, 6 mg/kg/day, for 12 weeks. Hair regrowth in the scalp of all patients occurred within the second and fourth weeks of therapy, but cosmetically acceptable regrowth occurred in only three patients. In no case did this persist 3 months after stopping the drug.

A randomized, double-blind, placebo- and active-controlled, half head study to evaluate the effects of platelet-rich plasma on alopecia areata

Trink A, Sorbellini E, Bezzola P, Rodella L, Rezzani R, Ramot Y, et al. Br J Dermatol 2013; 169: 690–4.

A controlled study with 45 subjects. Platelet-rich plasma (PRP) was obtained by centrifugation of 36 mL peripheral blood and injected intralesionally on three occasions at monthly intervals. PRP was significantly superior to no treatment, placebo, and triamcinolone acetonide in stimulating hair growth in assessments at 2, 6, and 12 months.

Evaluation of oral minoxidil in the treatment of alopecia areata

Fiedler-Weiss VC, Rumsfield J, Buys CM, West DP, Wendrow A. Arch Dermatol 1987; 123: 1488–90.

Sixty-five patients with severe AA were treated with oral minoxidil 5 mg twice daily. Cosmetic response was reported in 18% of patients. The drug was well tolerated at this dose, provided the recommended restriction on sodium intake (2 g daily) was observed. Higher sodium intake increased the risk of fluid retention.

Treatment of persistent alopecia areata with sulfasalazine

Rashidi T, Mahd AA. Int J Dermatol 2008; 47: 850–2.

An uncontrolled prospective trial of sulfasalazine in 39 patients with persistent AA demonstrated regrowth of more than 60% in 25.6% of patients and a moderate response in 30.7% of patients.

Long-term follow-up of the efficacy of methotrexate alone or in

combination with low doses of oral corticosteroids in the treatment of alopecia areata totalis or universalis

Chartaux E, Joly P. *Ann Dermatol Venereol* 2010; 137: 507–13.

In a long-term follow-up study of methotrexate in 33 patients with AA, complete regrowth was achieved in 57% of patients who took 15 to 25 mg methotrexate a week and in 63% of patients who took 10 to 20 mg prednisone a day. Recurrence of AA occurred in 57% of responders after a decrease in the methotrexate dose or after stopping treatment.

Efficacy and tolerability of methotrexate in severe childhood alopecia areata

Royer M, Bodemer C, Vabres P, Pajot C, Barbarot S, Paul C, et al. *Br J Dermatol* 2011; 165: 407–10.

In this retrospective study of 14 children aged 8 to 18 with AA, 5 experienced a clinically relevant therapeutic response. The treatment was administered once weekly with a mean maximal dose of 18.9 mg weekly (0.38 mg/kg) and a mean duration of treatment of 14.2 months.

The authors have subsequently reported that response was maintained in two of the five responders at 6 and 4.3 years after treatment.

Could azathioprine be considered as a therapeutic alternative in the treatment of alopecia areata? A pilot study

Farshi S, Mansouri P, Safar F, Khiabanloo SR. *Int J Dermatol* 2010; 49: 1188–93.

A total of 20 patients with minimum 6 months, history of AA were included in this pilot study. Azathioprine was taken at a dose of 2 mg/kg of body weight. The mean regrowth was 52.3% and the mean hair loss before treatment was 72.7%, compared with 33.5% after 6 months of treatment.

Killing two birds with one stone: oral tofacitinib reverses alopecia universalis in a patient with plaque psoriasis

Craiglow BG, King BA. *J Invest Dermatol* 2014; 134: 2988–90.

A patient demonstrated improvement of both conditions, including complete regrowth of hair at all body sites at 8 months, on treatment with the JAK inhibitor, tofacitinib, 10 mg in the morning and 5 mg at night. The drug was well tolerated.

There is also a report of AA responding to baricitinib, another JAK inhibitor. This is a relatively novel class of immunosuppressants. Tofacitinib is used in the treatment of psoriasis. In that indication, topical application can be effective, and perhaps this might be developed into a safer approach for AA.

Inosiplex for treatment of alopecia areata: a randomized placebo-controlled study

Georgala S, Katoulis AC, Befon A, Georgala K, Stavropoulos PG. *Acta Dermatol Venereol* 2006; 86: 422–4.

In this double-blind trial 32 subjects were randomized to two groups of 16 subjects: oral inosiplex 50 mg/kg/day in five divided doses for 12 weeks or placebo. Patients had treatment-resistant disease for 11 to 34 months; 21 with AA, 9 with ophiasis, and 2 with AT. In the 15 treatment patients who completed the trial, 33% achieved full regrowth and 53% achieved more than 50% regrowth. None of the 14 placebo patients responded completely, and 28.5% achieved more than 50% regrowth. After a further 6 months, tapering to half-dose, there were no recurrences.

A parallel study of inosine pranobex, diphencyprone and both treatments combined in the treatment of alopecia totalis

Berth-Jones J, Hutchinson PE. *Clin Exp Dermatol* 1991; 16: 172–5.

Thirty-three subjects with AT were randomized into three groups and treated with inosine pranobex 50 mg/kg/day, topical DPCP, or both. There was no response to inosine pranobex in the 22 subjects who received this treatment. Only 2 of 22 patients responded to DPCP.

Treatment of alopecia areata with topical nitrogen mustard

Arrazola JM, Sendagorta E, Harto A, Ledo A. *Int J Dermatol* 1985; 9: 608–10.

Cosmetically acceptable hair regrowth was seen in 7 of 11 patients (including 2 of 6 with AT) after 4 to 8 weeks of self-treatment with mechlorethamine hydrochloride 0.2 mg/mL once daily. Two patients became sensitized and treatment was discontinued.

Topical nitrogen mustard in the treatment of alopecia areata: a bilateral comparison study

Bernardo O, Tang L, Lui H, Shapiro J. *J Am Acad Dermatol* 2003; 49:

291–4.

In this half-head controlled study 10 patients with AA for at least 1 year and >50% head involvement applied nitrogen mustard three times weekly for 16 weeks. A significant change was seen in only one patient, and another four did not complete the trial.

Dermatography as a new treatment for alopecia areata of the eyebrows

Van der Velden EM, Drost RHIM, Ijsselmuiden OE, Baruchin AM, Hulsebosch HJ. *Int J Dermatol* 1998; 37: 617–21.

Thirty-three patients with AA of the eyebrows were treated. The eyebrow areas were covered with a halftone pattern of tiny dots of color pigments, using a Van der Velden Derma-injector, without anesthesia. On average, two or three dermatography sessions of 1 hour each were required. The follow-up was 4 years. The results were excellent in 30 patients and good in 3 patients.

Effect of superficial hypothermic cryotherapy with liquid nitrogen on alopecia areata

Lei Y, Nie Y, Zhang JM, Liao DY, Li HY, Man MQ. *Arch Dermatol* 1991; 127: 1851–2.

Seventy-two patients with AA involving >25% of their scalp (disease duration 3 days–15 years) were treated with liquid nitrogen on a cotton swab for 2 to 3 seconds on a double freeze–thaw cycle. This was repeated weekly for 4 weeks. Forty comparable controls were treated with glacial acetic acid in a bland emollient vehicle three times a day for 4 weeks. More than 60% regrowth occurred in 70 (97.2%) of the active group, compared with 14 (35%) of the controls.

Use of the pulsed infrared diode laser (904 nm) in the treatment of alopecia areata

Waiz M, Saleh AZ, Hayani R, Jubory SO. *J Cosmet Laser Ther* 2006; 8: 27–30.

An open study of 16 patients with 34 patches of treatment-resistant alopecia, duration 12 months to 6 years. Patients were treated with four sessions of 904-nm pulsed diode laser once weekly. Seven patients had control patches. Regrowth occurred in 32 patches (94%) but not in the 7 control patches and was maintained for the 2 months of follow-up.

308-nm excimer laser for the treatment of alopecia areata

Al-Mutairi N. *Dermatol Surg* 2007; 33: 1483–7.

Eighteen patients with 42 patches of alopecia on the scalp and other sites for more than 6 months were treated twice weekly with the 308-nm excimer laser for 24 sessions. One patch in each patient was not treated; 41.5% of treated patches and 76.5% of scalp patches had cosmetically acceptable regrowth. No untreated patches regrew. Two patients relapsed at 6 months.

Phase I/II randomized bilateral half-head comparison of topical bexarotene 1% gel for alopecia areata

Talpur R, Vu J, Bassett R, Stevens V, Duvic M. *J Am Acad Dermatol* 2009; 61: 592–8.

In this bilateral half-head study, hair regrowth of at least 50% on treated sites was noticed in 11/42 (26%) patients treated with 1% bexarotene gel.

Comparison of azelaic acid and anthralin for the therapy of patchy alopecia areata: a pilot study

Sasmaz S, Arican O. *Am J Clin Dermatol* 2005; 6: 403–6.

Thirty-one subjects with patchy AA were randomized to apply either 20% azelaic acid (15 subjects) or 0.5% anthralin (16 subjects) for 12 consecutive weeks. In a subsequent 8-week follow-up period no cream was applied. A complete response was observed in 53.3% of cases in the azelaic acid group and in 56.2% of cases in the anthralin group.

Treatment of alopecia areata with simvastatin/ezetimibe

Latouf C, Jimenez JJ, Tosti A, Miteva M, Wikramanayake TC, Kittles C, et al. *J Am Acad Dermatol* 2015; 72: 359–61.

A series of 29 patients with AA were treated with simvastatin 40 mg and ezetimibe 10 mg daily. Nineteen completed 24 weeks treatment, and 14 of these were considered responders (20% hair regrowth). Five out of seven responders who discontinued the treatment relapsed, whereas five out of seven who continued for a further 24 weeks maintained the response.

Alopecia areata (AA) and treatment with simvastatin/ezetimibe: experience of 20 patients

Loi C, Starace M, Piraccini BM. *J Am Acad Dermatol* 2016; 74: e99–

100.

No convincing response was observed in this study, which seems to have sampled a more severely affected population.

Possible advantage of imiquimod and diphenylcyclopropenone combined treatment versus diphenylcyclopropenone alone: an observational study of nonresponder patients with alopecia areata

Wasylyszn T, Borowska K. *Australas J Dermatol* 2016; doi:[10.1111/ajd.12478](https://doi.org/10.1111/ajd.12478). [epub ahead of print]

A study with 20 subjects. A group receiving the combined therapy responded better than the group using DPCN alone.

Successful treatment of alopecia totalis with hydroxychloroquine: report of 2 cases

Stephan F, Habre M, Tomb R. *J Am Acad Dermatol* 2013; 68: 1048–9.

“Spectacular” and “excellent” results at 2 months and 5 months on 200 mg twice daily.

Hydroxychloroquine is ineffective in treatment of alopecia totalis and extensive alopecia areata: a case series of 8 patients

Nissen CV, Wulf HC. *JAAD Case Rep* 2016; 2: 117–8.

Sadly, these authors were unable to demonstrate any convincing response using 200 mg twice daily for 101 to 300 days.

Alopecia universalis successfully treated with adalimumab

Gorcey L, Gordon Spratt EA, Leger MC. *JAMA Dermatol* 2014; 150: 1341–4.

A patient improved within 2 weeks of starting treatment with adalimumab 40 mg subcutaneously every other week, relapsed on discontinuation, and improved again after resuming treatment.

Evaluation of utility of phenol in alopecia areata

Chikhalkar S, Jerajani H, Madke B. *Int J Trichology* 2013; 5: 179–84.

An open-label study on 50 patients with patchy hair loss. Three applications of 88% phenol were performed at 3-week intervals. Some regrowth was seen in 49 patients, with terminal hair in 20. Moderate improvement was observed in 78% of untreated patches. The treatment, which induced a mild-to-moderate burning sensation, frosting, and peeling, is believed to work as a result of the irritant

reaction.

Randomized trial of aromatherapy. Successful treatment for alopecia areata

Hay IC, Jamieson M, Ormerod AD. Arch Dermatol 1998; 134: 1349–52.

The active group massaged essential oils (thyme, rosemary, lavender, and cedarwood) in a mixture of carrier oils (jojoba and grape seed) into their scalp daily. The control group used only carrier oils for their massage. Nineteen (44%) of 43 patients in the active group showed improvement, compared with 6 (15%) of 41 in the control group.

Perhaps the nicest-smelling treatment!

Onion juice (*Allium cepa* L.), a new topical treatment for alopecia areata

Sharquie KE, Al-Obaidi HK. J Dermatol 2002; 29: 343–6.

Sixty-two patients with patchy alopecia were randomized to either topical onion juice or tap water twice daily for 2 months. Mean duration of disease was 3 weeks and 2.7 weeks, respectively. Twenty-three of the 45 onion juice group completed the trial, with full regrowth occurring in 20 patients. In the tap water–treated group, hair regrowth occurred in 2 of 17 patients. Mild erythema occurred in 14 of the onion juice group.

Combination of topical garlic gel and betamethasone valerate cream in the treatment of localized alopecia areata: a double-blinded randomized controlled study

Hajheydari Z, Jamshidi M, Akbari J, Mohammadpour R. Indian J Dermatol Venereol Leprol 2007; 73: 29–32.

In this double-blinded randomized controlled trial, 40 patients were divided into two groups of garlic gel and placebo. Garlic gel was rubbed on the alopecia patches under dressing and left for 1 hour, twice daily for 3 months, in the garlic group. The same procedure was carried out in the control group with placebo gel. Both groups received topical corticosteroid (betamethasone cream 0.1% in isopropyl alcohol) twice daily. Good and moderate responses were observed in 19 (95%) patients in the group treated with garlic gel and 1 (5%) patient in the placebo group.

Undoubtedly the worst-smelling treatments!

Amyloidosis

William Y-M. Tang, and Loi-Yuen Chan

Amyloid is an altered, insoluble protein folded in β -pleated sheets that is deposited extracellularly. Amyloid can accumulate in one or many organs, thereby causing dysfunction. There is an increasing number (more than 28) of proteins identified to be amyloidogenic. The common amyloid entities are AL (amyloid light chain), AA (amyloid associate), ATTR (transthyretin), and β_2 -microglobulin.

Systemic amyloidosis consists of primary systemic amyloidosis (AL amyloidosis), secondary systemic amyloidosis (AA amyloidosis), dialysis-associated amyloidosis (β_2 -microglobulin), and senile systemic amyloidosis. Skin changes such as petechiae, ecchymoses, waxy papules and plaques, nail dystrophy, and, rarely, blisters may occur. Management of systemic amyloidosis is complex. Treatment of any skin lesions is dependent on treating the underlying systemic amyloidosis and is beyond the scope of this chapter.

Cutaneous amyloidosis may be primary or secondary. The latter refers to deposition of amyloid within skin tumors such as seborrhoeic keratosis, porokeratosis, pilomatricoma, and basal cell carcinoma and is detectable histologically. Primary localized cutaneous amyloidosis (PLCA) is characterized by the deposition of amyloid in the skin without involving any internal organ. It occurs more commonly in Southeast Asians, Chinese, Middle Easterners, and South Americans. There are three types of primary localized cutaneous amyloidosis: lichen amyloidosis, macular amyloidosis (keratinic amyloid in both types, derived from degenerated keratinocytes), and nodular amyloidosis (AL amyloid, derived from immunoglobulin light chains). *Biphasic amyloidosis* refers to the co-occurrence of macular and lichen amyloidosis in a patient.

Lichen amyloidosis (LA) (see Figure) is a persistent eruption of multiple red-brown hyperkeratotic papules often affecting extensor aspects of extremities, especially the pretibial surfaces. The male-to-female ratio varies among studies from 2:1 and 1:2. Apart from its cosmetic nuisance, marked itching can occur. Although familial cases of lichen amyloidosis have been reported, most are isolated cases without any association with systemic disease.

Macular amyloidosis (MA) is characterized by an eruption consisting of small, dusky-brown or grayish pigmented macules distributed symmetrically over the upper back and upper arm. It has a reticulated or rippled pattern. Itch is variable, and patients seek medical advice for esthetic issues.

Nodular amyloidosis is the rarest subtype of PLCA. It is characterized by single or multiple waxy, firm, brown or pink nodules involving the legs, head, trunk, arms, and genitalia. It is usually asymptomatic.

Both lichen and macular amyloidosis run a benign course. However, for primary localized cutaneous nodular amyloidosis (PLCNA), an estimated 7% risk of progression to systemic

amyloidosis has been reported. Further, a case of PLCNA associated with CREST and Sjögren syndrome was also reported.

Management Strategy

Pruritus and unsightly presentation are common in localized cutaneous amyloidosis. Currently, effective treatment of cutaneous amyloidosis is lacking. *Antihistamines* and *topical corticosteroids* are commonly prescribed.

Phototherapy (ultraviolet B or PUVA) has been used to treat lichen amyloidosis successfully for relief of pruritus. Acitretin may be added for combined therapy. Laser treatments reported to be successful in treating cutaneous amyloidosis include carbon dioxide laser, pulsed dye laser (PDL), and neodymium:yttrium aluminum garnet (Nd:YAG) laser.

Dermabrasion has been successful in treating lichen and nodular amyloidosis. This improves cosmesis and alleviates pruritus, but brings accompanying procedural pain and possible skin atrophy. There is an anecdotal report that dermabrasion of lichen amyloidosis under tumescent anesthesia reduced procedural pain.

Other treatment choices include tacrolimus, transcutaneous electrical nerve stimulation (TENS), capsaicin, tocotrienol, and amitriptyline. Topical dimethyl sulfoxide (DMSO) also has been reported to benefit lichen and macular amyloidosis. However, a more recent study on 25 patients reported a lack of efficacy.

Specific Investigation

- Skin biopsy

All forms of amyloidosis have similar histologic findings. On light microscopy, amyloid is characteristically a pink, amorphous material. Special stains, such as Congo red and crystal violet, can highlight the amyloid deposit. Amyloid can be metachromatically stained red by crystal violet staining of an aqueous mount of the specimen. Congo red staining of amyloid shows apple-green birefringence under polarized light microscopy.

First-Line Therapies

• Sedating antihistamines	E
• Topical high-potency corticosteroids	E

Although there are no specific studies evaluating the efficacy of antihistamines and topical corticosteroids for treating cutaneous amyloidosis, they are considered first-line therapies. Sedating antihistamines and high-potency steroids help in the relief of pruritus and thinning of lesions.

Second-Line Therapies

• Phototherapy/photochemotherapy	D
• Oral retinoids	D
• Laser	D
• Tacrolimus	E
• TENS	D
• Capsaicin	E
• Tocoretinate	D
• Amitriptyline	E

Thermosensitive lichen amyloidosis

Parsi K, Kossard S. Int J Dermatol 2004; 43: 925–8.

A 26-year old man with a 3-year history of lichen amyloidosis with

lesions characteristically sparing areas with higher cutaneous temperatures. The clinical response to topical steroids and moisturizers was unsatisfactory. The patient received an average of three treatment sessions per week for a total of 55 sessions of narrowband ultraviolet B phototherapy over a 5-month period. This resulted in a marked improvement of pruritus and clearing of the amyloid deposit.

Successful treatment of lichen amyloidosis with combined bath PUVA photochemotherapy and oral acitretin

Grimmer J, Weiss T, Weber L, Meixner D, Scharffetter-Kochanek K. Clin Exp Dermatol 2007; 32: 39–42.

Two male patients with lichen amyloidosis over the extensor surfaces of the lower legs were treated with bath PUVA three to four times per week for 11 weeks, plus oral administration of acitretin 0.5 mg/kg/day for 7 months. There was almost complete resolution of skin lesions in both patients. No relapse was observed for 8 months after discontinuation of treatment.

Widespread biphasic amyloidosis: response to acitretin

Hernandez-Nunez A, Dauden E, Moreno de Vega MJ, Fraga J, Aragues M, Garcia-Diez A. Clin Exp Dermatol 2001; 26: 256–9.

A 73-year-old man with a 15-year history of biphasic amyloidosis was treated with acitretin 35 mg once daily (0.5 mg/kg/day). Pruritus resolved completely after 2 weeks of treatment. Acitretin was continued for 6 months and then stopped. There was no recurrence during the subsequent 6 months of follow-up.

Efficacy of different modes of fractional CO₂ laser in the treatment of primary cutaneous amyloidosis: a randomized clinical trial

Esmat SM, Fawzi MM, Gawdat HI, Ali HS, Sayed SS. Lasers Surg Med 2015; 47: 388–95.

Twenty-five patients with primary cutaneous amyloidosis (16 MA and 9 LA) were treated by fractional CO₂ laser using superficial ablation and deep rejuvenation to equal areas of randomly assigned lesions after the application of a topical anesthetic cream. Each patient received four sessions with 4-week intervals. Both modes yielded significant reduction of pigmentation, thickness, itching, and amyloid

deposit. The superficial ablation was better tolerated by patients.

Successful treatment of lichen amyloidosis using a CO₂ surgical laser

Norisugi O, Yamakoshi T, Shimizu T. *Dermatol Ther* 2014; 27: 71–3.

Two male patients with LA on their legs not responding to topical corticosteroids were treated with CO₂ laser twice a month, using a setting of 10 to 15 W with a 0.12-second pulse duration, 0.36-second rest duration, and a 5-mm laser spot size. The papules gradually flattened, and there was marked reduction of the itching as assessed by the Visual Analog Scale (VAS) score. No complications of the treatment were noted.

A case of lichen amyloidosis treated with pulsed dye laser

Sawamura D, Sato-Matsumura KC, Shibaki A, Akiyama M, Kikuchi T, Shimizu H. *J Eur Acad Dermatol Venereol* 2005; 19: 262–3.

A 59-year-old man with lichen amyloidosis for 5 years was treated with two sessions of 585-nm PDL. The treatment parameters were 7-mm spot size and a fluence of 6.0 J/cm². Reassessment at 8 weeks showed great reduction of itch with decreasing size of papules, although complete clearance was not achieved. The improvement persisted for more than 15 months after treatment.

532-nm and 1064-nm Q-switched Nd:YAG laser therapy for reduction of pigmentation in macular amyloidosis patches

Ostovari N, Mohtasham N, Oadras MS, Malekzad F. *J Eur Acad Dermatol Venereol* 2008; 22: 442–6.

Twenty patients with histology-confirmed macular amyloidosis were treated with Q-switched Nd:YAG laser with 532 nm in a part of their plaques and with 1064 nm in another part of their plaques. Assessment of efficacy was done by colorimetric scores and digital photographs before laser therapy and 8 weeks after treatment. Both lasers were effective in reducing pigmentation, with the 532 nm more effective. Ninety percent of cases treated by 532 nm had good or very good response, and for the 1064 nm–treated patches, 60% of cases had a good or very good response.

Lichen amyloidosis improved by 0.1% topical tacrolimus

Castanedo-Cazares JP, Lepe V, Moncada B. *Dermatology* 2002; 205:

420–1.

One patient with lichen amyloidosis diagnosed clinically was treated with tacrolimus 0.1% ointment twice daily. Resolution of pruritus was noted after 2 weeks of therapy, and marked improvement of plaque thickness was observed after 2 months.

Transcutaneous electrical nerve stimulation for reduction of pruritus in macular amyloidosis and lichen simplex

Yüksek J, Sezer E, Aksu M, Erkokmaz U. J Dermatol 2011; 38: 546–52.

Eight patients with macular amyloidosis and eight with lichen simplex were treated with high-frequency TENS thrice weekly for 4 weeks, 30 minutes duration, to areas with most intense itching. All patients with macular amyloidosis and six (75%) with lichen simplex had relief of their pruritus.

Successful treatment of lichen amyloidosis using capsaicin 8% patch

Zeidler C, Metze D, Ständer S. J Eur Acad Dermatol Venereol 2016; 30(7): 1236–8.

Two male patients with long-standing lichen amyloidosis not responding to topical corticosteroid and systemic antihistamine were treated with an 8% capsaicin patch applied once directly over the itchy area for 60 minutes. Pruritus subsided totally the next day, and the improvement lasted for at least 2 to 3 months. The mechanism of action is due to capsaicin inducing regrowth of anatomically normal nerves and restoring normal neuronal function over the treated areas.

Clinical effect of tocoretinate on lichen and macular amyloidosis

Terao M, Nishida K, Murota H, Katayama I. J Dermatol 2011; 38: 179–84.

Tocoretinate is a synthetic esterified compound of retinoic acid and tocopherol that is used for treating skin ulcers and improving skin manifestations of scleroderma, morphea, and hypertrophic scars. Ten patients with lichen amyloidosis and macular amyloidosis were treated daily with topical tocoretinate ointment. The outcome was very good for four, good for two, moderate for two, and poor for two. Normalization of epidermal differentiation shown in vivo is thought to be beneficial in the treatment of amyloidosis.

Itch in familial lichen amyloidosis: effective treatment with

amitriptyline in two cases

Yew YW, Tey HL. *Dermatol Ther* 2014; 27: 12–5.

Two Chinese male patients with lichen amyloidosis had extensive, pruritic, and hyperkeratotic papules affecting the shins. In both patients, the pruritus was not improved with potent topical steroids and oral antihistamines. Amitriptyline was started at a dose of 10 mg every other night, resulting in significant reduction of itch score and Dermatology Life Quality Index score assessed 3 weeks after commencement of treatment. Itch was well controlled at 8 months and 6 months, respectively. Side effects were minimal. However, the lesions of lichen amyloidosis remained unchanged. The action of amitriptyline may be related to inhibition of the reuptake of 5-HT and noradrenaline in the brainstem and spinal cord and the inhibition of voltage-dependent sodium and potassium channels in peripheral nerves.

Androgenetic alopecia

Walter P. Unger, and Robin H. Unger

Androgenetic alopecia (AGA) is the most common type of hair loss affecting both men and women. The hair loss is secondary to the

involution of hair follicles due to both genetic predisposition and hormonal influences. Other factors may cause telogen effluvium and thus accelerate the process, including those such as endocrine imbalances, nutritional deficiencies, general anesthesia, drug therapies, anabolic supplements, and seborrheic dermatitis. The main hormone implicated in male pattern baldness (MPB) is dihydrotestosterone (DHT), which induces miniaturization, shortens anagen duration, and prolongs telogen in genetically susceptible hair follicles. The primary cause of female pattern hair loss (FPHL) is still unclear. Although the pathogenesis in the hair follicles in FPHL is largely similar to MPB and DHT may have a significant role in FPHL in women with elevated levels of androgens, decreased intracutaneous synthesized estrogens, prolactin, and other factors may have a greater influence in the majority of patients with FPHL.

Specific Investigations

- Full blood count
- Ferritin
- Thyroid function tests
- Female androgen screen
- Trichoscopy
- Photographic documentation
- Scalp biopsy

Management begins with a thorough physical examination of the patient, relevant blood tests, and scalp biopsies where indicated. The use of dermoscopy (such as the FotoFinder system) in the evaluation of patients presenting with alopecia is especially helpful. Many other conditions (alopecia areata, frontal fibrosing alopecia, and lichen planopilaris) can mimic AGA or unmask an underlying patterned hair loss.

MPB is most commonly graded by the Hamilton–Norwood patterns and may affect up to 80% of Caucasian men by the age of 70 years. Patients presenting with early onset of MPB are particularly important to address with medical management. FPHL is also exceptionally common. Dawber found that 87% of premenopausal women had Ludwig type I to III loss. Women may also present with a pattern more similar to MPB—79% of women develop type II MPB after puberty, and that number increases to Hamilton type IV in 25%

of women by age 50 years and 50% by age 60 years. FPHL has traditionally been graded by the Ludwig scale; however, a group of esteemed dermatologists have recently proposed a new FPHL Severity Index that combines measurements of hair shedding, midline hair density, and scalp trichoscopy criteria.

Towards a consensus on how to diagnose and quantify female pattern hair loss – The ‘Female Pattern Hair Loss Severity Index (FPHL-SI).’

Harries M, Tosti A, Bergfeld W, Blume-Peytavi U, Shapiro J, Lutz G, et al. Eur Acad of Dermatol and Venereol 2016; 30: 667–76.

The Ludwig scale has long been utilized to evaluate patients with FPHL, yet it is insufficient in many regards. Early-stage loss cannot be graded, and the scale is not precise enough to evaluate efficacy of treatments. Nine experts in the field have proposed a new scale to describe FPHL that can be used in clinical practice. It is a three-point scale with a maximum score of 20 that evaluates hair shedding, midline hair density, and scalp trichoscopy.

Imposters of androgenetic alopecia: diagnostic pearls for the hair restoration surgeon

Rogers N. Facial Plast Surg Clin North Am 2013; 21: 325–35.

This is a detailed review of the potential causes for hair loss, which may be mistakenly ascribed to AGA. The article discusses diagnostic tools, including trichoscopy and scalp biopsy, to determine the underlying etiology. This is particularly important for hair restoration surgeons, as it may lead to poor growth or future loss of transplanted hair.

Management Strategy

Medical treatment for AGA, if utilized appropriately in the early stages of loss, may reverse miniaturization and slow the future rate of loss. Topical *minoxidil* 5% has been proven to be an effective therapy for AGA, with minimal side effects. It is a biologic response modifier, and its active metabolite, minoxidil sulfate, opens potassium channels and growth factor production, thus increasing the duration of the anagen cycle and enlarging miniaturized follicles. The recommendation is twice-daily use, and the peak hair growth is seen

between 26 and 52 weeks. Some clinical improvement is seen after 2 years of use in 40% to 60% of patients. The vertex has the best response; however, recent studies have proven that in a smaller percentage of patients the frontal area may also benefit from treatment. The bioavailability of sulfotransferase differs among patients and may account for the variable response rate. Continued use is necessary for long-term efficacy, and patients may experience a significant telogen effluvium 3 to 4 months after stopping treatment.

The second option for medical therapy in MPB is the use of 5-alpha-reductase inhibitors. *Finasteride* is a competitive inhibitor of type II 5-alpha-reductase, which at 1 mg/day achieves close to a 70% reduction in serum and scalp levels of DHT. The use of finasteride for 2 years prevents progression of the disease in 99% of patients and produces clinical improvement in 66%. Continued improvement has been shown to be related to the reentry of resting follicles into the anagen phase and anagen prolongation. If the drug is discontinued, return to baseline hair counts is seen within 1 year. The side effects of finasteride use in men include primarily decreased libido, erectile dysfunction, and decreased semen volume. Additional side effects that have been reported include gynecomastia, depression, and lowering of sperm count and motility. A meta-analysis performed in 2015 suggests that toxicity information and drug safety were not accurately presented in studies performed. *Dutasteride* blocks type I and II 5-alpha-reductase and is used as an off-label treatment for AGA by many practitioners. Studies have shown that a dose of 0.5 mg/day is more effective than finasteride for the treatment of AGA.

The only Food and Drug Administration (FDA)-approved treatment for FPHL is topical minoxidil; the 5% strength is now approved for once-daily use, which is easier with respect to compliance and more effective than the twice-daily 2% preparation. Clinical improvement may be seen in up to 80% of patients. It is contraindicated in pregnancy and may cause scalp pruritus, palpitations, or headaches in women with very low blood pressure, but is usually very well tolerated.

Women with FPHL may also benefit from the use of antiandrogens, although these have been shown to be most effective in women with clear endocrine disorders resulting in hyperandrogenism. Other than minoxidil, all medications are off-label use for FPH, including *cypoterone acetate*, *flutamide*, and *spironolactone*. Finasteride 1 to 5 mg daily has been used by many practitioners for the treatment of FPHL.

Its efficacy has been debated and remains unproven in controlled studies. Furthermore there is no defined safety profile in women, and the increase in estrogen (due to conversion of testosterone to estradiol) may be of particular concern in patients with uterine fibroids, as well as a known personal or family history of breast/ovarian cancer.

Surgical treatment is an effective option for treatment in patients who have not responded to medical therapy or in whom the results have not provided a significant cosmetic improvement. Advances in *hair transplant surgery* have enabled surgeons to create a very natural and cosmetically significant increase in hair density even after one operation. The photos included show an example of the results that can typically be achieved after just one hair replacement surgery. Hair from the relatively permanent fringe may be harvested with either a single elliptical excision (strip) or utilizing follicular unit extraction (FUE). The latter method is becoming increasingly popular, whether via robot, manual punch, or motorized punch. Both methods have advantages and disadvantages, and a good surgeon should have all tools at their disposal. Grafts produced from a single-strip harvest have the distinct advantage of being taken from the center of the area, with the highest percentage of permanent hairs in the donor area, and the limited studies performed to date indicate the grafts from the strip have a higher survival rate than those obtained with FUE. An initial small study presented at the 2015 annual ISHRS international conference found that 14 months after surgery 547/890 grafts grew in the FUE study area (61.4%) compared with 765/890 follicles in the strip graft study area—a difference of 24.6%. Hopefully further refinements and studies will show improved results in FUE. Regardless of technique, the follicular units harvested are placed into small incisions created between existing hairs, and therefore it produces an excellent increase in density in both men and women with AGA.

Platelet-rich plasma (PRP) treatment for hair loss is still an unproven therapy, although limited studies, case reports, and anecdotal reports are very encouraging. It may be used adjunctively as part of hair transplant surgery or as a treatment on its own. Physicians who use PRP as a stand-alone treatment for AGA may also use microneedling or ACell powder to increase efficacy. Unfortunately, there is no consensus on the best method of treatment or on the efficacy of each technique.

Additional management strategies include camouflage aids. These include various tinted powders or sprays, tattooing of the scalp, hairpieces, or wigs. Hair extensions add density and length, but can produce permanent traction alopecia. *Hair-thickening shampoos* and sprays may also help to temporarily increase the look of volume. *Low-level laser light* has some supporting evidence.

First-Line Therapies

• Topical minoxidil	A
• Finasteride	A
• Spironolactone	B

Androgenetic alopecia: an evidence-based treatment update

Varothai S, Bergfeld W. Am J Clin Dermatol 2014; 15: 217–30.

A thorough review of the treatment options for AGA grounded in evidence-based medicine. Studies of hair loss and growth are notoriously difficult to perform, and this leads to studies with limited patient populations or poor controls. The authors review studies of clinical relevance.

A single-centre, randomized, double-blind, placebo controlled clinical trial to investigate the efficacy and safety of minoxidil topical foam in frontotemporal and vertex androgenetic alopecia in men

Hillman K, Garcia-Bartels N, Kottner J, Stroux A, Canfield D, Blume-Peytavi U. Skin Pharmacol Physiol 2015; 28: 236–44.

Although the efficacy of 5% minoxidil in vertex and midscalp AGA has been proven in multiple studies, this is the first study to prove its efficacy in the frontotemporal area. Maximum improvement was seen at 16 weeks, but continued to 24 weeks in all regions. The cumulative

nonvellus hair caliber showed the most significant increase from baseline. The subject self-assessment also revealed a significant improvement in scalp coverage in all areas. A follow-up study was published in September 2015, indicating that cosmetic effectiveness continued to 104 weeks without significant regional differences, although hair counts had returned to baseline.

A randomized, single-blind trial of 5% minoxidil foam once daily versus 2% minoxidil solution twice daily in the treatment of androgenetic alopecia in women

Blume-Peytavi U, Hillmann K, Dietz E, Canfield D, Garcia Bartels N. J Am Acad Dermatol 2011; 65: 1126–34.

A 6-month study involving 113 women with AGA demonstrated that once-daily 5% minoxidil foam is as effective for stimulating hair growth and caliber increase as twice-daily propylene glycol containing 2% topical minoxidil. Patients were more compliant with the once-daily 5% foam due to convenience of use and low levels of side effects.

Efficacy and safety of finasteride therapy for androgenetic alopecia: a systematic review

Mella JM, Perret MC, Manzotti M, Catalano HN, Guyatt G. Arch Dermatol 2010; 146:1141–50.

A meta-analysis of 12 studies (3927 male patients) revealed moderate-quality evidence suggesting that daily use of oral finasteride (1 mg or 5 mg) significantly increases hair count and improves patient and investigator assessment of hair appearance, while increasing the risk of sexual dysfunction. A Jadad score was used to assess the methodology of each study analyzed (through 2009).

Finasteride treatment of female pattern hair loss

Iorizzo M, Vincenzi C, Voudouris S, Piraccini BM, Tosti A. Arch Dermatol 2006; 142: 298–302.

Thirty-seven women with FPHL were treated with oral finasteride, 2.5 mg a day, while taking an oral contraceptive containing drospirenone and ethinyl estradiol. At 12 months' follow-up, 23 of the 37 patients were rated as improved using global photography (12 were slightly improved, 8 were moderately improved, and 3 were greatly improved). No improvement was recorded in 13 patients. One

patient experienced worsening of the condition. There was a statistically significant increase in the hair density score in 12 patients. It was unclear whether the success was due to a higher dosage of finasteride than used in prior studies (2.5 mg instead of 1 mg) or to its association with the oral contraceptive containing drospirenone, which has an antiandrogenic effect.

Treatment of female pattern hair loss with oral anti-androgens

Sinclair R, Wewerinke M, Jolley D. Br J Dermatol 2005; 152: 466–73.

The results of this study of 80 women treated with either spironolactone or cyproterone acetate indicated a positive effect with treatment. In the treatment group 44% of women showed regrowth, 44% demonstrated no progression of hair loss, and 12% continued with progressive hair loss. Women with more severe baseline FPHL were more likely to be responders. This study did not compare results with a placebo group, nor were the investigators blinded.

Spironolactone is generally used at 100 to 200 mg a day and cyproterone at 52 mg a day on days 5 to 15 of the menstrual cycle, with Estinyl 20 µg twice daily on days 5 to 24 of the menstrual cycle.

Second-Line Therapy

• Dutasteride

A

Long-term safety and efficacy of dutasteride in the treatment of male patients with androgenetic alopecia

Tsunemi T, Irisawa R, Yoshiie H, Brotherton B, Ito H, Tsuboi R, et al. J Dermatol 2016; 43: 1051–8.

This study aimed to determine long-term safety, tolerability, and efficacy of dutasteride 0.5 mg, an inhibitor of type 1 and 2 5- α -reductase, in Japanese male patients with AGA.

A multicenter, open-label, prospective outpatient study of 120 men given dutasteride 0.5 mg once daily for 52 weeks.

Nasopharyngitis, erectile dysfunction, and decreased libido were

the most frequently reported adverse events, and most adverse events were mild. Drug-related adverse events were reported, with an incidence of 17%, none of which led to study withdrawal. Hair growth (mean target area hair count at week 52), hair restoration (mean target area hair width at week 52), and global appearance of hair (mean of the median score at week 52) improved from baseline during the study. Dutasteride exhibited long-term safety in this Japanese population.

Regenerative medicine and hair loss: how hair follicle culture has advanced our understanding of treatment options for androgenetic alopecia

Higgins CA, Christiano AM. Regen Med 2014; 9: 101–11.

A review of the current research being done on hair follicle culture. Growth modulators found to be effective in culturing hair follicles may lead to treatment options for AGA that were previously unexplored. The article also describes the current state of research in follicular stem cell implantation—a potential future treatment modality.

Third-Line Therapies

• Hair transplant surgery	A
• Lasers	C
• Platelet-rich plasma	C

Female hair restoration

Unger R. Facial Plast Surg Clin North Am 2013; 21: 407–19.

A detailed article describing the latest surgical techniques used in treating female hair loss. The article describes the treatment of women with AGA, as well as those with cicatricial or trauma-induced alopecia. Technical surgical pearls are explained. Most importantly,

the article addresses the most significant aspects in the unique approach required for planning female hair restoration surgery.

Planning and organization

Unger WP. In: Unger WP, Shapiro R, Unger RH, Unger M, eds. Hair Transplantation, 5th edn. New York: Marcel Dekker, 2011; 106–52.

An in-depth review of the most important aspects in planning a successful hair transplant, including the nomenclature of scalp anatomic landmarks and determination of patient candidacy, in addition to surgical techniques and esthetic principles essential to achieving *long-term* esthetic results. Key background factors for surgical planning are highlighted in both women and men, with a particular emphasis on addressing the areas of future hair loss in younger patients.

Robotic hair restoration

Rose P, Nusbaum B. Dermatol Clin 2014; 32: 97–107.

The authors describe the use of robotic FUE. Included are challenges and benefits of this method of harvesting grafts, which are fairly similar to those with FUE performed with a manual or motorized punch. Challenges include the time necessary for extraction, the availability of only two punch sizes, and the requirement of shaving the donor area. The robot does allow physicians to include hair transplantation in their practice without a significant number of additional support staff; however, good results are still dependent on surgical planning and artistry in the recipient area.

Efficacy and safety of a low-level laser device in the treatment of male and female pattern hair loss: a multicenter, randomized, sham device-controlled, double-blind study

Jiminez J, Wikramanayake T, Bergfeld W, Hordinsky M, Hickman J, Hamblin M, et al. Am J Clin Dermatol 2014; 15: 115–27.

Multiple centers enrolled a total of 128 male and 141 female patients to evaluate an at-home low-level light therapy (LLLT) device with differing number of beams. The patients were randomly assigned to the device or the sham device in sealed packages and instructed to use them three times a week for 26 weeks. Terminal hair density was evaluated at baseline, 16 weeks, and 26 weeks, and a blinded independent evaluator looked at Canfield photographs to

determine the change in hair counts. Meta-analyses were conducted and showed a significant mean terminal hair density increase at 26 weeks. Compared with the sham device, there was a statistically significant improvement from baseline.

The effect of platelet-rich plasma in hair regrowth: a randomized placebo-controlled trial

Gentile P, Garcovich S, Bielli A, Scioli MG, Orlandi A, Cervelli A. Stem Cells Transl Med 2015; 4: 1317–23.

This study is a randomized, half-head, placebo-controlled evaluation of PRP. Results were evaluated by a blinded evaluator using computerized trichograms. The main weakness in the study is that only 20 patients were enrolled. The results were evaluated after three treatments at 30-day intervals, and a mean increase of 33.6 hairs in the target area and a mean increase in total hair density of 45.9 hairs per cm² were found compared with baseline values. Biopsies were also evaluated and showed increased epidermis thickness and number of hair follicles, as well as increased Ki-67 indicating cell proliferation.

Angiolymphoid hyperplasia with eosinophilia

William Y.M. Tang, and Loi Yuen Chan

Angiolymphoid hyperplasia with eosinophilia (ALHE) was first

described by Wells and Whimster in 1969. It is a benign vascular proliferation of unknown etiology with a characteristic component of epithelioid endothelial cells. It is an uncommon disease, so data on its natural course and treatment response are based on a small number of patients.

ALHE usually affects women in their third decade and presents as cutaneous papules or subcutaneous nodules, sometimes with inflammatory features on the head, neck, and periauricular region. Involvement elsewhere is rare. Approximately 20% of patients have blood eosinophilia. Although considered benign in nature, the etiology of ALHE is unknown, but neoplastic proliferation of vascular tissue, arteriovenous shunting, and reactive hyperplasia of vascular tissue secondary to trauma, infection, renin, or hyperestrogenic states have been proposed as causal factors. ALHE may cause symptoms such as disfigurement, bleeding, itch, and pain. It has been associated with various lymphoproliferative conditions, supporting the contention that it may represent a monoclonal T-cell process.

The differential diagnoses of ALHE include Kimura's disease, pyogenic granuloma, lymphocytoma cutis, insect bite, sarcoidosis, Kaposi sarcoma, and angiosarcoma. ALHE and Kimura's disease are generally regarded as separate clinicopathologic entities. Kimura's disease is a chronic inflammatory condition of unknown etiology often affecting young male Asians and typically presents as cervical lymphadenopathy and subcutaneous nodules in the head and neck region. However, coexistence of ALHE and Kimura's disease in the same patient has been reported.

Management Strategy

Treatment is usually required for ALHE, as spontaneous remission is rare. *Complete surgical excision* is preferred for persistent lesions. Recurrence may occur if excision is incomplete. *Laser therapy and radiofrequency ablation* are alternative surgical options. *Cryotherapy*, inexpensive and easily available, is a conventional treatment, but reports on its efficacy are lacking. Other treatments reported effective include *topical and intralesional corticosteroids, propranolol, topical imiquimod, topical tacrolimus, isotretinoin, suplatast tosilate, intralesional interferon- α_{2b} , thalidomide, and photodynamic therapy*.

Specific Investigations

- Histopathology
- Imaging

Microscopically, ALHE is characterized by a proliferation of blood vessels of varying sizes lined by plump endothelial cells. These histiocytoid endothelial cells are enlarged, with abundant eosinophilic or clear cytoplasm and large vesicular nuclei. The cells are mostly cuboidal with occasional “hobnailing,” which is related to the presence of cytoplasmic vacuoles in these cells, causing cytoplasmic protrusion into lumina. There is also an accompanying perivascular lymphocytic and eosinophilic infiltrate.

The location and extent of underlying vascular anomalies may be assessed by angiography, angiomagnetic resonance imaging, and angiocomputed tomography.

Due to its predominant occurrence in females, hyperestrogenic states may have a causative role in ALHE. However, successful treatment of ALHE using hormonal therapy has not yet been reported.

Angiolymphoid hyperplasia with eosinophilia associated with pregnancy: a case report and review of the literature

Zarrin-Khameh N, Spoden JE, Tran RM. Arch Pathol Lab Med 2005; 129: 1168–71.

The authors reported a 33-year-old woman who developed ALHE in her right ear during the second trimester of pregnancy. The lesion was completely excised. The authors also reviewed a total of five other ALHE cases associated with pregnancy. Lesions in some of these patients increased in size during pregnancy. One patient improved with cessation of oral contraceptive pills, whereas the lesions in another patient reduced in size by half during the postpartum period. Two patients had skin biopsy expressing a significant amount of estrogen and progesterone receptors but not in the uninvolved skin.

First-Line Therapies

• Surgery	D
• Laser therapy	D
• Corticosteroid, topical or intralesional	E

A refractory case of angiolymphoid hyperplasia with eosinophilia successfully treated by surgery

Baghestani S, Firooz A, Ghazisaidi MR. J Dermatolog Treat 2011; 22: 49–51.

The authors reported a 30-year-old woman with ALHE on her right ear successfully treated by surgery after several unsuccessful attempts with other conventional therapies, including cryotherapy, electrodesiccation, and intralesional plus oral corticosteroids.

Epidemiology and treatment of angiolymphoid hyperplasia with eosinophilia (ALHE): a systematic review

Adler BL, Krausz AE, Minuti A, Silverberg JI, Lev-Tov H. J Am Acad Dermatol 2016; 74: 506–12.

This report includes 416 studies detailing 908 patients. The authors concluded that surgical excision was the best option, albeit suboptimal. Pulsed dye lasers or other lasers may represent other reasonable therapeutic options.

Facial angiolymphoid hyperplasia with eosinophilia: sustained remission following treatment with carbon dioxide laser

Ali FR, Madan V. Clin Exp Dermatol 2016; 41: 96–8.

A 35-year-old woman presented with biopsy-proven ALHE lesions on her left temple, which had developed during pregnancy 5 years previously. Ablation with CO₂ laser (15W, 4-mm spot, 10,600 nm) was undertaken in three sessions over the course of 8 months, with an excellent clinical response. There was no recurrence after 30 months.

Angiolymphoid hyperplasia successfully treated with an ultralong pulsed dye laser

Angel CA, Lewis AT, Griffin T, Levy EJ, Benedetto AV. Dermatol Surg 2005; 31: 713–6.

A 72-year-old man with ALHE presented with a tender, enlarging lesion over the left posterior helix and mastoid region for 1 year not responding to intralesional steroids. He was successfully treated with two sessions of ultralong pulsed dye laser (PDL) (595 nm, 7-mm round spot, 3.0-ms pulse width, 15 J/cm²). There was no recurrence 3 years after treatment. The longer wavelength produces deeper penetration into dermal tissue and more uniform coagulation necrosis across the entire diameter of the targeted blood vessel.

Angiolymphoid hyperplasia with eosinophilia: successful treatment with the Nd:YAG laser

Kadurina MI, Dimitrov BG, Bojinova ST, Tonev SD. *J Cosmet Laser Ther* 2007; 9: 107–11.

This is the first review of Nd:YAG laser for treating ALHE. A 31-year-old woman presented with a rapidly enlarging, itchy, and bleeding tumor of ALHE affecting the right ear tragus and ear canal. The lesion was treated with 1064-nm Nd:YAG (6-mm round spot, two pulses of 7.0 ms with a 20-ms interpulse delay, fluence of 100–150 J/cm²). A total of five treatments were administered with an interval of 30 days between each procedure. The patient showed complete remission after 1-year follow-up.

Angiolymphoid hyperplasia with eosinophilia treated with vascular laser

Alcántara González J, Boixeda P, Truchuelo Díez MT, Pérez García B, Jaén Olasolo P. *Lasers Med Sci* 2011; 26: 285–90.

The sequential laser combines 595-nm PDL with 1064-nm Nd:YAG targeting structures at different dermal levels using two different wavelengths. Greater effectiveness and lower recurrence rates are possible with the Nd:YAG laser, which allows the destruction of deeper vessels than does PDL. Three patients with ALHE were treated with this sequential laser system. Complete resolution was observed in two of them 3 years after their last treatment; the other patient showed a marked improvement.

Second-Line Therapies

• Propranolol	E
• Imiquimod	E
• Tacrolimus	E
• Isotretinoin	E
• Radiofrequency ablation and sclerotherapy	E

Propranolol: a novel treatment for angiolymphoid hyperplasia with eosinophilia

Horst C, Kapur N. Clin Exp Dermatol 2014; 39: 810–2.

A 32-year-old woman presented with multiple ALHE lesions in the left periauricular area and the vertex of her scalp. She was started on oral propranolol 40 mg daily. Within 6 weeks, several lesions had decreased in size, and all were less erythematous. Propranolol was subsequently stopped within a few months of initiating treatment. Propranolol targets the vascular proliferative element of ALHE. It is also effective in decreasing the vasculature of hemangiomas of infancy.

Angiolymphoid hyperplasia with eosinophilia treated successfully with imiquimod

Isohisa T, Masuda K, Nakai N, Takenaka H, Katoh N. Int J Dermatol 2014; 53: e43–4.

A 49-year-old woman with multiple ALHE lesions in her left postauricular area and external auditory canal was treated with 5% imiquimod cream five times per week. The pruritus improved markedly within 2 weeks. By 22 weeks of treatment, the small lesions had almost completely regressed. The authors suggested that topical imiquimod should be considered for treatment of ALHE because of its excellent cosmetic results and safety record, especially for those with multiple lesions. The underlying mechanism may be related to the immunomodulating and antiangiogenic effect of imiquimod.

Angiolymphoid hyperplasia with eosinophilia: efficacy of isotretinoin?

El Sayed F, Dhaybi R, Ammoury A, Chababi M. Head Face Med 2006; 2: 32.

The authors report a 32-year-old man with multiple pruritic lesions of ALHE treated with isotretinoin 0.5 mg/kg/day for 1 year with complete resolution of one of the two scalp nodules. Two lesions on the cheeks and two in the preauricular region that decreased in size, but did not totally resolve, were surgically removed. The success of isotretinoin was due to its antiangiogenic properties via a reduction of vascular endothelial growth factor production by keratinocytes.

Angiolymphoid hyperplasia with eosinophilia treated with a novel combination technique of radiofrequency ablation and sclerotherapy

Khunger N, Pahwa M, Jain RK. Dermatol Surg 2010; 36: 422–5.

Three patients with ALHE were treated with radiofrequency ablation (RFA) after intralesional sclerotherapy with 3% polidocanol. Lesions were mostly treated with cutting plus coagulation mode with an intensity of 4 U. One to four sessions of treatment were required to achieve complete response. No recurrence was seen after a follow-up period of 6 months to 2 years. The synergistic effect is due to sclerosants treating the deeper vascular component while RFA ablates the lesion.

Third-Line Therapies

• Suplatast tosilate	E
• Interferon- α_{2b}	E
• Thalidomide	E
• Photodynamic therapy	E

Angiolymphoid hyperplasia with eosinophilia on the leg successfully treated with T-helper cell 2 cytokine inhibitor suplatast tosilate

Bito T, Kabashima R, Sugita K, Tokura Y. J Dermatol 2011; 38: 300–2.

Suplatast tosilate is a Th2 cytokine inhibitor that inhibits T helper cell production of interleukin (IL)-4 and IL-5. This results in reduced eosinophil infiltration and suppression of IgE production in B cells. A 63-year-old man with ALHE on the right calf was treated with suplatast tosilate both orally and topically. The lesions dramatically improved after 4-week administration and completely disappeared 4 months after the beginning of the treatment. No recurrence was observed even 15 months later.

There is an earlier report on a 32-year-old man with ALHE successfully treated with suplatast tosilate 300 mg/day.

Angiolymphoid hyperplasia with eosinophilia responding to interferon-alpha 2B

Oguz O, Antonov M, Demirkesen C. J Eur Acad Dermatol Venereol 2007; 21: 1277–8.

Interferon- α is a potential treatment in benign angioproliferative disorders. Local intralesional injection of interferon- α_{2b} was reported effective for a 27-year-old female with occipital lesions of ALHE. Recurrence of lesions 9 years later was noted, but this time the response to repeated interferon- α_{2b} treatment was poor.

In another report (Shenefelt PD et al. Arch Dermatol 2000; 136: 837–9) intralesional interferon alfa-2a caused almost complete resolution of lesions in one patient. However, recurrence of lesions was noted within about 1 year of the last injection, and no response occurred with the second course of injection.

Successful management of refractory angiolymphoid hyperplasia with eosinophilia with thalidomide

Rongioletti F, Cecchi F, Pastorino C, Scaparro M. J Eur Acad Dermatol Venereol 2016; 30: 527–9.

A 58-year-old woman with multiple ALHE lesions on the occipital area unresponsive to oral propranolol, cryotherapy, topical and systemic steroids, and topical tacrolimus was put on thalidomide 50 mg twice a day for 2 months, then three times daily for 4 months, with progressive decolorization, flattening, and regression of the

lesions. After 6 months of therapy, the lesions almost resolved; however, she developed neuropathy necessitating the discontinuation of thalidomide. No new lesions were noted at 3 months of follow-up. The action of thalidomide is considered to be due to its antiangiogenic, antiinflammatory, and antitumor effects.

Angiolymphoid hyperplasia with eosinophilia: good response to photodynamic therapy

Sotiriou E, Apalla Z, Patsatsi A, Panagiotidou DD, Ioannides D. Clin Exp Dermatol 2009; 34: e629–31.

Photodynamic therapy (PDT) causes suppression of tumor growth by damaging endothelial cells in the tumor neovasculature. A 60-year-old woman with multiple ALHE lesions on the forehead was treated with two sessions of aminolevulinic acid (ALA) PDT, with a 2-week interval. A 20% 5-ALA cream occluded from light for 4 hours, followed by exposure to red light (570–670 nm, dose 80 J/cm²) from a noncoherent light source was used. Marked improvement, though not complete regression, was achieved 8 weeks after treatment and maintained at 4 months after treatment. The moderate response achieved in this study could be due to poor penetration of the photosensitizer to the deep part of the lesion.

Angular cheilitis

Jennifer K. Chen, and Janellen Smith

Angular cheilitis. With permission from Mayo Foundation for Medical Education and Research. All rights reserved.

Angular cheilitis is a chronic reactive inflammatory condition of the oral commissures characterized by atrophy, fissures, crusting, erythema, and scaling. The etiology is often multifactorial, and causes may be mechanical (intertrigo), infectious, nutritional, hormonal, or inflammatory. Angular cheilitis may be a sign of systemic disease (see later).

Management Strategy

Successful therapy is based on identifying and correcting any underlying condition(s). The presence of dentures, palatal erythema, and/or edema may suggest candidiasis and denture stomatitis. A pale, depapillated, atrophic tongue suggests iron deficiency. A tender depapillated tongue suggests folate or vitamin B₁₂ deficiency. An eczematous dermatitis of the lower face suggests a staphylococcal infection (infectious eczematoid dermatitis). A history of allergic contact dermatitis may suggest an allergy.

Unilateral lesions are usually short lived and induced by mechanical factors. This has also been reported to be a manifestation of plasma cell cheilitis. Bilateral lesions tend to be chronic and caused by infection or nutritional deficiency and are more likely to be associated with an underlying disease process.

Maceration of the commissural epithelium and adjacent skin is a common, noninfectious cause of mechanical angular cheilitis. Trauma from dental flossing, habitual lip-licking, and excessive salivation all contribute. Periods of oral hydration and then dryness disrupt epithelial integrity, causing fissuring of the commissures. This provides an ideal environment for low-grade candidiasis and infectious eczematoid dermatitis. Other mechanical factors are ill-fitting dentures, loss of vertical dimension of the jaws, sagging skin folds, xerostomia, and perioral dermatitis.

Infectious and systemic causes must be investigated. Angular cheilitis is frequently present in patients with HIV disease, where 10% may have localized candidiasis. Highly active antiretroviral therapy (HAART) may decrease this incidence. Both *Candida albicans* and *Staphylococcus aureus* can colonize the fissures. Anemia, nutritional deficiencies, Down syndrome, acrodermatitis enteropathica, pemphigus vulgaris, diabetes mellitus, orofacial granulomatosis, and Crohn disease may be present.

Recurrence of angular cheilitis may be prevented by eliminating offending organisms from their reservoirs. Denture stomatitis, candidiasis, and nasal colonization by staphylococci should be investigated. *Topical imidazole creams* after meals and at bedtime may treat candidiasis, whereas *topical mupirocin* is valuable in treating staphylococcal colonization. Dentures should be removed from the mouth nightly and cleansed well before reinsertion in the morning. *New dentures* may restore facial contours, increasing the vertical

dimension of the jaws and face. *Injection of fillers* into the commissures may alleviate causative mechanical factors.

Specific Investigations

- Culture or wet mount to evaluate for candidiasis
- Culture for bacteria
- For refractory or recurrent cases, laboratory evaluation should include a complete blood cell count; iron panel; vitamin B, folate, and zinc levels; glucose; hemoglobin A_{1c}; and HIV testing
- Patch testing

Angular cheilitis, part 1: local etiologies

Park KK, Brodell RT, Helms SE. *Cutis* 2011; 87: 289–95.

Angular cheilitis, part 2: nutritional, systemic, and drug-related causes and treatment

Park KK, Brodell RT, Helms SE. *Cutis* 2011; 88: 27–32.

A discussion of the multifactorial nature and evaluation of angular cheilitis.

Epidemiology and etiology of denture stomatitis

Angular cheilitis

Scully C, Bagan J-V, Eisen D, Porter S, Rogers RS III, eds. *Dermatology of the Lips*. Oxford: Isis Medical, 2000; 68–73.

Excellent clinical photographs and summary.

Nickel-induced angular cheilitis due to orthodontic braces

Yesudian PD, Memon A. *Contact Dermatitis* 2003; 48: 287–8.

First-Line Therapies

• Topical miconazole, ketoconazole, or nystatin cream two or three times daily for 2 to 3 weeks	D
• Topical polymyxin B or mupirocin ointments	D
• Remove dentures nightly and cleanse overnight with chlorhexidine 2% solution or sodium hypochlorite 0.02% solution. Rinse and air-dry before reinsertion. <i>Please note that chlorhexidine and nystatin inactivate each other and therefore should not be used together.</i>	D

Oral candidiasis and angular cheilitis

Sharon V, Fazel N. Dermatol Ther 2010; 23: 230–42.

An excellent review of topical and systemic therapy of candidiasis. The authors also recommend prophylaxis with chlorhexidine 0.12% mouthwash in recurrent cases.

Diseases of the lips

Rogers III, RS, Bekic M. Semin Cutan Med Surg 1997; 16: 325–36.

Discussion of the evaluation and treatment of angular cheilitis

Evren BA, Uludamar A, Iseri U, Ozkan YK. Arch Gerontol Geriatr 2011; 53: 252–7.

The association between socioeconomic status, oral hygiene practice, denture stomatitis, and oral status in elderly people living in different residential homes, is stressed.

Second-Line Therapies

• Systemic antifungal therapy (fluconazole)	E
• Amphotericin B cream	E

Oral candidiasis and angular cheilitis

Sharon V, Fazel N. Dermatol Ther 2010; 23: 230–42.

Reviews the treatment of candidiasis, highlighting challenges in the immunocompromised patient.

Third-Line Therapies

• Filler injections	E
• Prosthodontic evaluation and treatment	E
• Chewing gum with xylitol or chlorhexidine acetate and xylitol	B
• Gentian violet 0.5% solution twice daily	E
• Photodynamic therapy	E

Collagen implant in management of perleche (angular cheilosis)

Chernosky ME. J Am Acad Dermatol 1985; 12: 493–6.

Soft tissue augmentation may be used to decrease the depth of the fold at the oral commissures, thus decreasing salivary stasis.

Prosthodontic management of angular cheilitis and persistent drooling: a case report

Lu DP. Compend Contin Educ Dent 2007; 28: 572–7.

The author describes a method to incorporate a cannula into the dental prosthesis to channel saliva toward the oropharynx, suitable for elderly or handicapped patients who suffer from chronic drooling and angular cheilitis.

The effects of medicated chewing gums on oral health in frail older people: a 1 year clinical trial

Simons D, Brailsford SR, Kidd EA, Beighton D. J Am Geriatr Soc 2002; 50: 1348–53.

A controlled, double-blind trial of 111 dentate patients in residential homes showed significant reductions in denture stomatitis and angular cheilitis in patients using chlorhexidine acetate/xylitol gums.

Oral candidiasis and angular cheilitis

Sharon V, Fazel N. Dermatol Ther 2010; 23: 230–42.

Gentian violet solution may be difficult to tolerate given the side effects of purple staining, skin irritation, and occasionally mucosal ulceration.

Antimicrobial photodynamic therapy to treat chemotherapy-induced oral lesions: report of three cases

Rocha BA, Filho MRM, Simoes A. Photodiagnosis Photodyn Ther 2016; 13: 350–2.

A case of angular cheilitis nonresponsive to nystatin alone responded within 48 hours to nystatin and miconazole 2% gel four times daily, in combination with photodynamic therapy with diode laser followed 2 days later by low-level laser therapy for improved wound healing and pain control.

Antiphospholipid syndrome

Julia S. Lehman, and Mark D.P. Davis

FIG. 15.1 Livedo reticularis, characterized by reticulated violaceous changes of the skin. This is a nonspecific skin finding that may be seen in patients with antiphospholipid

Antiphospholipid syndrome (APS; Hughes syndrome) is characterized by the propensity for recurrent venous and arterial thrombosis in the presence of circulating antibodies against phospholipid-binding proteins. Diagnostic criteria for APS require that patients experience vascular thrombosis (venous or arterial) or pregnancy morbidity (e.g., three or more unexplained consecutive spontaneous abortions before the tenth week of gestation with exclusion of other causes) and harbor at least one serum antiphospholipid (aPL) antibody (i.e., lupus anticoagulant, anticardiolipin, anti- β_2 -glycoprotein 1) on two or more occasions over a 12-week period. It is important that patients not be diagnosed with APS based on isolated laboratory test abnormalities, as no laboratory test for APS is entirely specific.

Although cutaneous manifestations of APS are not part of the diagnostic criteria, they may represent the initial presentation of APS. Cutaneous signs result from thromboocclusion of the cutaneous vasculature and may include livedo reticularis or racemosa, livedoid vasculopathy (atrophie blanche), superficial thrombophlebitis, or ulceration. Patients with Sneddon syndrome, a condition characterized by cerebrovascular disease in patients with livedo reticularis, may have persistently positive serum aPL. Whether Sneddon syndrome represents a subset of APS is controversial.

Management Strategy

In some cases, APS may represent a primary condition. However, a search for underlying causes or other contributing factors, such as infection, prothrombotic medications (such as oral contraceptives), primary hematologic coagulopathies (e.g., factor V Leiden, prothrombin G20210A gene mutation), and connective tissue diseases (e.g., systemic lupus erythematosus [SLE]), is warranted. Patients should be offered subspecialty referral where available.

Because patients with APS are at increased risk for recurrent thromboembolism, the goal of therapy is thromboprophylaxis. Nonpharmacologic interventions include reduction of other prothrombotic risk factors, such as prolonged immobility and oral contraceptive use. Pharmaceutical interventions should be guided by the patient's age and comorbidities, pregnancy status, presence of

correctable prothrombotic factors, and coagulation history. In patients with persistently elevated aPL antibodies but no history of thrombosis (thereby not meeting strict criteria for APS), *aspirin* has **not** been shown to be effective in preventing future thromboembolic events. In patients with definitive APS and a history of venous thromboembolism, the mainstay of treatment is long-term *warfarin* therapy. The optimal duration of warfarin therapy has not been established. Based on limited available data, indefinite treatment with warfarin appears to be associated with reduced rates of recurrent thromboembolism without an elevated risk for hemorrhagic complications, compared with treatment discontinuation after 6 months. Decisions regarding termination of warfarin therapy should be individualized. Long-term *heparin* use is discouraged because of the risk of heparin-induced osteopenia. Early reports of oral direct thrombin inhibitors (dabigatran) and factor Xa inhibitors (rivaroxaban, apixaban, edoxaban) are inconclusive; randomized clinical trials are ongoing.

Inferior vena cava filters may be required in patients with recurrent venous thromboembolism to prevent pulmonary embolism.

In patients with APS who have experienced arterial thromboembolism or have developed recurrent thrombosis despite achieving target international normalized ratio (INR) on warfarin, other treatment options must be pursued. These modalities, such as *rituximab*, *intravenous immunoglobulin*, and *plasmapheresis*, address circulating pathogenic antibodies directly rather than the resultant coagulopathy.

In patients with SLE and APS, *hydroxychloroquine* has been shown to reduce aPL antibody levels and to have intrinsic anticoagulative properties. Potential future APS therapies may include *mTOR inhibitors*, *factor Xa inhibitors*, *oral direct thrombin inhibitors*, and *statins*. Correction of reversible prothrombotic factors, such as oral contraceptive use and smoking, is advisable.

Warfarin is contraindicated in pregnancy, a particularly high-risk state for patients with APS. Women with APS should be treated with aspirin before conception, with the introduction of low-molecular-weight heparin thereafter.

In acute thrombosis, monitored intravenous *unfractionated heparin* or subcutaneous *low-molecular-weight heparin*, with or without subsequent initiation of *warfarin*, is standard therapy. Thrombolytic medications (e.g., *streptokinase*, *tissue plasminogen activator* [tPA]) or

percutaneous or surgical interventions may be necessary in life- or limb-threatening thrombotic events. Catastrophic antiphospholipid syndrome (CAPS), the development of widespread thromboses with end-organ damage, requires intensive multidisciplinary interventions to halt disease progression and to reverse end-organ damage. *Plasma exchange* may have a role in the treatment of CAPS.

Specific Investigations

- Inquiry into history of thromboembolism, pregnancy morbidity, and medication use
- aPL antibodies (i.e., lupus anticoagulant, anticardiolipin IgG and IgM antibodies, anti- β_2 -glycoprotein 1 antibodies)
- Coagulopathy screen (i.e., INR, partial thromboplastin time [PTT], protein C, protein S, antithrombin III, prothrombin G20210A gene mutation, antiprothrombin antibodies, factor V Leiden, homocysteine level)
- Screening for underlying disease state (hematology, fasting blood glucose, fasting lipids, connective tissue serology, HIV testing, hepatitis serology) and other prothrombotic risk factors

International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS)

Miyakis S, Lockshin MD, Atsumi T, Branch DW, Brey RL, Cervera R, et al. *J Thromb Haemost* 2006; 4: 295–306.

Consensus guidelines require a history of thromboembolism and documentation of elevated aPL antibodies on at least two occasions separated by at least 12 weeks for definitive diagnosis of APS.

Controversies and unresolved issues in antiphospholipid syndrome pathogenesis and management

Baker WF Jr, Bick RL, Fareed J. *Hematol Oncol Clin North Am* 2008; 22: 155–74.

Thorough investigation into underlying (and potentially correctable) conditions is recommended.

First-Line Therapies

• Observation (persistent aPL elevation but no thromboembolic events)	A
• Long-term warfarin, target INR 2.0 to 3.0	A
• Correction of reversible prothrombotic factors	B
• Long-term warfarin, target INR >3.0 (recurrent or arterial thrombosis)	B
• Low-molecular-weight heparin and low-dose aspirin (pregnancy)	B
• Heparin followed by warfarin (acute thrombosis)	C
• Hydroxychloroquine with low-dose aspirin (SLE)	D
• Thrombolytic therapy or percutaneous/surgical intervention (critical thrombosis)	E
• Reduction of prothrombotic risk factors, such as prolonged immobilization	E

Aspirin for primary thrombosis prevention in the antiphospholipid syndrome

Erkan D, Harrison MJ, Levy R, Peterson M, Petri M, Sammaritano L. *Arthritis Rheum* 2007; 56: 2382–91.

A randomized, double-blind, placebo-controlled trial of aspirin versus placebo in asymptomatic patients with persistently positive aPL antibodies found no benefit of aspirin in primary thromboprophylaxis.

A comparison of two intensities of warfarin for the prevention of recurrent thrombosis in patients with the antiphospholipid syndrome

Crowther MA, Ginsberg JS, Julian J, Denburg J, Hirsch J, Douketis J, et al. *N Engl J Med* 2003; 349: 113–8.

A randomized clinical trial of high-intensity warfarin vs. conventional antithrombotic therapy for the prevention of recurrent thrombosis in patients with the antiphospholipid syndrome

Finazzi G, Marchioli R, Brancaccio V, Schinco P, Wisloff F, Musial J, et al. *Thromb Haemost* 2005; 3: 848–53.

These two randomized, double-blind trials comparing high-intensity warfarin (target INR 3.0–4.0) and moderate-intensity warfarin (target INR 2.0–3.0) in patients with APS found no significant difference in preventing secondary thrombosis between

the two treatment regimens.

A systematic review of secondary thromboprophylaxis in patients with antiphospholipid antibodies

Ruiz-Irastorza G, Hunt BJ, Khamashta MA. *Arthritis Rheum* 2007; 57: 1487–95.

In several cohort studies of patients with APS, INR at the time of recurrent thromboembolism on warfarin was <3.0 in 86%. The authors propose that the target INR should be >3.0 in patients with recurrent or arterial thrombosis.

Treatment of antiphospholipid antibody syndrome (APS) in pregnancy: a randomized pilot trial comparing low-molecular-weight heparin to unfractionated heparin

Stephenson MD, Ballen PJ, Tsang P, Purkiss S, Ensworth S, Houlihan E, et al. *J Obstet Gynaecol Can* 2004; 26: 729–34.

In a randomized trial, 28 women with APS received low-dose aspirin and either low-molecular-weight heparin or unfractionated heparin before conception or early in pregnancy. Pregnancy was successful in 9 of 13 (69%) women treated with low-molecular-weight heparin and low-dose aspirin and in 4 of 13 (31%) women treated with unfractionated heparin and low-dose aspirin.

In addition, the obstetrics literature tends to favor low-molecular-weight over unfractionated heparin because of its superior safety profile.

Second-Line Therapies

• Long-term low-molecular-weight heparin (recurrent thrombosis)	D
• Rituximab (SLE)	D
• Hydroxychloroquine (SLE)	E
• Intravenous immunoglobulin (IVIG) (in pregnancy)	E

Rituximab usage in systemic lupus erythematosus-associated antiphospholipid antibody syndrome: a single-center experience

Wang CR, Liu MF. *Semin Arthritis Rheum* 2016; 46(1): 102-8.

A series of six patients with APS treated with rituximab suffered no

relapse of thrombosis with a mean follow-up period of over 3 years.

Evidence-based management of thrombosis in the antiphospholipid antibody syndrome

Petri M. Curr Rheum Rep 2003; 5: 370–3.

Hydroxychloroquine appears to reduce aPL antibody titers and the risk for recurrent thrombosis in patients with SLE.

An excellent evidence-based review of APS treatments.

A multicenter, placebo-controlled pilot study of intravenous immune globulin (IVIG) treatment of antiphospholipid syndrome during pregnancy

Branch DW, Peaceman AM, Druzin M, Silver RK, El-Sayed Y, Silver RM. Gen Obstet Gynecol 2000; 182: 122–7.

In this pilot study of 16 pregnant women with APS, patients were randomized to receive IVIG or placebo. All patients also received heparin and low-dose aspirin. A trend toward decreased fetal growth restriction was observed in the IVIG group compared with the placebo group, but differences were not statistically significant.

Intravenous immunoglobulins and antiphospholipid syndrome: how, when and why? A review of the literature

Tenti S, Cheleschi S, Guidelli GM, Galeazzi M, Fioravanti A. Autoimmun Rev 2016; 15: 226–35.

Results of this literature analysis indicate that the addition of IVIG to low-dose aspirin and low-molecular-weight heparin in the setting of obstetric APS is controversial.

Third-Line Therapies

• Plasma exchange (pregnancy)	D
• Placement of inferior vena cava (IVC) filter (medically refractory, recurrent venous thromboses)	D
• Statins (recurrent venous thromboses)	E
• IVIG (recurrent venous thromboses)	E
• Sirolimus (APS-related arterial vasculopathy)	E

Plasma exchange in the management of high risk pregnant patients with primary antiphospholipid syndrome. A report of 9

cases and a review of the literature

Ruffatti A, Marson P, Pengo V, Favaro M, Tonello M, Boralati M, et al. *Autoimmunity Rev* 2007; 6: 196–202.

Nine patients with APS and triple-positive aPL antibodies were treated with plasma exchange for secondary prophylaxis during pregnancy. The authors found that combined plasma exchange and IVIG therapy contributed to favorable pregnancy outcomes in high-risk patients.

Insertion of inferior vena cava filters in patients with the antiphospholipid syndrome

Zifman E, Rotman-Pikielny P, Berlin T, Levy Y. *Semin Arthritis Rheum* 2009; 38: 472–7.

Ten patients with APS who experienced recurrent thrombosis despite warfarin therapy received IVC filters. One patient had a documented pulmonary embolus (PE) after intervention, and two died suddenly of unknown causes (PE could not be excluded). The authors state that the results were suggestive of a protective effect of IVC filters in refractory APS.

A prospective open-label pilot study of fluvastatin on proinflammatory and prothrombotic biomarkers in antiphospholipid antibody positive patients

Erkan D, Willis R, Murthy VL, Bastra G, Vega J, Ruiz-Limon P, et al. *Ann Rheum Dis* 2014; 73: 1176–80.

This study showed that daily use of fluvastatin significantly reduced levels of proinflammatory and prothrombotic biomarkers in patients with positive aPL.

Though some small reports demonstrate benefit of IVIG when used as an additive therapy for secondary prophylaxis, large, well-designed studies are lacking.

The NF- κ B specific inhibitor DHMEQ prevents thrombus formation in a mouse model of antiphospholipid syndrome

Nishimura M, Nii T, Trimova G, Miura S, Umezawak K, Ushiyama A, et al. *J Nephropathology* 2013; 2: 114–21.

Catastrophic Antiphospholipid Syndrome

• Anticoagulation, systemic corticosteroids, and plasmapheresis or IVIG	D
• Eculizumab	E

Catastrophic antiphospholipid syndrome (CAPS): proposed guidelines for diagnosis and treatment

Asherson RA, Espinosa G, Cervera R, Font J, Carles Reverter J. J Clin Rheumatol 2002; 8: 157–65.

Based on experience from 130 cumulative cases of CAPS, the authors recommend heparin, systemic corticosteroids, and plasmapheresis in the treatment of CAPS.

Catastrophic antiphospholipid syndrome presenting with multiorgan failure and gangrenous lesions of the skin

Incalzi RA, Gemma A, Moro L, Antonelli M. Angiology 2008; 59: 517–8.

A 38-year-old woman with CAPS triggered by abrupt withdrawal of systemic corticosteroids recovered completely after treatment with immunosuppressive and antibiotic treatment combined with plasmapheresis.

Brief report: induction of sustained remission in recurrent catastrophic antiphospholipid syndrome via inhibition of terminal complement with eculizumab

Shapira I, Andrade D, Allen SL, Salmon JE. Arthritis Rheum 2012; 64: 2719–23.

First report of eculizumab's efficacy in CAPS. Larger studies are ongoing.

Aphthous stomatitis

Maryam Liaqat, and Justin J. Green

Recurrent aphthous stomatitis (RAS) is the most common cause of oral ulceration, affecting 5% to 25% of the population. It is characterized by the recurrence of one or more painful, shallow, sharply margined ulcerations with a fibrinous base and surrounding erythematous halo on mobile oral mucosa. Three main

types include minor, major, and herpetiform aphthae, which differ in size, duration, number, potential for scarring, and location of ulcerations. The etiology remains unclear; however, genetic predisposition (with at least 40% of patients having a positive family history), nutritional deficiencies, infections, hormonal alterations, immunodeficiency, and environmental agents have been implicated. It is important to differentiate aphthae from other causes of mucosal ulcers. The differential diagnosis would include viral and bacterial infections (herpes simplex virus [HSV], Epstein-Barr virus, cytomegalovirus, varicella zoster virus, Coxsackie virus, syphilis, gonorrhea, tuberculosis), erythema multiforme, lichen planus, autoimmune bullous diseases (pemphigus vulgaris and cicatricial pemphigoid), contact dermatitis, chronic ulcerative stomatitis, and trauma. Malignancy and systemic vasculitis must also be considered in lesions that are not self-resolving.

Management Strategy

The therapeutic approach to aphthae is dependent on the frequency of recurrence, duration, and severity of symptoms. In addition, underlying hematologic abnormalities, nutritional deficiencies, and medications should be considered as causative agents, as well as systemic disorders such as Crohns disease, Behcet disease, mouth and genital ulcers with inflamed cartilage syndrome (MAGIC syndrome), cyclic neutropenia, Sweet syndrome, reactive arthritis, HIV infection, and autoinflammatory syndromes such as periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis syndrome (PFAPA syndrome). Stress is also thought to play a role in exacerbation of the disease. Unfortunately, because there is no curative treatment to date, the emphasis of treatment is on measures that may afford symptomatic relief and decrease occurrence, without causing significant adverse effects.

Topical corticosteroids are the mainstay of therapy. For milder disease, corticosteroids such as *fluocinonide* can be used. Superpotent corticosteroids such as *clobetasol* or *halobetasol* are appropriate for more severe episodes. Most practitioners suggest the use of topical therapy after meals. These can be applied in equal parts with an occlusive agents such as *Orabase* for better adherence. Drug delivery can be enhanced by cotton-tip applications for 30 seconds and avoidance of eating and drinking for 30 minutes after application.

Initial concentrations of 3 to 10 mg/mL of *intralesional triamcinolone acetonide* are helpful for major aphthae. Repeat injections over 2- to 4-week intervals are suggested. *Dexamethasone elixir* 0.5 mg/5 mL three times daily used as a mouthwash or *beclomethasone dipropionate* aerosol spray can target ulcers on the soft palate or oropharynx. Elixirs can be combined with *sucralfate* or *Kaopectate* to improve adhesion to ulceration. When used for less than 3 weeks, systemic absorption and hypothalamic–pituitary–adrenal axis suppression are unlikely.

RAS that elicits severe pain may require intermittent *systemic corticosteroid therapy*. Prednisone 1 mg/kg (40–60 mg) daily can be given with a 2-week taper or as “burst therapy” for shorter periods. Concomitant therapy with topical corticosteroids may be helpful. *Thalidomide* 50 to 200 mg daily is the most effective steroid-sparing agent. It is also the only Food and Drug Administration (FDA)–approved treatment for major aphthae in HIV-positive patients. *Dapsone* 100 mg daily, *pentoxifylline* 400 mg three times daily, and *clofazimine* 100 mg daily may also lead to suppression of aphthae. Oral *rofecoxib* 50 mg on the first day and 25 to 50 mg per day on the following days or oral *tinidazole* 1 g per day may have some benefit. *Antitumor necrosis factor (TNF)- α* therapies may be effective in recalcitrant cases. Those patients who require suppressive therapy but cannot tolerate the side effects of systemic agents can try medications such as *topical cyclosporine* rinse 500 mg/5 mL three times daily, or *interferon- α_{2a}* 1200 IU daily as a 1-minute rinse and swallow.

Application of *amlexanox* 5% *paste* four times daily has been shown to reduce aphthous ulcer healing time, and the application of amlexanox OraDisc four times daily to prodromal areas of the buccal mucosa has shown promise in the prevention of recurrent minor aphthous ulceration.

Lidocaine gel or spray, *dyclonine*, diphenhydramine (12.5/5 mL), or *benzocaine* are helpful for pain reduction. Patients must avoid desensitization of the entire oral vault, which may lead to self-induced trauma. A compounded *anesthetic mouthwash* (aluminum hydroxide–magnesium hydroxide, diphenhydramine, and lidocaine) has better mucosal adherence. Systemic *nonsteroidal antiinflammatory drugs (NSAIDs)*, *sucralfate suspension*, 0.2% *chlorhexidine gluconate* mouthwash, triclosan, or *tetracycline* suspension (250 mg/5 mL) may provide pain relief and reduce healing time, although these are less effective than potent topical corticosteroids. Bioadhesives such as

carboxymethylcellulose provide a protective film and may reduce healing time. Use of laser therapies, including CO₂ laser, Nd:YAG, and low-level light therapies in recurrent aphthous stomatitis, has also been shown to improve symptoms caused by consumption of food, beverages, and brushing of teeth.

Trigger avoidance can be useful. Predisposing factors include food (nuts, chocolate, tomatoes, citrus fruits, and spices), alcohol and carbonated beverages, trauma, menstruation, and stress. A *food diary* may be of value in identifying an offending agent. Certain medications, such as β -blockers, NSAIDs, and antioxidants, as well as sensitivity to sodium lauryl sulfate found in toothpaste, may contribute to the recurrence of aphthae. *Hormonal therapy* may alleviate RAS associated with menstruation. *Reassurance* of the benignity of this condition is paramount, and *relaxation techniques* or *biofeedback* can be discussed if stress is found to be a significant trigger.

Specific Investigations

- Complete blood count
- Vitamins B₁, B₂, B₆, and B₁₂; folate, zinc, and iron levels
- Culture/polymerase chain reaction of aphthae to exclude HSV
- Consider HIV testing

Aphthous ulcers

Messadi DV, Younai F. *Dermatol Ther* 2010; 23: 281–90.

Review article containing the summary of possible etiologies and clinical presentations of aphthae, differential diagnosis, and treatment options.

Oral mucosal disease: recurrent aphthous stomatitis

Scully C, Porter S. *Br J Oral Maxillofac Surg* 2008; 46: 198–206.

Review article highlighting possible etiologies and differential diagnosis of RAS. This article recommends checking complete blood count, folate, iron studies, and B₁₂, as well as excluding infections or systemic diseases that may include aphthae-like ulcerations, namely Behçet disease and HSV.

Haematological deficiencies in patients with recurrent aphthosis

Compilato D, Carroccio A, Calvino F, Di Fede G, Campisi G. J Eur Acad Dermatol Venerol 2010; 24: 667–73.

Thirty-two patients with RAS and 29 healthy controls were subjected to hematologic investigations. Deficiencies were noted in 56.2% of RAS patients and in 7% of controls. All patients with a negative family history of RAS showed complete remission after replacement therapy, whereas patients with a family history of RAS showed reduction in frequency and severity. The authors recommended that routine screening for serum iron, folic acid, and vitamin B₁₂ deficiencies should be performed.

First-Line Therapies

• Vitamin and mineral deficiency replacement	A
• Topical corticosteroids	A
• Amlexanox 5% paste	A
• Intralesional corticosteroids	B
• Tetracycline suspension	A
• Antimicrobial mouth rinses	A
• Sucralfate	A
• Hydroxypropyl cellulose/carboxymethylcellulose	C
• Herbal supplements	D

Urban legends: recurrent aphthous stomatitis

Baccaglini L, Lalla RV, Bruce AJ, Sartori-Valinotti JC, Latortue MC, Carrozzo M, et al. Oral Dis 2011; 17: 755–70.

Review article examining several myths about aphthous ulcerations, with specific emphasis of literature review of treatments in the last 6 years. The authors concluded that low-dose topical tetracyclines and amlexanox showed possible benefit.

Topical corticosteroids in recurrent aphthous stomatitis.

Systematic review

Quijano D, Rodriguez M. Acta Otorhinolaringol Esp 2008; 59: 298–307.

This is a systematic review of published literature evaluating the effectiveness of topical corticosteroids in treating RAS. The authors were able to show a trend toward reduced healing times and decreased pain but commented on the lack of high-quality experiments in the literature.

Efficacy and safety of dexamethasone ointment on recurrent aphthous ulceration

Lui C, Zhou Z, Lui G, Wang Q, Chen J, Wang L, et al. Am J Med 2012; 125: 292–301.

This study is a randomized, double-blind, placebo-controlled, parallel, multicenter clinical trial which showed that dexamethasone 0.1% ointment three times a day for 5 days safely reduced the size and duration of aphthae compared with placebo.

Amlexanox for the treatment of recurrent aphthous ulcers

Bell J. Clin Drug Investig 2005; 25: 555–6.

A review of four double-blind randomized controlled trials (RCTs) indicating that amlexanox 5% paste up to four times per day significantly reduced ulcer size compared with placebo.

Double-blind trial of tetracycline in recurrent aphthous ulceration

Graykowski EA, Kingman A. J Oral Pathol 1978; 7: 376–82.

A suspension of tetracycline 250 mg/5 mL was used four times daily in patients with RAS. The suspension was held in the mouth for 2 minutes and then swallowed. This study found that tetracycline therapy significantly reduced ulcer duration, size, and pain, but did not alter the recurrence rate.

Other studies using tetracycline or its derivatives (topically or orally) have drawn similar conclusions.

Chlorhexidine gluconate mouthwash in the management of minor aphthous ulceration: a double-blind, placebo-controlled cross-over trial

Hunter L, Addy M. Br Dent J 1987; 162: 106–10.

This crossover study included 38 patients who used 0.2% chlorhexidine gluconate mouthwash three times daily for 6 weeks.

The total number of days with ulcers was significantly reduced, and the interval between successive ulcers was increased.

Gel and mouthwash formulations of 0.1% chlorhexidine have also been efficacious. Chlorhexidine mouthwash can stain teeth.

Effect of an antimicrobial mouth rinse on recurrent aphthous ulcerations

Meiller TF, Kutcher MJ, Overholser CD, Niehaus C, DePaola LG, Siegel MA. Oral Surg Oral Med Oral Pathol 1991; 72: 425–9.

A 6-month double-blind study compared Listerine antiseptic and a hydroalcoholic control used as a vigorous mouthwash twice daily. The duration of ulcers and pain severity were significantly reduced in the Listerine group. Both the Listerine group and the control group experienced a reduced incidence of ulcers.

Mouth rinses containing triclosan reduce the incidence of recurrent aphthous ulcers (RAU)

Skaare AB, Herlofson BB, Barkvoll P. J Clin Periodontol 1996; 23: 778–81.

In a double-blind crossover study, 0.15% triclosan mouthwash caused a significant reduction in the number of ulcers during the experimental period. Compared with the 7.8% ethanol and triclosan formulation, the efficacy of the mouthwashes was reduced when propylene glycol or a higher concentration of ethanol (15.6%) was used as a solubilizing agent.

Sucralfate suspension as a treatment of recurrent aphthous stomatitis

Rattan J, Schneider M, Arber N, Gorsky M, Dayan D. J Intern Med 1994; 236: 341–3.

Sucralfate applied four times daily to ulcers was found to be superior to antacid (aluminum hydroxide and magnesium hydroxide) and placebo with regard to duration of pain, reduction in healing time, response to first treatment, and duration of remission. The 2-year prospective, randomized, double-blind, placebo-controlled, crossover trial included 21 patients unresponsive to conventional therapy.

A randomized, placebo-controlled, double-blind study of sucralfate applied four times daily to oral and genital ulcerations of Behçet disease resulted in reduced frequency, healing time, and pain in oral ulcerations, and reduced

healing time and pain in genital ulcers.

Performance of a hydroxypropyl cellulose film former in normal and ulcerated mucosa

Rodu B, Russell CM. Oral Surg Oral Med Oral Pathol 1988; 65: 699–703.

Zilactin, which contains hydroxypropyl cellulose, led to pain relief after an acidic challenge followed by rechallenge.

Orabase, which contains carboxymethylcellulose, has been beneficial in trials when combined with topical corticosteroids, possibly due to its adhesive properties.

Efficacy and safety of topical herbal medicine treatment on recurrent aphthous stomatitis: a systemic review

Li CL, Huang HL, Wang WC, Li CL. Drug Des Devel Ther 2015; 10: 107–15.

Nine electronic databases in English and Chinese were evaluated for RCT, and clinical controlled trials were searched and narrowed to 13 trials with a total of 1515 patients included in the analysis. The authors concluded there is some benefit with regard to previously established RAS outcomes with fewer side effects. No single supplement recommendations were made by the authors.

Second-Line Therapies

• Oral corticosteroids	A
• Colchicine	A
• Thalidomide	A
• Dapsone	A
• Zinc sulfate	A
• Low-level laser therapy	B
• Omega 3	B

Systemic interventions for recurrent aphthous stomatitis

Brocklehurst P, Tickle M, Glenny AM, Lewis MA, Pemberton MN, Taylor J, et al. Cochrane Database Syst Rev 2012, 9: CD005411.

Review article in which a total of 25 trials were included, 22 of which were placebo controlled and 8 made head-to-head comparisons with a total of 21 interventions that were reviewed. These included immunomodulators including clofazimine, colchicine, prednisone vs. uncertain category including homeopathy, tetracycline, vitamin B₁₂, and propolis. The main conclusions were that no single treatment was found to be effective; therefore no recommendations regarding best systemic intervention for RAS were made. The reviewers' primary concern was the methodologic rigor of the trials and high risk of bias.

Systemic treatment in severe cases of recurrent aphthous stomatitis: an open trial

Mimura MA, Hirota SK, Sugaya NN, Sanches JA Jr, Migliari DA. Clinics 2009; 64: 193–8.

An open, 4-year clinical trial of 21 patients with RAS treated with

thalidomide (100 mg/day), dapsone (100 mg/day), colchicine (1.5 mg/day), and pentoxifylline (400 mg three times a day). Thalidomide was the most efficient and well tolerated. Dapsone and colchicine provided good results; however, dapsone was not well tolerated. Pentoxifylline was mildly effective.

Comparison of colchicine versus prednisolone in recurrent aphthous stomatitis: a double-blind randomized clinical trial

Pakfetrat A, Mansourian A, Momen-Heravi F, Delavarian Z, Momen-Beitollahi J, Khalilzadeh O, et al. Clin Invest Med 2010; 33: E189–95.

In this double-blind RCT, 34 patients with RAS were split into two groups: prednisolone 5 mg daily or colchicine 0.5 mg daily for 3 months. Both medications were equally effective in reducing pain, recurrence, size, and number of aphthae, although colchicine had a higher rate of side effects.

Clinical, historic, and therapeutic features of aphthous stomatitis: literature review and open trial employing steroids

Vincent SD, Lilly GE. Oral Surg Oral Med Oral Pathol 1992; 74: 79–86.

“Burst therapy” with prednisone 40 mg once daily for 5 days, followed by 20 mg every other day for 1 week, in addition to topical triamcinolone acetonide 0.1% or 0.2% four times daily, led to complete or partial control of aphthae in 12 of 13 patients.

Effects of colchicine treatment on mean platelet volume and the inflammatory markers in recurrent aphthous stomatitis

Seçkin HY, Bütün I, Baş Y, Takcı Z, Kalkan G. J Dermatolog Treat 2016; 1–3.

RAS is associated with increased inflammatory markers. Fifteen male and 45 female RAS patients who were taking colchicine were investigated retrospectively. The whole blood parameters of the patients were observed before starting colchicine treatment and in the third month of colchicine treatment. It was determined that colchicine lowers the levels of neutrophil–lymphocyte ratio (NLR), white blood cell count, and red cell distribution width (RDW). Furthermore, no changes were seen on mean platelet volume, platelet–lymphocyte ratio, and hemoglobin.

Thalidomide for the treatment of oral aphthous ulcers in patients with human immunodeficiency virus infection

Jacobson JM, Greenspan JS, Spritzler J, Ketter N, Fahey JL, Jackson JB, et al. National Institute of Allergy and Infectious Diseases AIDS Clinical Trials Group. *N Engl J Med* 1997; 336: 1487–93.

Fifty-seven HIV-positive patients were included in this double-blind, randomized, placebo-controlled study of thalidomide 200 mg daily versus placebo as therapy for oral aphthous ulcers in HIV-infected patients. Sixteen of 29 patients in the thalidomide group (55%) had complete healing of their aphthous ulcers after 4 weeks, compared with only 2 of 28 patients in the placebo group (7%).

Refractory aphthous ulceration treated with thalidomide: a report of 10 years' clinical experience

Cheng S, Murphy R. *Clin Exp Dermatol* 2012; 37: 132–5.

Retrospective review of 15 patients treated with thalidomide after failing topical and oral steroids. Out of 15 patients, 14 showed improvement with thalidomide; however, 9 patients showed a decline in their nerve conduction study, independent of dose. Despite these findings only three patients stopped the medication, and the patient with the largest decline in nerve conduction (80%) opted to continue thalidomide rather than risk recurrence of the ulcers.

The therapeutic and prophylactic role of oral zinc sulfate in management of recurrent aphthous stomatitis (RAS) in comparison with dapsone

Sharquie KE, Najim RA, Al-Hayani RK, Al-Nuaimy AA, Maroof DM. *Saudi Med J* 2008; 29: 734–8.

In this double-blind placebo-controlled study of 45 patients with RAS, patients were treated with zinc sulfate 150 mg twice daily, dapsone 50 mg twice daily, and glucose 250 mg daily as placebo. Results showed that both zinc sulfate and dapsone had significant therapeutic effects in decreasing ulcer size. They concluded that zinc sulfate had much more rapid and sustained action.

Recurrent aphthous stomatitis and pain management with low-level laser therapy: a randomized controlled trial

Albrektson M, Hedstrom L, Bergh H. *Oral Surg Oral Med Oral Pathol Oral Radiol* 2014; 117: 590–4.

This study is a randomized, single-blinded, placebo-controlled trial conducted with low-level laser therapy (wavelength, 809 nm; power, 60 mW; pulse frequency, 1800 Hz; duration, 80 seconds per treatment;

dose, 6.3 J/cm²) in 40 patients with RAS. Improvement was assessed with visual analog scale (VAS) and patients' experience of eating, drinking, and brushing teeth. Compared with placebo there was a statistically significant decrease in VAS score, as well as the other symptoms noted.

Efficacy of omega-3 in treatment of recurrent aphthous stomatitis and improvement of quality of life: a randomized, double-blind, placebo-controlled study

El Khouli AM, El-Gendy EA. Oral Surg Oral Med Oral Pathol Oral Radiol Endod 2014; 117: 191–6.

A parallel-design, double-blind, placebo-controlled study was conducted on 50 participants divided into treatment to receive omega-3 (1 g three times daily) and control group for 6 months. Results indicated a significant reduction in the number of ulcer outbreaks, the average level of pain, and the duration of ulcer episodes per month starting in the third month of treatment.

Third-Line Therapies

• Pentoxifylline	A
• Clofazimine	B
• Ascorbate (Vitamin C)	C
• Vitamin B ₁₂	A
• Topical cyclosporine	D
• Oral interferon- α_{2a}	C
• CO ₂ laser	D
• Penicillin G potassium troches	A
• TNF- α inhibitors	D
• Silver nitrate	B
• Montelukast	A

A randomized, double-blind, placebo-controlled trial of pentoxifylline for the treatment of recurrent aphthous stomatitis

Thornhill MH, Baccaglini L, Theaker E, Pemberton MN. Arch Dermatol 2007; 143: 463–70.

Twenty-six patients were randomized to pentoxifylline 400 mg three times daily or placebo. Patients taking pentoxifylline had less pain, smaller ulcers, fewer ulcers, and more ulcer-free days, but this was not statistically significant. However, smaller median ulcer size in the treatment group was statistically significant. Adverse events were common and included dizziness, headaches, gastrointestinal symptoms, and fatigue.

According to the study, patients taking the active drug stated that if it was shown to be effective in the treatment of aphthous ulcers, they would not want to use it because of the side effects.

Topical cyclosporine for oral mucosal disorders

Eisen D, Ellis CN. J Am Acad Dermatol 1990; 23: 1259–64.

Four of eight patients with severe aphthous stomatitis obtained nearly complete suppression of ulcers during an 8-week course of topical cyclosporine 500 mg/5 mL, swish and rinse three times daily.

Chronic recurrent aphthous stomatitis: oral treatment with low-dose interferon alpha

Hutchinson VA, Angenend JL, Mok WL, Cummins JM, Richards AB. Mol Biother 1990; 2: 160–4.

Oral administration of interferon- α_2 (1200 IU daily) resulted in remissions of aphthae within 2 weeks of initiating therapy compared with no improvement in the placebo group. The placebo group was then treated similarly with interferon- α_2 leading to complete remission of their aphthae.

Managing aphthous ulcers: laser treatment applied

Colvard M, Kuo P. J Am Dent Assoc 1991; 122: 51–3.

Pain alleviation was observed in 16 of 18 patients after CO₂ laser therapy of minor aphthae.

Evaluation of penicillin G potassium troches in the treatment of minor recurrent aphthous ulceration in a Chinese cohort: a randomized, double-blinded, placebo and no-treatment-controlled, multicenter clinical trial

Zhou Y, Chen Q, Meng W, Jiang L, Wang Z, Liu J, et al. Oral Surg Oral Med Oral Radiol Endod 2010; 109: 561–6.

A randomized double-blinded control trial in 258 nonpenicillin-allergic Chinese patients was performed with subjects split between placebo, treatment, and no-treatment groups. Patients treated with penicillin G potassium troches showed significant objective decreased ulcer size and subjective decrease in pain.

Efficacy and safety of TNF- α inhibitors in refractory primary complex aphthosis: a patient series and overview of the

literature

Sand FL, Thomsen SF. J Dermatolog Treat 2013; 24: 444–6.

In this case series, a total of 18 patients were treated with etanercept, adalimumab, infliximab, or golimumab for frequent recurrent oral and genital aphthae or continuous aphthous stomatitis. Of these patients, 16 had complete or almost clearance of the aphthosis, whereas 5 had adverse reactions.

Treatment of recurrent aphthous stomatitis with clofazimine

de Abrue MA, Hirata CH, Pimentel DR, Weckx LL. Oral Surg Oral Med Oral Pathol Radiol Endod 2009; 108: 714–21.

In this randomized controlled partially blinded study, clofazimine (100 mg daily for 30 days, then 100 mg every other day) and colchicine (0.5 mg three times a day) were investigated for 6 months in the treatment of RAS. Patients taking clofazimine showed significant improvement to colchicine at the second, third, fifth, and sixth months of therapy.

The effect of ascorbate on minor recurrent aphthous stomatitis

Yasui K, Kurata T, Yashiro M, Tsuge M, Ohtsuki S, Morishima T. Acta Paediatr 2010; 99: 442–5.

In this study, 16 patients with minor RAS were given daily vitamin C (2000 mg/m²) for 3 months. Treatment was then discontinued for 3 months and then restarted for another 3 months. Patients experienced a significant decrease in stomatitis during treatment months compared with months without treatment.

Effectiveness of vitamin B₁₂ in treating recurrent aphthous stomatitis: a randomized, double-blind, placebo-controlled trial

Volkov I, Rudoy I, Freud T, Sardal G, Naimer S, Peleg R, et al. J Am Board Fam Med 2009; 22: 9–16.

In this randomized, double-blind, placebo-controlled trial, 58 patients with RAS were split into treatment groups of 1000 µg of sublingual vitamin B₁₂ and placebo. No patients had baseline B₁₂ levels less than 150 pg/mL. The treatment group had significantly fewer outbreaks than the controls, regardless of baseline B₁₂ level.

Of note, there have also been several studies negating the benefits of vitamin replacement in the literature.

Silver nitrate cautery in aphthous stomatitis: a randomized controlled trial

Alidaee MR, Taheri A, Mansoori P, Ghodsi SZ. Br J Dermatol 2005; 153: 521–5.

Ninety-seven patients with painful minor aphthae were randomized to receive one stick application of silver nitrate cautery or placebo. After 1 day, a statistically significant reduction in severity of pain was shown. Silver nitrate did not prolong or shorten healing time examined after 7 days. No side effects were noted.

The authors note that the treatment is simple and cost effective for patients, with few recurrences.

Pilot study on recurrent aphthous stomatitis (RAS): a randomized placebo-controlled trial for the comparative therapeutic effects of systemic prednisone and systemic montelukast in subjects unresponsive to topical therapy

Femiano F, Buonaiuto C, Gombos F, Lanza A, Cirillo N. Oral Surg Oral Med Oral Pathol Oral Radiol Endod 2010; 109: 402–7.

In this double-blind, randomized, placebo-controlled trial of 60 patients with minor RAS, patients were split equally into treatment groups of prednisone 25 mg daily tapered over 2 months, 10 mg montelukast daily for 1 month, then every other day for the second month, and cellulose (placebo). Both interventions significantly reduced number of lesions and pain relief compared with placebo; however, prednisone was more effective than montelukast. This suggests montelukast may be a safer alternative to prednisone.

Atopic dermatitis

Jeremy Udkoff, and Lawrence F. Eichenfield

Atopic dermatitis (AD) is a chronic, relapsing, and intensely pruritic dermatosis that develops most commonly during early infancy and childhood and is, in most cases, associated with a personal or family history of atopy (allergic rhinitis, asthma, or eczema). It is frequently associated with abnormalities in skin barrier function and immune dysregulation. Skin involvement ranges from acute weeping and crusted areas of eczema to papular lesions or lichenified plaques.

Management Strategy

Successful AD therapy considers the patient's age and needs, the extent and localization of AD at presentation, and the overall disease course. Other factors to consider include previous response to treatment, disease persistence, frequency of flares, and susceptibility to and past history of infection (especially those due to *Staphylococcus aureus* and herpes simplex virus). The goals of management are to educate patients and caregivers about the disease, promote excellent skin care, reduce the degree and frequency of flares, monitor medication quality/quantity of use, and, if possible, modify the overall disease course and the atopic march.

Interventional education

Education concerning chronic disease management is a core part of therapy. Learning modalities beyond in-office disease education may be useful, including handouts, Internet-based written material, and instructional videos. Comprehensive multispecialty “eczema clinics” offer intensive education as a distinct component of long-term AD management. This model, with its longer appointments, focused educational curricula, patient support networks, and the ability to elicit patient and family feedback, parallels strategies shown to be effective for managing asthma, diabetes, and other chronic diseases. These methods empower patients and caregivers while improving both clinical and quality-of-life outcomes. Long-term comparative evaluations are required to examine the cost-effectiveness and suitability of these educational programs. Shared decision making—where therapeutic options and the rationales for recommending them, along with weighing the risks and benefits, are discussed with patients to arrive at therapeutic strategies—is an evolving method thought to improve patient outcomes (e.g., www.eczemacenter.org; www.nationaleczema.org; www.eczema.org).

Skin care

Excellent skin care remains a cornerstone of management. Emollients improve the xerosis and skin barrier dysfunction associated with AD and may improve pruritus and spare the use of prescription antiinflammatory medications. With little evidence to recommend the

use of one emollient or moisturizer over another, patient and caregiver preference should be considered, with product selection based on the premise that “an emollient that is applied works better than one that remains on a shelf.” Very occlusive ointments may not be tolerated during the summer months or in humid climates because of interference with the function of eccrine sweat ducts and the induction of folliculitis; in these situations, a cream may be a more practical choice. It is best to avoid preparations that contain topical sensitizers such as fragrance, neomycin, benzocaine, etc. Emollients and moisturizers should be applied after any topical pharmacologic therapies to allow active medications to penetrate the skin with full effect.

The value of *bathing* and the frequency with which it should be undertaken remain controversial, though most experts believe that daily bathing with application of emollients to follow is well tolerated and may be beneficial. The chief benefits of bathing include cleansing, debridement of infected eczema, improved penetration of topical therapies, and skin hydration (when postbath emollients are used to “lock in” moisture). Potential drawbacks of bathing are drying of the skin and disruption of the stratum corneum barrier during water evaporation when emollients are not used.

Fillagrin is a structural protein found in the stratum corneum. Loss of function mutations in the fillagrin gene can lead to increased transepidermal water loss and an increased risk of developing AD, as well as asthma, allergies, and herpes simplex virus infections. Recent data regarding transepidermal water loss suggest that the frequency of application of emollients or moisturizers may be more important than timing the application to coincide strictly with bathing (the traditional “soak and seal” approach); this finding remains to be confirmed in larger, more controlled studies.

Several *barrier repair products* thought to target and correct epidermal molecular deficiencies have been approved by the U.S. Food and Drug Administration (FDA) as 510(k) medical devices. However, there are limited comparative effectiveness or safety studies of these prescription devices and specially formulated emollients against traditional emollients or moisturizers for AD management.

Wet wraps are a useful tool in the intensive treatment of severe AD and/or disease that is refractory to standard topical therapies. They may increase skin hydration, serve as an effective mechanical barrier

to scratching, and act as an occlusive layer that promotes penetration of topical corticosteroids into the skin, thereby increasing the amount of medication delivered to the most severely affected areas.

Temporary systemic bioactivity of the corticosteroids and potential hypothermia are concerns. When wet wraps are overused or used incorrectly, maceration of the skin may occur. Because of these concerns, wet wraps should only be used under close supervision of a physician.

Topical therapies

Topical corticosteroids remain the first-line therapy for inflammation and pruritus associated with AD that is unresponsive to good skin care and moisturizers. Variations in corticosteroid-prescribing habits (e.g., quantity, frequency, and duration of therapy) are common even among dermatologists. Some clinicians start treatment with high-potency topical corticosteroid preparations in order to induce remission, followed by a relatively quick tapering down of potency as the dermatitis improves. Alternatively, other clinicians use short bursts of high-potency corticosteroids followed by moisturizers alone until relapse occurs. Another treatment regimen advocates more prolonged treatment with less potent steroid preparations. Weekend topical steroids to prevent flares have gained popularity. Drug-specific FDA indications and an expanding body of clinical trial data should help guide clinicians when educating and instructing patients on topical corticosteroid usage.

The *topical calcineurin inhibitors* (TCIs) tacrolimus and pimecrolimus have the important advantage of not being associated with skin atrophy. Current indications for TCI use are as “*second-line therapy* for the short-term and noncontinuous chronic treatment” of mild to moderate AD (pimecrolimus) or moderate to severe AD (tacrolimus) in nonimmunocompromised adults and children “who have failed to respond adequately to other topical prescription treatments for atopic dermatitis, or when those treatments are not advisable.” Patients who are especially likely to benefit include those in whom the clinical course of AD is marked by steroid tachyphylaxis (versus simple noncompliance), disease persistence, and/or frequent flares, which would otherwise result in an almost continuous need for topical corticosteroid (TCS) treatment. TCIs may also be specifically indicated in sensitive thin skin areas, such as around the eye, face, neck, and

genital area where local safety and systemic absorption are of special concern.

The safety and efficacy of tacrolimus and pimecrolimus have been studied in multiple short (6 weeks) and long-term (longer than 2 years) clinical trials. Data from these trials demonstrate that pimecrolimus reduces the number and severity of flares, extends the period between major flares, and reduces pruritus and other cutaneous signs associated with AD. Prospective studies spanning up to 10 years have investigated the clinical use of TCI in pediatric populations and have suggested that the use of TCI is not associated with systemic immunosuppression or an increased risk of skin cancer; nor does it appear to affect the delayed-type hypersensitivity response. In most countries, regulatory agencies do not recommend the use of TCI in patients under 2 years of age. Tacrolimus ointment 0.03% is indicated for adults and children aged 2 to 15 years, whereas tacrolimus ointment 0.1% is indicated only for adults.

“Proactive” treatment with intermittent TCS or TCI is recommended for disease maintenance for persistent or frequently flaring disease. Long-term, intermittent maintenance use of tacrolimus ointment in patients with stabilized AD has been shown to significantly increase the period between disease exacerbations and the total number of disease-free days compared with vehicle. Despite the frequency of use, the incidence of side effects in these studies was generally low and most commonly included transient application-site stinging.

Phosphodiesterase (PDE)-4 inhibitors are a new class of therapy for AD. Studies have shown the topical agent crisaborole to be an effective therapy for AD with a good short-term safety profile. However, future studies are required to elucidate crisaborole’s long-term efficacy and safety.

Careful *supervision*, combined with appreciation of the risk–benefit profiles of moisturizers, barrier repair agents, topical corticosteroids, and TCIs, allows for individualized and optimized patient care. Treatment should be readily adjusted on an “as-needed” basis that takes advantage of available therapeutic modalities. For children with severe flares, this may mean using short-term bursts of mid- to high-potency topical steroids—with or without wet wraps—instead of relying on long-term use of less potent agents. Close re-examination of the patient at regular intervals to evaluate the efficacy and tolerability of local and systemic therapies is warranted. Once control

of a flare is achieved, topical corticosteroids can be tapered to a lower-potency agent and/or from daily to intermittent (e.g., twice- or thrice-weekly) application. Transition to, or incorporation of, nonsteroid agents may also be considered. There is a positive risk-to-benefit ratio of proactive, scheduled (biweekly), topical antiinflammatory agents applied to frequently relapsing areas in preventing AD flares. During quiescent periods, therapy should shift to a less intense regimen with a focus on maintenance and proper skin care at its core. The use of TCIs or topical PDE-4 inhibitor monotherapy to control flare recurrence while limiting patients' extended exposure to corticosteroids is supported by some physicians.

Other treatment considerations

Total avoidance of environmental aeroallergens is almost impossible and may not significantly influence atopic dermatitis; however, *avoidance of known triggers* is a reasonable approach. Food allergy is more common in children with atopic dermatitis than without, and in a subset of individuals clinically relevant food allergy may exacerbate atopic dermatitis. U.S. national guidelines for food allergy recommend evaluation for milk, egg, peanut, wheat, and soy food allergies be considered in children less than 5 years old with moderate to severe AD if the child has a reliable history of an immediate reaction after ingestion of any of these foods, or the child has persistent AD in spite of optimized management and topical therapy. In addition, recent national guidelines recommend that children in the first year of life with severe AD and/or egg allergy have early evaluation with serum immunoglobulin E (IgE) or skin prick tests and also recommend early feeding of peanut as a method to decrease development of peanut allergy. Specific serum IgE and skin prick tests have high rates of false positives and poor predictive value for food allergy diagnosis, and severely restrictive diets based on positive tests rather than true allergy can be harmful. Thus positive IgE testing should be verified through controlled food trials or other means unless there is a reliable history of an immediate allergic reaction after ingestion of a specific food. Maternal dietary restrictions during pregnancy and lactation are not considered to have a significant role in development of AD and are generally not recommended.

Although they do not appear to have direct effects on the pruritus associated with AD, *sedating systemic antihistamines* such as

hydroxyzine and diphenhydramine may be useful in improving sleep in flaring patients. This practice has not been evaluated rigorously in large, randomized, double-blind, placebo-controlled trials, and the drowsiness that may be associated with daytime use is a legitimate concern for school-age children. Second-generation, nonsedating antihistamines are less useful in managing AD, but may benefit patients with allergic triggers and, with chronic use, are suggested in some studies to reduce the rate of progression to other atopic disease (the atopic march). It is important to note that *topical antihistamines* are not recommended because of potential cutaneous sensitization.

Oral doxepin hydrochloride, a tricyclic antidepressant with anxiolytic effects, is a strong H₁- and H₂-receptor antagonist. It is typically used in doses of 10 to 75 mg orally at night or up to 75 mg twice daily in adult patients; it is not approved for use in children. As oral doxepin possesses a side effect profile that includes daytime sedation, hypotension, tolerance, and an increased risk of depression/suicide, it is generally reserved for severe cases of AD. Topical 5% doxepin cream has been reported to reduce pruritus; however, these topical formulations have also been associated with reports of allergic contact dermatitis and sedation.

Patients may have sudden exacerbations of AD due to overgrowth of *Staphylococcus aureus*—honey-colored crusting, folliculitis, and pyoderma are signs of overt infection. Topical and/or oral antibiotic therapy—typically of short duration to avoid the development of bacterial resistance—is indicated in these cases. Skin cultures and sensitivity testing should be considered before initiating treatment, as methicillin-resistant *S. aureus* (MRSA) may be an important pathogen in some patients. Recurrent, deep-seated *S. aureus* infections should raise the possibility of an immunodeficiency syndrome such as hyper-IgE syndrome or Dedicator of cytokinesis 8 (DOCK8) deficiency.

The addition of *antiseptics* to bath water, for example, diluted bleach baths (“like swimming in pool water”), may help reduce the number of local skin infections and the need for systemic antibiotics in AD patients with heavily colonized and/or superinfected skin. A bleach bath can be prepared by mixing one-quarter to one-half a cup of sodium hypochlorite 6% solution (chlorine liquid bleach) in a bathtub full of lukewarm water; the goal is to create a modified Dakin’s-like solution with a final bleach concentration that approximates 0.005%. The patient may soak for 5 to 10 minutes, with or without a rinse of the skin with fresh water, pat dry, and then apply their topical

therapy and/or emollient/moisturizer. Proprietary bath additives containing antiseptics are also available. For added convenience, newer formulations of bleachlike products are specially formulated and available as body washes, sprays, or gels.

Eczema herpeticum may be easily misdiagnosed as bacterial superinfection and presents a serious risk in patients with widespread AD. Patients can present with multiple vesiculopustular lesions and painful “punched-out” erosions that fail to respond to oral antibiotics. Document herpes infection before treatment via culture and/or direct fluorescent antibody, and initiate *antiviral therapy* as soon as possible. Intravenous treatment is certainly indicated in cases of severe disseminated eczema herpeticum. Oral acyclovir (or equivalent dosage of another antiherpetic medication) may be useful in adults with herpes simplex confined to the skin; 400 mg three times daily for 10 days or 200 mg four times daily for 10 days usually provides a sufficient dosage.

Antifungal therapy has been shown to reduce the severity of AD lesions exacerbated by *Malassezia furfur*, particularly in the seborrheic areas of the skin and scalp. Patients with documented dermatophyte infection or IgE antibodies to *Malassezia* may benefit from a trial of topical or systemic antifungal therapy.

Due to a greater understanding of immunologic reaction patterns in the skin, gut, and airways there has been great interest in *probiotics*. As the findings to date on their utility in preventing or modifying AD are conflicting, the long-term significance of probiotics in the treatment of atopic dermatitis warrants further investigation.

Although the exact mechanism of action is unknown, *phototherapy* in AD is thought to suppress proinflammatory cytokines (such as IL-2 and IL-12) and induce T-cell apoptosis. Broadband ultraviolet (UV)B, broadband UVA, narrowband UVB (311 nm), UVA1 (340–400 nm), and combined UVA-B phototherapy have been reported to be useful for widespread or recalcitrant disease. Photochemotherapy with psoralen and UVA light may be indicated in severe cases. Multiple treatments are usually required to be effective, and this can be inconvenient for patients and their families, depending on location and accessibility to a suitable light source. Side effects can include skin pain, erythema, pruritus, and pigment changes. Likewise, UV radiation may increase the long-term risk of premature skin aging and cutaneous malignancies. Shielding and appropriate eye protection may help minimize unnecessary exposure.

Systemic therapies

Systemic corticosteroids are often prescribed in pediatric outpatient and emergency settings for AD exacerbations, though there are limited data surrounding their use. The temptation to use systemic corticosteroids can be great, given the dramatic clinical improvement that can occur. The propensity to flare with abrupt discontinuation of treatment and the well-known associated systemic side effect profile, however, suggest that systemic corticosteroids should be reserved for “crisis cases” — and, even then, used with the intent to bridge to another systemic agent or phototherapy.

Cyclosporine is a calcineurin inhibitor that blocks activation of T lymphocytes and reduces the transcription of cytokines, including IL-2, shown to be involved in the pathogenesis of AD. It may be used as a short-term treatment or as a bridge between other steroid-sparing alternatives. Cyclosporine is typically dosed at 2.5 to 5 mg/kg/day, and a response may be seen in 2 to 3 weeks. Alternatively, some experts prefer dosing cyclosporine microemulsion at 3 mg/kg/day in children, or 150 mg (low dose) or 300 mg (high dose) in adults, as the microemulsion offers more predictable absorption. Flares can occur after discontinuation of therapy; therefore gradual tapering or use of another immunosuppressive for maintenance therapy should be considered. The safety, efficacy, and risks of cyclosporine are well documented in both adults and children, and treatment with this agent is associated with reduced skin disease and an improved quality of life. Hypertension and renal toxicity, as well as concerns about malignancy, are limitations to long-term therapy. Continuous therapy beyond 1 year is not recommended, and it is unknown how many short courses may be given safely. Blood pressure, complete blood cell count, renal and hepatic function tests, magnesium, and uric acid should be monitored.

Azathioprine, a 6-mercaptopurine analog that inhibits purine synthesis and demonstrates cytotoxic and immunosuppressive properties, can be an effective monotherapy for AD. Marrow suppression and liver toxicity are major concerns; blood cell counts and liver function tests should be monitored closely. One in 300 individuals is homozygous for low metabolic activity alleles that correlate with higher risk of bone marrow suppression; azathioprine should be dosed according to thiopurine methyltransferase (TPMT) genotype/levels. Dosing in children and adults is generally 2.5

mg/kg/day in patients with normal TPMT activity and adjusted to lower doses for carriers of mutant alleles and/or definite intermediate TPMT levels (e.g., 1.0 mg/kg/day). Higher doses, up to 5 mg/kg/day, have been utilized in children. Very low or absent TPMT activity indicating homozygous TPMT mutations may be associated with life-threatening myelotoxicity. Drug hypersensitivity and gastrointestinal disturbances have been reported. An increased risk of malignancy is recognized with long-term use to prevent transplant rejection or manage inflammatory bowel disease.

Methotrexate is a folic acid analog that inhibits dihydrofolate reductase and interferes with DNA synthesis and lymphocyte proliferation leading to antiinflammatory effects; however, its greatest advantage may be that the relatively low doses used for skin disease appear less immunosuppressive than other AD systemic therapies. An open-label, prospective, 24-week trial of adults with AD demonstrated a response plateau at approximately 12 weeks with little additional improvement at doses greater than 15 mg weekly. Alternatively, some experts dose methotrexate at 2.5 mg daily for 4 days per week. A retrospective review of children showed that AD was well controlled with effective dosing of 0.5 to 0.8 mg/kg/week (either as a single weekly dose or divided 3 or 4 days/week). There is a long history of methotrexate use in pediatric and adult inflammatory disease. Nausea and liver function abnormalities/hepatotoxicity may limit dosing. Pulmonary toxicity may be another potential concern. It is unclear what role folic acid supplementation plays in the treatment of AD with methotrexate.

Mycophenolate mofetil (MMF) has a good safety profile and represents a possible therapeutic alternative for severe, refractory AD. It is an inhibitor of inosine monophosphate dehydrogenase involved in de novo purine synthesis and has been used as an immunosuppressant in organ transplantation. Several adult studies have demonstrated efficacy at doses up to 2 g daily. A retrospective review of MMF as monotherapy in 14 pediatric AD patients showed it to be safe and effective at doses of 40 to 50 mg/kg/day in younger children (presumably due to increased surface area-to-volume ratios) and 30 to 40 mg/kg/day in adolescents, with maximal effect after 8 to 12 weeks of therapy. Patients should be monitored for leukopenia and anemia, and drug levels may be increased in the setting of renal insufficiency. MMF has been loosely linked to herpes retinitis, dose-related bone marrow suppression, and increased infection. Further

prospective controlled studies are needed for this promising therapy.

Interferon- γ (IFN- γ) is well known to inhibit Th2-cell proliferation/function and to suppress IgE responses. Several adult AD studies have demonstrated efficacy with three-times-weekly high-dose (150 $\mu\text{g}/\text{m}^2$) and low-dose (50 $\mu\text{g}/\text{m}^2$) therapy. Disadvantages of therapy include flulike symptoms (which are especially common early in the treatment course), myelosuppression, neurotoxicity/confusion, hypotension, tachycardia, and high cost.

Systemic biologic therapies specifically developed and tested for atopic dermatitis are rapidly evolving. Dupilumab, an IL4 receptor alpha blocker that targets IL-4 and IL-13, has been shown to be efficacious in treating moderate to severe AD, with generally good safety data in phase II and III clinical trials.

Referral, quality of life issues, and educational resources

Referral to a pediatric dermatologist or an adult dermatologist/AD specialist may help with comprehensive management of skin care and barrier repair. Referral should be considered in patients with a diagnosis of moderate or severe AD, those who are unresponsive to standard treatments (including midpotency topical corticosteroids), those with persistent disease and/or frequent flares, those who have been hospitalized as a direct consequence of their AD, and those requiring systemic therapies for flares and/or maintenance. *Allergy testing* is not generally a first-line referral recommendation in the routine evaluation and treatment of uncomplicated AD. However, consultation with an allergist can be useful when proper skin care alone is not effective and/or when the clinical picture hints strongly at specific allergic triggers. Immunotherapy with aeroallergens has not been proven effective in the treatment of AD. Referral to immunology or gastroenterology is warranted if underlying systemic infections are frequent or when eosinophilic gastroenteritis/esophagitis becomes a concern in younger children with concomitant failure to thrive.

Emotional stress can exacerbate AD in some patients who may respond to frustration, anxiety, embarrassment, or other psychologically stressful events with a perceived increase in pruritus and subsequent scratching. This may be particularly important in the adolescent population, where even very mild skin disease may be considered “disfiguring.” In some cases, patients may use scratching

for secondary gain, and in others scratching has simply become habitual. *Relaxation*, *biofeedback*, and *behavioral modification* techniques may be helpful in such patients. *Psychosocial evaluation* and counseling should be considered in families where emotional triggers appear to function as obstacles to disease management, or where quality of life is clearly affected. *Therapeutic education* has been shown beneficial in managing AD and may be accomplished through extended in-office discussion, written handouts, eczema “school programs,” and/or web resources, which include video training modules (e.g., www.eczemacenter.org). Families may also benefit from *support groups* such as the U.S. National Eczema Association (www.nationaleczema.org) and the UK National Eczema Society (www.eczema.org).

Hospitalization

Erythrodermic AD patients, those with suspected widespread superinfection, or those with severe recalcitrant disease may benefit from hospitalization. Removal from environmental or emotional stressors, intensive therapy, and caregiver education should be the goals. Hospitalization may be particularly useful in those patients being transitioned to systemic therapies and also provides an opportunity for coordinated care between multiple specialty services.

Specific Investigations

In selected cases only

- Skin biopsy: Especially in adult onset-AD and when cutaneous T-cell lymphoma is being considered as an alternative diagnosis
- Quantification of IgE, IgA, IgM, and IgG levels
- Specific serum IgE assays for food or environment allergens and oral food challenges
- Patch testing for allergic contact dermatitis: Allergic contact dermatitis may be both an alternative diagnosis and exacerbator of AD
- Bacterial cultures and sensitivities
- HIV enzyme-linked immunosorbent assay (ELISA) screening

Translating atopic dermatitis management guidelines into

practice for primary care providers

Eichenfield LF, Boguniewicz M, Simpson EL, Russell JJ, Block JK, Feldman SR, et al. *Pediatrics* 2015; 136: 554–65.

This paper presents an overview of the strategy for diagnosis and management of AD in the pediatric population.

Guidelines of care for the management of atopic dermatitis: section 1. Diagnosis and assessment of atopic dermatitis. Eichenfield LF, Tom WL, Chamlin SL, Feldman SR, Hanifin JM, Simpson EL, et al. *J Am Acad Dermatol* 2014; 70: 338–51.

Guidelines of care for the management of atopic dermatitis: section 2. Management and treatment of atopic dermatitis with topical therapies. Eichenfield LF, Tom WL, Berger TG, Krol A, Paller AS, Schwarzenberger K, et al. *J Am Acad Dermatol* 2014; 71: 116–32.

Guidelines of care for the management of atopic dermatitis: section 3. Management and treatment with phototherapy and systemic agents. Sidbury R, Davis DM, Cohen DE, Cordoro KM, Berger TG, Bergman JN, et al. *J Am Acad Dermatol* 2014; 71: 327–49.

Guidelines of care for the management of atopic dermatitis: Section 4. Prevention of disease flares and use of adjunctive therapies and approaches. Sidbury R, Tom WL, Bergman JN, Cooper KD, Silverman RA, Berger TG, et al. *J Am Acad Dermatol* 2014; 71: 1218–33.

This comprehensive set of guidelines discusses the management of AD—from diagnosis to treatment and prevention—in both adult and pediatric populations.

Guidelines for the diagnosis and management of food allergy in the United States: report of the NIAID-sponsored expert panel

Boyce JA, Assaad A, Burks AW, Jones SM, Sampson HA, Wood RA et al. *J Allergy Clin Immunol* 2010; 126: S1–58.

This includes consensus definition for food allergy and discussion of comorbid conditions and IgE-mediated and non-IgE-mediated reactions to food.

Addendum guidelines for the prevention of peanut allergy in the United States: Report of the National Institute of Allergy and Infectious Diseases-Sponsored Expert Panel

Togias A, Cooper SF, Acebal ML, Assa'ad A, Baker JR Jr, Beck LA et al. *Pediatr Dermatol* 2017; 34: e1–21.

This paper presents guidelines for infants at various risk levels for the development of peanut allergy, including the highest-risk group,

and infants with severe AD and/or egg allergy. Topics addressed include the definition of risk categories, appropriate use of testing (specific IgE measurement, skin prick tests, and oral food challenges), and the timing and approaches for introduction of peanut-containing foods.

Seborrheic dermatitis-like and atopic dermatitis-like eruptions in HIV-infected patients

Cockerell CJ. Clin Dermatol 1991; 9: 49–51.

Crusting and lichenification in the flexural areas or in a more widespread distribution, characteristic of an “AD-like” dermatitis, may represent advanced human immunodeficiency virus (HIV) infection.

First-Line Therapies

• Education	A
• Emollients *	A
• Topical corticosteroids	A
• Proactive therapy	A
• Wet wraps	B

* The choice of using an emollient or barrier repair cream should be made based on personal preference.

Age related, structured educational programmes for the management of atopic dermatitis in children and adolescents: multicentre, randomized controlled trial

Staab D, Diepgen T, Fartasch M, Kupfer J, Lob-Corzilius T, Ring J et al. *Br Med J* 2006; 332: 933–8.

A comparison of children with AD whose parents had received 6 weeks of intensive AD education versus those children whose parents received no education. The investigators taught age-appropriate interventions to the parents. Patients in the “treatment” group demonstrated significantly improved subjective quality-of-life scores and objective measures of eczema severity over the 12-month period.

Psychological and educational interventions for atopic eczema in children

Ersser SJ, Latter S, Sibley A, Satherley PA, Welbourne S. *Cochrane Database Syst Rev* 2007; 3:CD004054.

Emollients improve treatment results with topical corticosteroids in childhood atopic dermatitis: a randomized comparative study

Szczepanowska J, Reich A, Szepietowski JC. *Pediatr Allergy Immunol* 2008; 19: 614–8.

A randomized study of 52 patients aged 2 to 12 years found that the use of emollients can significantly improve xerosis and pruritus during corticosteroid treatment of AD and helped maintain clinical improvement after discontinuation of therapy.

Quantitative assessment of combination bathing and moisturizing regimens on skin hydration in atopic dermatitis

Chiang C, Eichenfield LF. *Pediatr Dermatol* 2009; 26: 273–8.

A crossover study in five pediatric patients with AD and five patients with healthy skin in whom objective parameters of cutaneous hydration status were assessed after various combinations of bathing and moisturizing regimens. This study found that bathing without moisturizer may compromise skin hydration. Bathing followed by moisturizer application provides modest hydration benefits, though less than that of simply applying moisturizer alone.

A pilot study of emollient therapy for the primary prevention of atopic dermatitis

Simpson EL, Chalmers JR, Hanifin JM, Thomas KS, Cork MJ, McLean WH, et al. *J Allergy Clin Immunol* 2014; 134: 818–23.

Emollient enhancement of the skin barrier from birth offers effective AD prevention, and early interventions to repair the

epidermal barrier may be useful as a primary prevention of AD. In one study, neonates at high risk for developing AD were randomized to apply daily emollient or receive no intervention. At 6 months of age, 21.8% (12/55) of completed subjects in the emollient group developed AD, whereas 43.4% (23/53) of completed subjects in the control group developed AD. Thus there is evidence to suggest that primary prevention of AD may be achieved through daily emollient use in high-risk neonates.

Application of moisturizer to neonates prevents development of atopic dermatitis

Horimukai K, Morita K, Narita M, Kondo M, Kitazawa H, Nozaki M, et al. *J Allergy Clin Immunol* 2014; 134: 824–30.e6.

A Japanese study of 118 neonates reported similar results. The 59 subjects who received daily moisturizer for the first 32 weeks of life were 32% less likely to develop AD compared with no intervention.

Scoping systematic review of treatments for eczema

Nankervis H, Thomas KS, Delamere FM, Barbarot S, Rogers NK, Williams HC. *NIHR Journals Library* 2016; 4: 1–528.

A systematic review of 287 trials covering 92 different AD interventions.

Topical corticosteroids for atopic eczema: clinical and cost effectiveness of once-daily vs. more frequent use

Green C, Colquitt JL, Kirby J, Davidson P. *Br J Dermatol* 2005; 152: 130–41.

A systematic review found no clear differences in outcomes between once-daily and more frequent application of topical corticosteroids.

A systematic review of the safety of topical therapies for atopic dermatitis

Callen J, Chamlin S, Eichenfield LF, Ellis C, Girardi M, Goldfarb M et al. *Br J Dermatol* 2007; 156: 203–21.

This review of topical therapies for AD found that although some systemic exposure to topical steroids does occur, physiologic changes appear to be uncommon, and systemic complications are rare when medications are used properly.

Efficacy and safety of wet-wrap dressings in children with severe atopic dermatitis: influence of corticosteroid dilution

Wolkerstorfer A, Visser RL, De Waard van der Spek FB, Mulder PG, Oranje AP. Br J Dermatol 2000; 143: 999–1004.

In children with severe refractory AD, 5%, 10%, and 25% dilutions of fluticasone propionate 0.05% cream proved highly efficacious, irrespective of dilution, when applied under wet-wrap dressings. Improvement occurred mainly during the first week, and the only significant adverse effect was folliculitis.

Wet dressing therapy in conjunction with topical corticosteroids is effective for rapid control of severe pediatric atopic dermatitis: experience with 218 patients over 30 years at Mayo Clinic

Dabade TS, Davis DM, Wetter DA, Hand JL, McEvoy MT, Pittelkow MR, et al. J Am Acad Dermatol 2012; 67: 100–6.

Intensive inpatient treatment (with wet dressings and topical corticosteroids) was highly effective in controlling severe and recalcitrant atopic dermatitis.

Second-Line Therapies

• Topical immunomodulators	A
• Against routine antimicrobial use	A
• Against routine antihistamines/anxiolytics use	A
• Avoidance of true IgE-mediated triggers	A
• Topical phosphodiesterase inhibitors	A*

* At the time of the writing of this chapter, this drug was not commercially available and was therefore listed as a second-line agent.

Efficacy and safety of crisaborole ointment, a novel, nonsteroidal phosphodiesterase 4 (PDE4) inhibitor for the topical treatment of atopic dermatitis (AD) in children and adults

Paller AS, Tom WL, Lebwohl MG, Blumenthal RL, Boguniewicz M, Call RS, et al. *J Am Acad Dermatol* 2016; 75: 494–503.e6.

Crisaborole's safety and efficacy were established through two phase III clinical trials. The studies included 1522 randomized patients; 1016 received crisaborole ointment and 506 received vehicle twice daily for 28 days. At the completion of the study, a statistically significant ≥ 2 grade improvement in Investigator's Static Global Assessment (ISGA) score ($p = 0.038$ for center 1 and $p < 0.001$ for center 2) was noted. In addition, there was a greater percentage of patients with clear or almost clear ISGA scores (51.7% and 40.6%) in the crisaborole groups than the vehicle groups (40.6% and 29.7, $p = 0.005$ and $p < 0.001$). A decrease in pruritus occurred by day eight in the crisaborole ointment group (pooled results from center 1 and 2, $p < 0.001$). Application site pain was the most common adverse effect, present in 4.4% of crisaborole-treated and 1.2% of vehicle-treated patients. However, 77.6% of patients had resolution of this symptom within 1 day of onset.

Efficacy and safety of pimecrolimus cream in the long-term management of atopic dermatitis in children

Sigurgeirsson B, Boznanski A, Todd G, Vertruyen A, Schuttelaar MA, Zhu X, et al. *Pediatrics* 2015; 135: 597–606.

This is a 5-year-long randomized control trial of pimecrolimus 1% cream compared with TCS. After 5 years, >85% of patients achieved overall and facial treatment success. In addition, safety of this treatment modality was demonstrated.

A meta-analysis of the efficacy and tolerability of proactive treatment with TCS versus TCI

Schmitt J, von Kobyletzki L, Svensson A, Apfelbacher C. *Br J Dermatol* 2011; 164: 415–28.

This meta-analysis suggests that topical fluticasone propionate (relative risk = 0.46) may be more efficacious in preventing disease flares than topical tacrolimus (relative risk = 0.78).

0.03% Tacrolimus ointment applied once or twice daily is more efficacious than 1% hydrocortisone acetate in children with moderate to severe atopic dermatitis: results of a randomized double-blind controlled trial

Reitamo S, Harper J, Bos JD, Cambazard F, Bruijnzeel-Koomen C,

Valk P, et al. European Tacrolimus Ointment Group. *Br J Dermatol* 2004; 150: 554–62.

This study involving 624 children aged 2 to 15 years with moderate-to-severe AD, demonstrated that tacrolimus 0.03% ointment applied once or twice daily resulted in a significantly greater reduction in modified Eczema Area and Severity Index (mEASI) scores than hydrocortisone acetate 1% ointment applied twice daily ($p < 0.001$).

Once- or twice-daily tacrolimus ointment 0.03% was significantly more effective than hydrocortisone acetate 1% in treating moderate to severe AD in children. Twice-daily application was particularly effective in patients with severe baseline disease compared with once-daily application.

Intermittent therapy for flare prevention and long-term disease control in stabilized atopic dermatitis: a randomized comparison of 3-times-weekly applications of tacrolimus ointment versus vehicle

Breneman D, Fleischer AB Jr, Abramovits W, Zeichner J, Gold MH, Kirsner RS, et al. *J Am Acad Dermatol* 2008; 58: 990–9.

A double-blind study in which 197 clinically clear patients with a history of moderate to severe AD were randomized to three-times-weekly topical tacrolimus or vehicle for 40 weeks; tacrolimus ointment was associated with significantly more flare-free days than vehicle and a significantly longer time until relapse.

Topical calcineurin inhibitors and malignancies in AD patients

Legendre L, Barnette T, Mazereeuw-Hautier J, Meyer N, Murrell D, Paul C. *J Am Acad Dermatol* 2015; 72: 992–1002.

A systematic review of the long-term safety of topical corticosteroids and topical calcineurin inhibitors in pediatric AD patients.

Systematic review of published trials: long-term safety of topical corticosteroids and topical calcineurin inhibitors in pediatric patients with atopic dermatitis

Siegfried EC, Jaworski JC, Kaiser JD, Hebert AA. *BMC Pediatr* 2016; 16: 75.

A systematic review of the literature included multiple tacrolimus trials for pediatric AD.

The study included over 5800 patients and did not note any cases of lymphoma.

Long-term efficacy and tolerability of tacrolimus 0.03% ointment in infants: a 2-year open-label study

Mandelin JM, Rubins A, Remitz A, Cirule K, Dickinson J, Ho V, et al. *Int J Dermatol* 2012; 51: 104–10.

Tacrolimus 0.03% ointment was associated with substantial clinical improvement of AD in infants aged <2 years. Treatment tolerability was similar to that seen in older children.

Effects of cefuroxime axetil on *Staphylococcus aureus* colonization and superantigen production in atopic dermatitis

Boguniewicz M, Sampson H, Leung SB, Harbeck R, Leung DY. *J Allergy Clin Immunol* 2001; 108: 651–2.

***Staphylococcus aureus*: colonizing features and influence of an antibacterial treatment in adults with atopic dermatitis**

Bath-Hextall FJ, Birnie AJ, Ravenscroft JC, Williams HC. *Br J Dermatol* 2010; 163: 12–26.

Twenty-six studies involving 1229 participants were included. The authors failed to find any evidence that commonly used antistaphylococcal interventions are clinically helpful in AD that is not clinically infected.

Children with atopic dermatitis appear less likely to be infected with community acquired methicillin-resistant *Staphylococcus aureus*: the San Diego experience

Matiz C, Tom WL, Eichenfield LF, Pong A, Friedlander SFF. *Pediatr Dermatol* 2011; 28: 6–11.

In this study, children with AD had a much lower rate of community-acquired MRSA infection compared with the general outpatient pediatric population. Clindamycin-inducible resistance was very low in both groups. Therefore first-line therapies such as cephalosporins may have a place for those patients with nonlife-threatening mild infections who do not possess risk factors for MRSA, pending culture results.

An evidence-based review of the efficacy of antihistamines in relieving pruritus in atopic dermatitis

Klein PA, Clark RA. Arch Dermatol 1999; 135: 1522–5.

This review of 16 AD-associated antihistamine trials found that the majority of studies were flawed in terms of sample size or study design.

A double-blinded, randomized, placebo-controlled trial of cetirizine in preventing the onset of asthma in children with atopic dermatitis: 18 months' treatment and 18 months' posttreatment follow-up

Warner JO, ETAC Study Group. J Allergy Clin Immunol 2001; 108: 929–37.

Infants between 1 and 2 years of age with AD in this double-blinded trial were randomized to 0.25 mg/kg body weight cetirizine administered twice daily compared with placebo. After 18 months of treatment, follow-up continued for a further 18 months. Although there was no difference in the cumulative prevalence of asthma between active and placebo treatment in the intention-to-treat population ($p = 0.7$), cetirizine did appear to delay (and in some cases to prevent) the development of asthma in those patients sensitized to grass pollen and, to a lesser extent, house dust mites.

Management of sleep disturbance associated with atopic dermatitis

Kelsay K. J Allergy Clin Immunol 2006; 118: 198–201.

The author suggests an algorithm for clinicians treating sleep problems associated with AD.

New treatments for restoring impaired epidermal barrier permeability: skin barrier repair creams

Draelos ZD. Clin Dermatol 2012; 30: 345–8.

This article examines the formulation and effect of skin barrier creams.

Third-Line Therapies

• Dupilumab	A*
• Dust mite reduction	A
• Timing of solid food introduction	A
• Phototherapy	B
• Azathioprine	B
• Cyclosporine	B
• Methotrexate	B
• Mycophenolate mofetil	C
• Interferon- γ	B
• Systemic corticosteroids	B

* At the time of the writing of this chapter, this drug was not commercially available but was added based on its merit in two phase III clinical trials.

Two phase 3 trials of dupilumab versus placebo in AD

Simpson EL, Bieber T, Guttman-Yassky E, Beck LA, Blauvelt A, Cork MJ, et al. *New Eng J Med* 2016; 375: 2335–48.

This two-center, double blind randomized controlled trial (RCT) compared dupilumab weekly and biweekly to placebo in 671 adults with moderate-to-severe AD not controlled by topical therapies. Dupilumab weekly and biweekly both resulted in an Investigator's Global Assessment (IGA) score reduction of 2 points or more in 36% of patients versus 10% in the placebo control group. Additionally, there was a significant improvement in AD severity observed in those receiving dupilumab compared with placebo based on a >75% change in EASI score ($p < 0.001$). Dupilumab therapy was also associated with

a statistically significant improvement in other clinical end points, including reduction in pruritus, symptoms of anxiety and depression, and improvement in quality of life. Side effects more frequent in the dupilumab therapy groups than placebo included injection-site reactions (8%–19% versus 6%) and conjunctivitis (3%–5% versus $\leq 1\%$).

Prescribing practices for systemic agents in controlling pediatric AD

Totri CR, Eichenfield LF, Logan K, Proudfoot L, Schmitt J, Lara-Corrales I, et al. *J Am Acad Dermatol* 2017; 76: 281–5.

The TREAT survey included 133 dermatologists from the Society for Pediatric Dermatology. Of these participants, 86.5% used systemic treatments for severe pediatric AD. Cyclosporine (45.2%), methotrexate (29.6%), and mycophenolate mofetil (30.4%) were the most frequently preferred initial treatments. Factors that discouraged systemic therapy use included side effect profiles and suspected risks of long-term toxicities.

Double-blind controlled trial of effect of housedust-mite allergen avoidance on atopic dermatitis

Tan BB, Weald D, Strickland I, Friedmann PS. *Lancet* 1996; 347: 15–8.

Measures to reduce house dust mites using a combination of Gore-Tex bedcovers, benzyl tannate spray, and a high-filtration vacuum cleaner were compared with cotton bedcovers, water spray, and a conventional vacuum cleaner in the households of 48 children and adults with AD. Both active and placebo treatments caused significant reductions in house dust mite antigen concentrations. The severity of eczema decreased in both groups, but the active group showed significantly greater improvement.

Rice nightmare: kwashiorkor in 2 Philadelphia-area infants fed Rice Dream beverage

Katz KA, Mahlberg MJ, Honig PJ, Yan AC. *J Am Acad Dermatol* 2005; 52: S69–72.

Probiotics during pregnancy and breast-feeding might confer immunomodulatory protection against atopic disease in the infant

Rautava S, Kalliomäki M, Isolauri E. *J Allergy Clin Immunol* 2002; 109: 119–21.

Probiotic supplementation for the first 6 months of life fails to reduce the risk of atopic dermatitis and increases the risk of allergen sensitization in high-risk children: a randomized controlled trial

Taylor AL, Dunstan JA, Prescott SL. *J Allergy Clin Immunol* 2007; 119: 184–91.

Effects of early nutritional interventions on the development of atopic disease in infants and children: the role of maternal dietary restriction, breastfeeding, timing of introduction of complementary foods, and hydrolyzed formulas

Greer FR, Sicherer SH, Burks AW. Committee on Nutrition and Section on Allergy and Immunology. *Pediatrics* 2008; 121: 183–91.

The role of psoralen photochemotherapy (PUVA) in the treatment of severe atopic eczema in adolescents

Atherton DJ, Carabott F, Glover MT, Hawk JL. *Br J Dermatol* 1988; 118: 791–95.

Oral PUVA resulted in initial clearance of eczema in 14 of 15 children, 9 of whom achieved complete remission. This was associated with resumption of normal growth in children who were previously growing poorly.

Phototherapy for atopic eczema with narrow-band UVB

Grundmann-Kollmann M, Behrens S, Podda M, Peter RU, Kaufmann R, Kerscher M. *J Am Acad Dermatol* 1999; 40: 995–7.

Five patients with moderate to severe AD were treated with narrowband UVB for a cumulative dose of 9.2 J/cm² over a mean of 19 treatments. Narrowband UVB was effective after 3 weeks in all patients.

Half-side comparison study on the efficacy of 8-methoxy-psoralen bath-PUVA versus narrow-band ultraviolet B phototherapy in patients with severe chronic atopic dermatitis

Der-Petrossian M, Seeber A, Honigsmann H, Tanew A. *Br J Dermatol* 2000; 142: 39–43.

In this randomized, investigator-blinded study of 12 patients, half-side irradiation with threshold erythemogenic doses of 8-methoxypsoralen bath-PUVA and narrowband UVB was performed three times weekly for 6 weeks. The two modalities were equally

effective in equierythemogenic doses.

Long-term efficacy of medium-dose UVA1 phototherapy in atopic dermatitis

Abeck D, Schmidt T, Fesq H, Strom K, Mempel M, Brockow K, et al. *J Am Acad Dermatol* 2000; 42: 254–7.

Thirty-two patients with acute exacerbated AD underwent medium-dose UVA1 therapy consisting of 15 treatments over 3 weeks (cumulative dose 750 J/cm²). There was a significant improvement in the skin condition at the end of the treatment period; this was still present 1 month later, but by 3 months the condition had returned to pretreatment levels.

Phototherapy in the management of atopic dermatitis: a systematic review

Meduri NB, Vandergriff T, Rasmussen H, Jacobse H. *Photodermatol Photoimmunol Photomed* 2007; 23: 106–12.

Azathioprine in severe adult atopic dermatitis: a double-blind, placebo-controlled, crossover trial

Berth-Jones J, Takwale A, Tan E, Barclay G, Agarwal S, Ahmed I, et al. *Br J Dermatol* 2002; 147: 324–30.

In this double-blind crossover trial, adult patients with severe AD were treated with azathioprine 2.5 mg/kg daily and placebo for 3 months each. There was a significant difference in favor of azathioprine in the improvement of the six area, six sign atopic dermatitis (SASSAD) sign score, decreasing by 26% during treatment with azathioprine versus 3% on placebo. Pruritus, sleep disturbance, and disruption of work/daytime activity all improved significantly on active treatment, but the difference in mean improvement between azathioprine and placebo was statistically significant only for disruption of work/daytime activity. The authors suggested that a longer period of treatment might have further improved the eczema. Gastrointestinal disturbances and deranged liver enzymes were common. Of the 37 patients enrolled, 12 prematurely terminated treatment with azathioprine and 4 with placebo.

A retrospective evaluation of azathioprine in severe childhood atopic eczema, using thiopurine methyltransferase levels to exclude patients at high risk of myelosuppression

Murphy LA, Atherton DJ. Br J Dermatol 2002; 147: 308–15.

Parallel-group randomized controlled trial of azathioprine in moderate to severe atopic eczema, using a thiopurine methyltransferase-based dose regimen

Meggitt SJ, Gray JC, Reynolds NJ. Br J Dermatol 2003; 149: 3.

There was again a significant improvement in sign score on azathioprine (39%) relative to placebo (24%). Pruritus and the physician's global assessment also improved significantly better in the azathioprine group. Six patients withdrew from azathioprine treatment because of nausea or hypersensitivity.

Efficacy and tolerability at 3 and 6 months following use of azathioprine for recalcitrant atopic dermatitis in children and young adults

Hon KL, Ching GK, Leung TF, Chow CM, Lee KK, Ng PC. J Dermatolog Treat 2009; 20: 141–5.

The clinical efficacy of azathioprine, and its hematologic and biochemical effects (serum IgE level, liver and renal function), were assessed at 3 months and 6 months in 17 patients with recalcitrant AD. Disease severity was evaluated with the scoring atopic dermatitis (SCORAD) score. Azathioprine reduced the severity of AD within 3 months in these children. Better efficacy was observed in females at 6 months. Mild transient elevation of glutamic-pyruvic transaminase was noted in one patient and mild elevation of serum bilirubin in two other patients.

Systemic treatment of pediatric atopic dermatitis with azathioprine and mycophenolate mofetil

Waxweiler WT, Agans R, Morrell DS. Pediatr Dermatol 2011; 28: 689–94.

Medical records of 28 pediatric patients with AD treated with either azathioprine (AZ) or mycophenolate mofetil (MM) were analyzed for laboratory values, TPMT levels, symptoms, infections, and other relevant data. Seventeen of 28 (61%) patients treated with AZ and 8 of 12 (66%) treated with MM reported significant improvement. Lower rates of laboratory abnormalities and side effects were seen with MM compared with AZ; however, similar rates of cutaneous infections were noted.

Oral azathioprine for recalcitrant pediatric atopic dermatitis: clinical response and thiopurine monitoring

Caufield M, Tom WL. *J Am Acad Dermatol* 2012; 68: 29–35.

This prospective study of 12 children with severe, recalcitrant AD who were treated with oral azathioprine showed that azathioprine can be of benefit in the treatment of recalcitrant pediatric AD. In addition, repeat assessment of TPMT activity (not thiopurine metabolite levels) may be helpful for evaluation of nonresponse or change in response to treatment.

Cyclosporine in the treatment of patients with atopic eczema – a systematic review and meta-analysis

Schmitt J, Schmitt N, Meurer M. *J Eur Acad Dermatol Venereol* 2007; 21: 606–19.

The authors conducted a systematic review of the effectiveness of systemic cyclosporine in patients with severe atopic eczema and included 15 studies comprising a total of 602 patients. In all studies analyzed, cyclosporine consistently decreased the severity of atopic eczema. Data from 12 of the 15 studies were pooled and showed a dose-related response with a mean decrease in disease severity of 22% (95% CI: 8%–36%) under low-dose cyclosporine (3 mg/kg) and 40% (95% CI: 29%–51%) at dosages ≥ 4 mg/kg after 2 weeks of treatment. After 6 to 8 weeks the relative effectiveness was 55% (95% CI: 48%–62%). Effectiveness of cyclosporine was similar in adults and children, but tolerability may be better in children.

Double-blind, controlled, crossover study of cyclosporine in adults with severe refractory atopic dermatitis

Sowden JM, Berth-Jones J, Ross J, Motley RJ, Marks R, Finlay AY, et al. *Lancet* 1991; 338: 137–40.

A multicenter, randomized, double-blind, controlled crossover clinical trial was conducted on 33 patients with severe refractory atopic dermatitis to determine the effects of cyclosporine (5 mg/kg/day) on their health-related quality of life. After treatment with cyclosporine, patients indicated significant improvement in quality of life; however, there was either no correlation or only a very poor correlation between the quality-of-life parameters and clinical measures of extent and activity of eczema. Twenty patients receiving cyclosporine reported adverse events, compared with eight taking placebo. Relapse was noted when cyclosporine was stopped;

however, the mean scores for disease activity and extent of disease in these patients were less than their baseline values.

Cyclosporine greatly improves the quality of life of adults with severe atopic dermatitis

Salek MS, Finlay AY, Luscombe DK, Allen BR, Berth-Jones J, Camp RD, et al. *Br J Dermatol* 1993; 129: 422–30.

In this study, both sign score and quality of life improved rapidly on 5 mg/kg cyclosporine daily. Whereas the sign score deteriorated rapidly on stopping treatment, the improvement in quality of life was more persistent.

Cyclosporine in atopic dermatitis: time to relapse and effect of intermittent therapy

Granlund H, Erkkö P, Sinisalo M, Reitamo S. *Br J Dermatol* 1994; 132: 106–12.

Forty-three patients with severe AD were treated with a 6-week course of cyclosporine 5 mg/kg daily and then retreated after a follow-up of 6 to 26 weeks (depending on the time to relapse) with an identical course of cyclosporine. A significant reduction in disease activity was observed after 2 weeks of cyclosporine treatment. After both treatment periods, approximately half of the patients relapsed after 2 weeks; after 6 weeks follow-up the relapse rates were 71% and 90%, respectively, for the two treatment periods. Notably, after the first treatment period, five patients did not relapse during the 26-week follow-up, and for the second treatment period two did not relapse. All of these seven patients were still in remission at 1 year.

Long-term efficacy and safety of cyclosporine in severe adult atopic dermatitis

Berth-Jones J, Graham-Brown RAC, Marks R, Camp RD, English JS, Freeman K, et al. *Br J Dermatol* 1997; 136: 76–81.

An open-label study of 100 patients over 48 weeks' duration. Improvements in sign score, itch, and sleep disturbance were maintained throughout treatment. Sixty-five subjects completed the trial, and only seven were withdrawn due to adverse events considered likely to have been related to treatment.

Cyclosporine in atopic dermatitis: review of the literature and outline of a Belgian consensus

Naeyaert JM, Lachapelle JM, Degreef H, de la Brassinne M, Heenen M, Lambert J. *Dermatology* 1999; 198: 145–52.

This excellent review summarizes all the major trials of cyclosporine for AD and gives practical recommendations for the clinician. These authors recommend that cyclosporine be reserved for adults with severe AD and only used in children with recalcitrant disease for short periods. A starting dosage of 2.5 mg/kg daily can be adjusted up after 2 weeks, depending on response, to a maximum dose of 5 mg/kg daily. Screening for gynecologic or prostate malignancy and skin biopsy to exclude cutaneous T-cell lymphoma, as well as close monitoring of renal function and blood pressure, are recommended.

An open-label, dose-ranging study of methotrexate for moderate-to-severe adult atopic eczema

Weatherhead SC, Wahie S, Reynolds NJ, Meggitt SJ. *Br J Dermatol* 2007; 156: 346–51.

This 24-week, open-label safety and efficacy study evaluated 12 adults with moderate to severe AD in a dose-ranging, prospective trial of methotrexate.

A randomized trial of methotrexate versus azathioprine for severe atopic eczema

Schram ME, Roekevisch E, Leeftang MM, Bos JD, Schmitt J, Spuls PI. *J Allergy Clin Immunol* 2011; 128: 353–9.

Forty-two patients were randomly assigned to receive either methotrexate or azathioprine for 12 weeks. Both treatments were found to be safe in the short term and achieved clinically relevant improvement with a 42% reduction in AD severity seen with methotrexate and 39% with azathioprine.

Treatment of atopic eczema with oral mycophenolate mofetil

Neuber K, Schwartz I, Itschert G, Dieck AT. *Br J Dermatol* 2000; 143: 385–91.

Ten patients with severe AD were treated with oral mycophenolate mofetil at an initial dose of 1 g/day during the first week and then 2 g daily for a further 11 weeks. Median scores for disease severity improved by 68% (100% in one patient, >75% in three patients, and >50% in the remainder).

Mycophenolate mofetil for severe childhood atopic dermatitis: experience in 14 patients

Heller M, Shin HT, Orlow SJ, Schaffer JV. Br J Dermatol 2007; 157: 127–32.

Enteric-coated mycophenolate sodium versus cyclosporin A as long-term treatment in adult patients with severe atopic dermatitis: a randomized controlled trial

Haeck IM, Knol MJ, Ten Berge O, van Velsen SG, de Bruin-Weller MS, Bruijnzeel-Koomen CA. J Am Acad Dermatol 2011; 64: 1074–84.

An observer-blinded, randomized controlled trial was conducted comparing enteric-coated mycophenolate sodium (EC-MPS) with cyclosporine A (CsA) as long-term treatment in adult patients with severe AD. This study showed that EC-MPS is as effective as CsA as maintenance therapy in patients with AD. However, clinical improvement with EC-MPS was delayed in comparison with CsA. Remission after stopping EC-MPS lasted longer compared with CsA.

Recombinant interferon gamma therapy for atopic dermatitis

Hanifin JM, Schneider LC, Leung DY, Ellis CN, Jaffe HS, Izu AE, et al. J Am Acad Dermatol 1993; 28: 189–97.

In this randomized, double-blind study, patients with moderate to severe AD received recombinant human IFN- γ (rIFN- γ , 50 $\mu\text{g}/\text{m}^2$) or placebo by daily subcutaneous injection for 12 weeks. Significant reductions in erythema, pruritus, and excoriation occurred in rIFN- γ -treated patients. Edema, papulation, induration, scaling, dryness, and lichenification showed greater improvement in the rIFN- γ group, but differences were not statistically significant.

Long-term effectiveness and safety of recombinant human interferon gamma therapy for atopic dermatitis despite unchanged serum IgE levels

Stevens SR, Hanifin JM, Hamilton T, Tofte SJ, Cooper KD. Arch Dermatol 1998; 134: 799–804.

The initial efficacy and adverse effects reported for rIFN- γ treatment of patients with AD were maintained after 2 years of long-term use.

Do some patients with atopic dermatitis require long term oral steroid therapy?

Sonenthal KR, Grammer LC, Patterson R. J Allergy Clin Immunol 1993; 91: 971–73.

Three patients with recalcitrant AD were successfully managed on oral corticosteroids.

Atypical fibroxanthoma

Min Deng, and Warren Heymann

Atypical fibroxanthoma (AFX) is an uncommon cutaneous neoplasm arising from mesenchymal or fibrohistiocytic cells. AFX is found predominantly in sun-damaged skin, especially of the head and neck of elderly males, and comprises approximately 0.2% of all skin tumors. Rare cases have also been reported in children with xeroderma pigmentosum. Risk factors include male sex, ultraviolet

(UV) exposure, history of radiation therapy, immunosuppression, and trauma. Clinically these lesions typically appear as rapidly growing, ulcerated, exophytic, dome-shaped nodules, usually <2 cm in diameter. Despite its severe cytologic atypia, it is considered a benign neoplasm. Care should be taken to distinguish these tumors from pleomorphic dermal sarcoma (PDS) and undifferentiated pleomorphic sarcoma (UPS).

The classification of fibrohistiocytic tumors is ambiguous and controversial. This has been compounded by the evolving nomenclature as understanding of the genetic and molecular basis of these tumors improved. Previously, fibrohistiocytic tumors encompassed the superficial AFX and its deep dermal/subcutaneous version, the malignant fibrous histiocytoma (MFH). Since 2002, the World Health Organization (WHO) has started dismantling the term MFH due to the heterogeneity of these tumors, most of which are better aligned under other classifications. The term MFH has been completely eliminated from the 2013 WHO classification of sarcomas.

In the current nomenclature, AFX is primarily a dermally based tumor that remains a diagnosis of exclusion by use of immunohistochemical stains. If invasion into subcutaneous tissue is observed, it is superficial and focal. The presence of extensive or deep subcutaneous tissue invasion, perineural invasion, lymphovascular invasion, or tumor necrosis in a tumor that otherwise resembles an AFX histologically is more appropriately classified as a pleomorphic dermal sarcoma, which carries a worse prognosis. *PDS* is a term newly proposed in 2012 by Dr. C.D. Fletcher, and therefore its adoption in the literature is included only in newer publications.

Although AFX and PDS likely represent a disease spectrum, this has not been conclusively proven. PDS is clinically indistinguishable from AFX, although reports suggest these tumors are typically larger on presentation (>2 cm). It similarly predominantly arises on sun-damaged skin of elderly men, especially on the scalp. Unlike AFX, PDS is associated with a recurrence rate of 29%, and estimates of metastasis are as high as 20%.

UPSs are a diagnosis of exclusion for sarcomas that do not fit into other categories, including AFX and PDS. When MFH was dismantled in 2002 many authors used UPS to describe what would now be considered PDS. Since the adoption of PDS in 2012, however, UPS should be limited to describing sarcomas arising from deeper tissues, often involving the extremities or retroperitoneum.

Management Strategy

Proper management relies on an adequate biopsy specimen that should include subcutaneous tissue to help distinguish between AFX and PDS. Because these are typically rapidly growing tumors, first-line management is aimed at complete eradication with surgery. Incomplete removal results in recurrences that typically manifest within a year postoperatively. In instances of incomplete removal of PDS, recurrence can manifest as satellite lesions that represent in-transit metastases.

Due to the rarity of these tumors, the lack of consensus for an excisional safety margin, and the overlap clinically with PDS, Mohs micrographic surgery with complete margin evaluation is preferable over wide local excision (WLE) for primary tumors, especially for tumors with substantial subcutaneous invasion. Recurrent tumors should be treated with Mohs micrographic surgery.

Although radiation and chemotherapy are often used as adjunctive therapies, local tumor control remains the first-line therapy. Because AFX and PDS are induced by radiation exposure, the utility of radiation therapy is unclear. There is also literature suggesting that radiation-induced sarcomas are less responsive to radiation therapy.

Specific Investigation

- Biopsy with adequate subcutaneous tissue

Diagnosis requires an adequate biopsy specimen with appropriate immunohistochemical stains (high-molecular-weight cytokeratins, S100, SMA, MelanA/MART1, EMA, CD34, and CD31) to exclude other spindle cell tumors, particularly squamous cell carcinoma, melanoma, angiosarcoma, and leiomyosarcoma. Biopsy and excision specimens should also evaluate for perineural invasion, lymphovascular invasion, and tumor necrosis to distinguish between AFX and PDS.

First-Line Therapy

More than 2 decades of treating atypical fibroxanthoma at Mayo Clinic: what have we learned from 91 patients?

Ang GC, Roenigk RK, Otley CC, Phillips PK, Weaver AL. *Dermatol Surg* 2009; 35: 765–72.

This is an updated retrospective chart review of 93 AFX tumors treated at the Mayo Clinic from 1980 to 2004. The average age at time of diagnosis was 71.7 years old. The majority of tumors (83.9%) were located on the face and scalp. The average clinical size was 1.5 cm, with immunosuppressed patients having slightly larger tumors (1.6 vs. 1.3 cm, $p = 0.10$). Treatment information was available for 88 cases. Sixty-six of 88 tumors (67%) were treated with Mohs micrographic surgery (MMS), 23/88 (26.1%) with WLE, 5 cases with electrodesiccation and curettage (ED&C), and 1 with shave excision. The authors report that based on their MMS experience, a 2-cm margin would be needed to clear 96.6% of AFX tumors. Tumors treated with MMS were larger than those treated with WLE (1.5 vs. 1.0 cm, $p = 0.02$). Of the 86 tumors with follow-up data, 2 recurred and both had been treated with WLE.

The median follow-up time for patients treated with MMS was shorter than those treated with WLE (4.5 years vs. 8.7 years); however, because recurrences typically occur within the first year postoperatively, this retrospective chart review suggests improved outcomes with MMS despite larger preoperative tumor size.

Clinical spectrum of atypical fibroxanthoma and undifferentiated pleomorphic sarcoma in solid organ transplant recipients: a collective experience

McCoppin HH, Christiansen D, Stasko T, Washington C, Martinez JC, Brown MD, Zwald FO. *Dermatol Surg* 2012; 38: 230–9.

This is a retrospective chart review of 17 cases of AFX and MFH/UPS in solid organ transplant recipients (renal, heart, liver, and lung transplants). Patients were younger on presentation (average age 62 for AFX, 65 for UPS/MFH) compared with immunocompetent patients. All patients were male and presented on average 10.5 years after transplantation. Fifteen of 17 (88%) presented on the head and

neck, 1 on the shin, and 1 on the arm. Of the 8 AFX and UPS/MFH tumors treated with MMS, there were no recurrences or metastases. In contrast, two thirds of AFX and 2/2 UPS/MFH cases treated with surgical excision recurred or metastasized.

This is a small case series of immunosuppressed patients treated with either MMS or WLE. Although there was no information on tumor characteristics between patients treated with the two modalities or the initial surgical margins used to excise the primary tumor, this suggests a better outcome with MMS.

Second-Line Therapies

• Wide local excision	C
• Radiation therapy	D
• Chemotherapy	B

Pleomorphic dermal sarcoma: adverse histologic features predict aggressive behavior and allow distinction from atypical fibroxanthoma

Miller K, Goodlad JR, Brenn T. Am J Surg Pathol 2012; 36: 1317–26.

This is an excellent retrospective chart review of histologically confirmed pleomorphic dermal sarcoma cases treated with WLE. The median age of patients at presentation was 81 years old, with a male-to-female ratio of 7:1. With the exception of one tumor, all presented on the head, with the majority presenting on the scalp. Tumors were large, with a median diameter of 2.5 cm and thickness of 1.15 cm. Local recurrence occurred in 28% of patients (three treated with ED&C and three with WLE) and metastasis in 10% of patients. The median time to recurrence was 10 months.

Atypical fibroxanthoma – histologic diagnosis,

immunohistochemical markers, and concepts of therapy

Koch M, Freundl AJ, Agaimy A, Kiesewetter F, Junzel J, Cicha I, et al. *Anticancer Res* 2015; 35: 5717–35.

This is a case series of 18 patients with 21 AFX treated with WLE as well as a literature review of 2912 patients with 2939 AFX cited in the literature between 1962 and 2014. Follow-up data for 17 of the authors' 18 patients were available. The authors report a 25% (5/20) recurrence rate with WLE. Recurrences developed within 24 months after initial diagnosis. Recurrences were typically <1 cm from the site of the primary tumor or scar. One patient (5%) developed locoregional parotid metastasis. In their review of the published literature on AFX, approximately 80% (1031/1289) of tumors were treated with WLE and 17.2% (222/1289) treated with MMS. The recurrence rate was approximately 7.6% (113/1488) and similar between those treated with WLE and MMS. The metastatic rate was 2.75%.

The authors report a case series of 21 AFX treated with WLE, with a recurrence rate of 25% and metastatic rate of 5%. Although this is a good comprehensive review of the published case reports on AFX, the authors' conclusion that MMS is not superior to WLE based on published cases is premature, as there is no information on whether tumor parameters (size, depth, AFX vs. PDS) between those treated with WLE and MMS are similar. The authors do suggest that based on the close vicinity of recurrences, WLE for AFX tumors smaller than 2 cm should encompass a safety margin of at least 1 cm.

Radiation-associated undifferentiated pleomorphic sarcoma is associated with worse clinical outcomes than sporadic lesions

Dineen SP, Roland CL, Feig R, May C, Zhou S, Demicco E, et al. *Ann Surg Oncol* 2015; 22: 3913–20.

This is a retrospective chart review of 1068 patients with the diagnosis of UPS/MFH treated at a single institution from 1990 to 2012. Patients with sarcomas arising from bone were excluded. Of these cases, 55 (5.1%) were radiation induced and the rest were sporadic. The median latency period between radiation and the development of radiation-associated sarcoma (RAS) was 9.33 years (range 1–40 years). The median dose of radiation these patients received was 50 ± 5.2 Gy. Twenty-four percent of patients with RAS underwent repeat radiation therapy without reduction in the rate of local recurrence.

Although radiation is often used as an adjunctive therapy to local control, this study suggests that radiation-induced sarcomas are not responsive to this treatment modality.

Pleomorphic dermal sarcoma: a more aggressive neoplasm than previously estimated

Tardio JC, Pinedo F, Aramburu JA, Suarez-Massa D, Pampin A, Requena, L et al. J Cutan Pathol 2016; 434: 101–12.

In this retrospective chart review of 18 histologically confirmed PDS cases, the ratio of males to females was 1:1. All lesions occurred on the head, with half occurring on the scalp. All cases were treated with WLE and two cases also received adjuvant radiation therapy. Of the 15 patients with follow-up data, 3 (20%) developed local recurrence and 3 (20%) developed distant metastases. Of the patients with recurrences, half had evidence of incomplete resection. One patient developed pulmonary metastases 11 months after surgery despite negative surgical margins followed by adjuvant radiation therapy.

Pleomorphic dermal sarcoma. Adverse histologic features predict aggressive behavior and allow distinction from atypical fibroxanthoma

Miller K, Goodlad JR, Brenn T. Ann J Surg Pathol 2012; 36: 1317–26.

The authors report a case of PDS with multiple cutaneous metastases and radiologically enlarged lymph nodes that responded to adriamycin and ifosfamide without evidence of recurrence or further metastasis 79 months later.

Randomized phase II study of gemcitabine and docetaxel compared with gemcitabine alone in patients with metastatic soft tissue sarcomas: results of sarcoma alliance for research through collaboration study 002

Maki RG, Wathen K, Patel SR, Priebat DA, Okuno SH, Samuels B, et al. J Clin Oncol. 2007; 25: 2755–63.

In this multicenter, open-label, phase II clinical trial of 122 patients with recurrent or progressive soft tissue sarcoma, patients were randomized to receive either gemcitabine alone or gemcitabine–docetaxel combination therapy. The combination therapy group achieved improved RECIST (Response Evaluation Criteria in Solid Tumors) partial response rate (16% vs. 8%). Within the subgroup of

patients with MFH/UPS, 4 of 11 patients (31.6%) achieved partial response in the gemcitabine–docetaxel treatment arm compared with 2 of 8 (25%) in the gemcitabine-only arm. The median overall survival was also improved in the combination therapy arm (17.9 months vs. 11.5 months).

The standard of care for the majority of soft tissue sarcomas, including AFX and PDS, is local tumor control with surgery. Therefore there is no literature for systemic chemotherapy treatment of localized tumors limited to the skin. However, metastatic soft tissue sarcoma typically has a poor prognosis. In this phase II clinical trial, which included multiple types of metastatic soft tissue sarcoma, the combination of gemcitabine with docetaxel showed improved outcomes in tumor size and overall survival.

Third-Line Therapy

• Electrodesiccation and curettage	D
------------------------------------	----------

Atypical fibroxanthoma: a case series and review of literature

Mahalingam S, Shah A, Stewart A. *Auris Nasus Larynx* 2015; 42: 469–71.

A case series of seven patients with AFX treated with ED&C (five) and local excision (two). At 2 years' follow-up, two of the five patients (40%) treated with ED&C had developed local recurrence. These patients subsequently underwent complete excision without further recurrences.

This case series, along with multiple other case series previously discussed, have all demonstrated a high recurrence rate when the primary tumor is inadequately removed.

Atypical nevi

Julia Newton-Bishop, and Sally O'Shea

Courtesy of Dr Angana Mitra.

The term *atypical nevi* refers to clinically diagnosed lesions, defined as nevi that are more than 5 mm in diameter with an irregular or diffuse edge and variable color. Biologically such nevi are believed to

be melanocytic neoplasms that result from more protracted proliferation (leading to a stromal reaction) than do banal benign melanocytic nevi. Histologically atypical nevi are characterized by elongated rete ridges, bridging of melanocytes between rete ridges, a predominance of single melanocytes over nested melanocytes, and a dermal inflammatory reaction with papillary dermal fibroplasia. Although these histologic changes are characteristic, there may be a lack of correlation between the clinical and histologic features, which has led to controversy which has largely been unhelpful. Suffice it to say that the entity remains an important one, which is clinically diagnosed, but characteristic histologic correlates are variably present in lesions that fulfill the clinical criteria.

We use the term *atypical nevi* to mean nevi that others might call dysplastic nevi. Atypical nevi may be considered more of a marker of patients at higher risk of melanoma than as frequent precursors of melanoma. The indication for excision is to exclude melanoma, not to make a diagnosis of an atypical nevus. There is no role for prophylactic excision except perhaps when a single atypical nevus appears in an individual who is older than the usual age for such nevi (over 50 years). It is important to note that two thirds of melanomas do not arise from previous nevi, so that removing all atypical nevi does not prevent melanoma even in patients who are genetically predisposed. It is mandatory to perform total-body skin examinations in patients at risk for melanoma, looking for the *ugly duckling nevus*, which stands out as different from that patient's typical *signature nevi*. The mnemonic ABCDE has been used as a clinical aid (*a*symmetry, *b*order irregularity, *c*olor variegation, *d*iameter >6 mm, and *e*volution or change in a lesion), but in practice most experts make the diagnosis based upon a global clinical examination. This is similar to a child who recognizes her written name without understanding the meaning of the individual letters.

Some authorities advocate grading atypical nevi as mild, moderate, or severe (NIH Consensus Conference: Diagnosis and treatment of early melanoma. JAMA 1992; 268: 1314–9). Others have argued that such grading has poor reproducibility, and therefore they do not grade the severity of the atypia. The majority of dermatopathologists prefer to grade the architectural and the cytologic atypia separately. It is not uncommon for severely atypical nevi to cause diagnostic difficulty. Histopathologists may report that such a lesion is of unknown malignant potential and recommend that the lesion best be

treated as melanoma with a wide local excision as for melanoma.

It is common to have a single atypical nevus. In a mildly atypical nevus with a bland dermoscopic appearance, the risk of malignant change under the age of 50 is very small. Such nevi therefore should not be excised. It is then important to educate the patient how to monitor the lesion and to give that patient information booklets with photographs of atypical nevi and melanoma so that the patient knows what to look for. Merely asking the patient to “keep an eye out for change” is insufficient.

Where the atypical nevus shows more markedly atypical features, and especially in older individuals, the lesion should probably be excised. In such cases, taking a photograph and reviewing is rarely helpful, as one usually feels no less comfortable to leave alone on review than at first visit; the hypothesis is that if an atypical nevus is single, the patient’s risk can be removed, or at least significantly reduced, by an excision of the lesion. If an atypical nevus causes concern, then it should be excised in its entirety rather than sampled incisionally. Although data have been published to suggest that there is a low rate of clinical recurrence after biopsy of benign moderately “dysplastic” nevi, sampling is risky as sample error may lead to histopathologic examination of a less atypical portion of the tumor. For the patient and the clinician, complete excision is a safer approach, as melanocyte pathology is difficult to interpret and the pathologist could make an error in this gray area—it is better to have excised the lesion completely in the face of ambiguity. Incisional biopsy may furthermore stimulate proliferation of residual melanocytes to lead to a clinically and histologically concerning lesion known as a *pseudomelanoma*; if there is enough clinical concern to sample such a nevus, an experienced clinician will be sampling a lesion with some clinically worrisome features, thereby supporting the argument that a complete excision is desirable.

Patients with increased numbers of banal nevi and/or multiple clinically atypical nevi are said to have the atypical mole syndrome and require different management. These patients have a melanoma risk that cannot be removed by excision of nevi. The key components of good treatment are:

- Taking a detailed family history to determine whether cases of melanoma have occurred in the family. Risk estimation is strongly modified by family history (see www.genomel.org).
- Education about monitoring of nevi.

- Follow-up/supervision in clinic for a period whose length is determined by risk estimation based upon family or personal history of melanoma and the clinical phenotype, as well as the patient's ability to discriminate change.
- Excision of atypical nevi where it is necessary to exclude melanoma.
- Education about ensuring sufficient sun protection without becoming vitamin D depleted. Sunburn avoidance is crucial in that sunburn is established to be associated with melanoma risk in multiple studies. Sunbathing, independently of sunburn, may also increase risk and so should be avoided in those with atypical moles.

Management Strategy

The strategy is essentially to excise clinically atypical nevi if there is a reasonable suspicion of malignancy while avoiding excessive numbers of procedures. The history of the lesion, the appearance to the naked eye, and the dermoscopic appearance are all important. Clinically atypical nevi that are behaving in an unusual fashion should prompt a decision to excise such lesions. Examples include a new atypical nevus over the age of 50 or a lesion that looks like an atypical nevus that has grown rapidly in the previous 6 months. Dermoscopy has been shown to increase diagnostic accuracy. Although anecdotal reports in the literature have utilized topical tretinoin, imiquimod, laser surgery, or cryosurgery, these modalities cannot be advocated for treating atypical nevi.

Treatment strategies for atypical nevi:

- Single nevi
 - Clinically assess
 - Reassure if banal but give photographic information about monitoring
 - If borderline consider photograph and review at 3 months
 - Excise if melanoma cannot be excluded after dermoscopy
 - Consider excision if nevus is new and/or the patient is over 50 years
- Multiple nevi
 - Excise nevi if melanoma cannot be excluded (not usually necessary)
 - Assess risk based upon history of change, clinical appearance, and family history
 - Consider genetic counseling if three or more cases of melanoma

in the family, especially if those cases have multiple primaries or pancreatic cancer, or uveal melanoma, mesothelioma, or meningioma, which may indicate inherited *BAP1* mutations (see www.genomel.org)

- Photograph atypical nevi at high magnification and with dermoscopy
- Educate the patient and partner about self-examination
- Educate the family about sun protection without becoming vitamin D deficient

Specific Investigations

The details of how to perform dermoscopy and the criteria for atypical nevi and melanoma are beyond the scope of this book, but there are increasing numbers of dermoscopy teaching sites on the intranet including www.genomel.org, and an Interaction Atlas of Dermoscopy CD from Medisave.

Bowling J. Wiley-Blackwell, 2012.

Dermoscopy: The Essentials

Soyer HP, Argenziano G, Hofman-Wellenhof, Zalaudek I. Philadelphia: Elsevier Saunders, 2012.

Dermoscopy increases diagnostic accuracy. We have not highlighted recent literature relating to dermoscopy, as its use is now routine in clinical practice. In the UK, the NICE Melanoma Clinical

Guideline recommends dermoscopy and dermoscopic photography in the assessment of all pigmented lesions suspicious for melanoma. [Macbeth F, Newton-Bishop J, O'Connell S, Hawkins JE. Melanoma: summary of NICE guidance. BMJ 2015; 351: h3708.] We have instead focused on published papers regarding excision because this is an area where there is current disagreement.

Diameter of dysplastic nevi is a more robust biomarker of increased melanoma risk than degree of histologic dysplasia: a case-control study

Xiong MY, Rabkin MS, Piepkorn MW, Barnhill RL, Argenyi, Z, Erickson L et al. J Am Acad Dermatol 2014; 71(6): 1257–8 e4.

In this study, 86 melanoma patients and their spouses had their most atypical nevus biopsied. Nine dermatopathologists, who were blinded to the source, were asked to evaluate the lesions. Interestingly the diameter of the lesion was associated with melanoma status in the person sampled. The degree of histologic dysplasia was however no more common in melanoma cases than controls in a multivariate analysis. Training of observers increased the concordance between them.

Selective use of sequential digital dermoscopy imaging allows a cost reduction in the melanoma detection process: a Belgian study of patients with a single or a small number of atypical nevi

Tromme I, Devleesschauwer B, Beutels P, Richez P, Praet N, Sacre L, et al. PLoS One 2014; 9(10): e109339.

In this retrospective study, dermoscopy and surgery for sufficiently atypical nevi were compared with dermoscopic imaging and possible delayed excision on review. In the dermoscopy and surgery group, 640 excisions were performed in 603 individuals, and the ratio of melanoma/nonmelanoma lesions excised was 1 to 8. In the dermoscopic imaging group, 111 excisions were carried out in 219 patients with a ratio of 1 melanoma to 2.5 nonmelanoma lesions overall.

This study is interesting and suggests an overall estimated cost difference per melanoma excised of 548 euros between the two groups, favoring the approach of dermoscopy imaging and delayed excision where appropriate. It is difficult to fully evaluate, however, as the two approaches were used in very different clinical settings. Dermoscopy and excision were carried out by 12 dermatologists in a

mixture of private and public settings, whereas digital dermoscopy imaging with delayed excision was performed by 2 dermatologists in a specialist clinic.

The impact of multispectral digital skin lesion analysis on German dermatologist decisions to biopsy atypical pigmented lesions with clinical characteristics of melanoma

Winkelmann RR, Hauschild A, Tucker N, White R, Rigel DS. *J Clin Aesthet Dermatol* 2015; 8(10): 27–9.

This study of 41 dermatologists attending a conference examined whether or not multispectral digital skin lesion analysis (MSDSLA) could improve the diagnostic accuracy of atypical pigmented lesions. This handheld device produces a score of disorganization and the likelihood of melanoma/dysplastic nevi in <1 minute per lesion. The dermatologists first diagnosed 12 lesions based on dermoscopic images: these were a mixture of melanoma, melanoma in situ, and dysplastic nevi. Diagnoses were then made after additional MSDSLA information was given.

Using MSDSLA, the overall accuracy improved by 8% ($p < 0.001$) and the data suggested a potential reduction of 16% in the biopsy rate of dysplastic nevi ($p < 0.001$). In the future, larger studies on MSDSLA will be helpful to see how useful and cost effective it could be in clinical practice. A limitation is that the device cannot be used for thicker lesions (>2.5 mm).

Impact of guidance from a computer-aided multispectral digital skin lesion analysis device on decision to biopsy lesions clinically suggestive of melanoma

Rigel DS, Roy M, Yoo J, Cockerell CJ, Robinson JK, White R. *Arch Dermatol* 2012; 148(4): 541–3.

In this study, 179 dermatologists attending a conference were asked whether or not they would biopsy 24 lesions. They were first provided with dermoscopic images only and then asked again after MSDSLA information. The average true positive rate before and after MSDSLA was 69% and 94%, respectively, but the true negative rate decreased from 54% to 40% after MSDSLA. Although the addition of information from MelaFind led to an increase in sensitivity, there was a reduction in specificity. The number of lesions evaluated was small. It is not clear whether or not the dermatologists had a special interest in pigmented lesions, which could affect the results.

To excise or not: impact of MelaFind on German dermatologists' decisions to biopsy atypical lesions

Hauschild A, Chen SC, Weichenthal M, Blum A, King HC, Goldsmith J, et al. *J Dtsch Dermatol Ges Deutsche* 2014; 12(7): 606–14.

In this online survey, 101 dermatologists evaluated 130 lesions using dermoscopic images, 101 had additional information from MelaFind, a computerized imaging system, and 9 pigmented skin lesion experts used dermoscopic images alone. The lesions included dysplastic nevi and early melanomas (ranging from in situ to 1.2 mm thick). The average number of melanomas that would have been missed with and without MelaFind information was 14 and 20, respectively. Although there was less likelihood of missing a melanoma using MelaFind, the biopsy rate would probably increase: MelaFind alone had a sensitivity of 97% but a specificity of only 9%. This study focused on early melanomas, which may be more difficult to diagnose.

First-Line Therapies

Consensus statement: addressing the knowledge gap in clinical recommendations for management and complete excision of clinically atypical nevi/dysplastic nevi **Pigmented Lesion Subcommittee consensus statement**

Kim CC, Swetter SM, Curiel-Lewandrowski C, Grichnik JM, Grossman D, Halpern AC, et al. *JAMA Dermatol* 2015; 151(2): 212–8.

This consensus statement from the Pigmented Lesion Subcommittee of the Melanoma Prevention Working Group Party addressed the management of dysplastic nevi with positive surgical margins but without residual clinical pigmentation. The committee judged that lesions suspicious for melanoma should be completely excised with narrow margins, whereas clinically atypical nevi could be monitored clinically. Additional recommendations were as follows: If there are positive margins and there is still doubt that the lesion could be a melanoma, reexcision is advised. Reexcision of dysplastic nevi with positive margins is recommended if the clinical suspicion for melanoma is high, even if the histology shows low-grade dysplasia. If there is severe dysplasia and positive margins, the lesion should be reexcised with a 2- to 5-mm margin. No further excision is needed for mildly and moderately dysplastic nevi with

clear histologic margins. Clinical observation is recommended for mildly dysplastic nevi with positive histologic margins but no residual clinical pigmentation. There is insufficient evidence for the management of moderately dysplastic lesions, but clinical observation may be appropriate. All biopsied sites should be monitored for recurrence, and patients should be counseled about how to do this.

Several studies have looked at the surgical approach to atypical pigmented lesions. Cheng et al performed a retrospective study of 607 melanocytic lesions that had been punch or shave biopsied and found that the rate of positive margins was comparable for each procedure. [Cheng R, Bialis RW, Chiu ST, Lawrence TJ, Lesesky EB. Punch biopsy vs. shave biopsy: a comparison of margin status of clinically atypical pigmented lesions. *Br J Dermatol*, 2015; **173**(3): 849–51.] However, positive margins were more likely with punch rather than shave biopsy when the trephine size was only 1 mm greater than the lesion. Lozeau et al performed a retrospective study of dysplastic nevi where a histopathologic diagnosis was provided without any grading of the degree of dysplasia. Two thirds of 17,024 nevi had positive margins, and of the 11% of cases where reexcision was advised, 80% had no residual melanocytic lesion; however, melanoma was diagnosed in 2% upon reexcision [Lozeau DF, Farber MJ, Lee JB. A nongrading histologic approach to Clark (dysplastic) nevi: a potential to decrease the excision rate. *J Am Acad Dermatol* 2016; 74: 68–74]. A study by Strazzula et al found positive margins in 42% of dysplastic nevi. Sixty-five per cent were reexcised: 18% had a residual atypical nevus and 2% were upgraded to severely dysplastic nevi. The authors suggest clinical monitoring of mild-to-moderately dysplastic nevi with positive histopathologic margins in view of the low yield on reexcision and the proposed low risk of malignant transformation [Strazzula L, Vedak P, Hoang MP, Sober A, Tsao H, Kroshinsky D. The utility of reexcising mildly and moderately dysplastic nevi: a retrospective analysis. *J Am Acad Dermatol* 2014; 71(6): 1071–6]. In Britain, the emphasis is on complete excision, with a 2-mm margin, as this provides the pathologist with the best information for diagnosis [Marsden JR, Newton-Bishop JA, Burrows L, Cook M, Corrie PG, Cox NH, et al. Revised U.K. guidelines for the management of cutaneous melanoma 2010. *Br J Dermatol* 2010; 163(2): 238–56]. The position of Strazzula et al to monitor these lesions clinically is held to be less feasible from an economic perspective: it is best to excise the lesion completely to minimize the risk of missing melanoma and to reduce

the need for further clinical follow-up.

Management of dysplastic nevi: a 14-year follow-up survey assessing practice trends among US dermatologists

Winkelman RR, Rigel DS. *J Am Acad Dermatol* 2015; 73(6): 1056–9.

In this follow-up survey, 78% of U.S. dermatologists in 2015 thought that patients with dysplastic nevi have an increased risk of melanoma compared with 59% in 2001. In spite of this, 69% aimed to completely excise dysplastic nevi in 2015 compared with 86% in 2001. In severely dysplastic nevi with positive margins, the vast majority of dermatologists would reexcise (98%), compared with 67% for moderate and 12% for mildly dysplastic nevi with positive margins. About half of dermatologists would not reexcise if the surgical margins were negative, but 39% would reexcise if the lesion was a severely dysplastic nevus (vs. 57% in 2001). The use of dermoscopy increased by 56% during the study interval.

The MPATH-Dx reporting schema for melanocytic proliferations and melanoma

Piepkorn MW, Barnhill RL, Elder DE, Knezevich SR, Carney PA, Reisch LM, et al. *J Am Acad Dermatol* 2014; 70(1): 131–41.

The Melanocytic Pathology Assessment Tool and Hierarchy for Diagnosis (MPATH-Dx) reporting system was developed in an effort to standardize the histopathologic reporting of melanocytic lesions. This tool includes a management recommendation.

Three dermatopathologists designed this reporting system over the course of a year. They initially performed a blinded, independent review of 240 randomly chosen melanocytic lesions from a database. They subsequently met several times to jointly assess 279 lesions and to reach a consensus about the diagnosis. Seven diagnostic categories were described, ranging from benign melanocytic lesions to melanoma. A treatment recommendation was provided, based on the pathologists' suspicion of risk. This included options such as no further treatment or wide local excision. The reliability and feasibility in clinical practice will be explored in future studies.

Autoimmune progesterone dermatitis

Ian Coulson, Adam Daunton, and Tashmeeta Ahad

Autoimmune progesterone dermatitis is an uncommon cyclical pruritic dermatosis affecting women of childbearing age. The diagnosis is suggested by premenstrual flares and improvement during pregnancy. It can present in a variety of morphologies, including eczematous, vesicular, and papulovesicular, with urticarial and erythema multiforme-like lesions the commonest. Angioedema

or anaphylaxis may accompany the skin eruptions. Hypersensitivity after exposure to exogenous progesterone, usually in the form of an oral contraceptive pill, has been implicated in some cases of autoimmune progesterone dermatitis. Endogenous progesterone may also serve as a trigger for autoimmune progesterone dermatitis in cases arising during menarche or pregnancy. The diagnosis is one of exclusion and is based upon the occurrence of cyclical premenstrual flares, the response to inhibition of ovulation, and the results of intradermal testing and hormone challenge.

Management Strategy

The mainstay of treatment is to *inhibit endogenous progesterone secretion* by suppressing ovulation. Classically, *conjugated estrogens* 0.625 to 1.25 mg daily in a 21-day cycle was a mainstay of therapy, but recently this treatment has been supplanted by gonadotropin-releasing hormone (GnRH) agonists. A transient worsening of the skin eruption is expected after initial treatment with GnRH agonists, with improvement thereafter. A major side effect of GnRH agonists is loss of bone density, which generally limits their use to 6 months of therapy. However, concomitant administration of osteoprotective agents may partly mitigate this risk and may allow longer treatment in carefully selected cases. Patients frequently require estrogen replacement while on GnRH agonist therapy.

The *antiestrogen tamoxifen*, 20 mg daily or 10 mg twice a day, exerts its effect by interfering with clinical estrogen sensitivity, possibly by competitive binding of the estrogen receptors.

Oral contraceptive pills have been implicated in triggering some cases of autoimmune progesterone dermatitis. However, in patients naïve to exogenous progesterone, inducing anovulation with oral contraceptive pills may be successful.

Mild cases of autoimmune progesterone dermatitis may be controlled with *short courses of systemic corticosteroids* before the luteal phase of the menstrual cycle. Very limited disease may respond to potent *topical corticosteroids and oral antihistamines*.

Danazol 200 mg twice daily for 1 to 2 days before menses and continued for 3 days thereafter may prevent the skin eruptions by inhibiting pituitary gonadotropins.

For severe, intractable cases, bilateral oophorectomy is curative. Autoimmune estrogen dermatitis is a separate entity that can be

difficult to distinguish clinically from autoimmune progesterone dermatitis. Intradermal testing that is positive to estrone and negative to progesterone clarifies the diagnosis. Autoimmune estrogen dermatitis responds to tamoxifen, progesterone, and oophorectomy.

The only alternative approach to the inhibition of endogenous progesterone production by suppressing ovulation is progesterone desensitization. This represents the only treatment option that preserves a patient's fertility, and it may be especially useful for patients undergoing in vitro fertilization (IVF) treatment, who are required to take high doses of exogenous progesterone.

There is wide variation between desensitization protocols. There is also a theoretical concern that desensitization treatment could aggravate latent autoimmunity in genetically predisposed women.

Specific Investigations

- Intradermal testing with progesterone
- Progesterone challenge (oral or intravaginal)
- Enzyme-linked immunosorbent assay (ELISA) and ELISpot testing

Different authors have advocated intradermal testing with progesterone in varying amounts and dilutions. One common method of intradermal testing is with 0.1 mL of aqueous progesterone suspension at 100 mg/mL diluted with normal saline to 0.1 mg/mL, 0.01 mg/mL, and 0.001 mg/mL, with normal saline serving as the control. There may be an immediate urticarial reaction within 30 minutes, or a delayed-type hypersensitivity reaction at 24 to 48 hours.

Progesterone challenge may also be attempted intramuscularly (medroxyprogesterone 10–20 mg) or orally (10 mg) in the first half of the menstrual cycle. Intramuscular skin testing with the depot form of medroxyprogesterone acetate is not advised because of the risk of severe systemic reactions.

ELISA and ELISpot testing can detect elevated levels of IFN- γ -producing peripheral blood mononuclear cells in response to progesterone.

If progesterone testing is negative, consider estrogen sensitivity. Intradermal testing with either estrone (0.1 mL at 1 mg/mL) or conjugated estrogen (0.1 mL of 1, 10, and 100 μ g/mL) can be attempted. A positive reaction may be immediate or delayed for

several hours and should persist for more than 24 hours.

The use of a progesterone pessary has recently been proposed as an effective tool in the diagnosis of autoimmune progesterone dermatitis.

Autoimmune progesterone dermatitis: update and insights

Nguyen T, Ahmed R. *Autoimmun Rev* 2016; 15: 191–7.

A systematic review of the 89 cases published in English, examining diagnostic tests and treatment methods.

Sixty four of sixty seven patients who underwent an intradermal progesterone challenge experienced a positive response within 24 hours. All six patients who underwent an intramuscular challenge experienced a positive response. One patient was diagnosed after an intravaginal challenge. The remaining patients did not undergo a progesterone challenge.

Complete remission was attained in 4/86 (5%) patients without any intervention. Fourteen of eighty six (16%) patients eventually underwent bilateral oophorectomy after failure of other treatment modalities, and all subsequently attained complete remission. Of 7 patients who underwent desensitization therapy, 4/7 (57%) attained complete remission, and 1/47 (14%) attained partial control. Four of twelve (33%) attained complete remission on GnRH analogs, whereas 3/12 attained partial remission. Five of five patients treated with tamoxifen attained a partial remission. One of nineteen patients treated with conjugated estrogen/ethinyl estradiol attained a complete remission, and 8/19 attained a partial remission. Seven of nine patients treated with the combined oral contraceptive pill attained a partial remission.

The role of intradermal skin testing and patch testing in the diagnosis of autoimmune progesterone dermatitis

Stranahan D, Rausch D, Deng A, Gaspari A. *Dermatitis* 2006; 17: 39–42.

A case report and a detailed review of the various methods of performing intradermal progesterone testing, highlighting the need for standardization.

Progesterone sensitive interferon- γ -producing cells detected by ELISpot assay in autoimmune progesterone dermatitis

Cristaudo A, Bordignon V, Palamara F, De Rocco M, Pietravalle M, Picardo M. *Clin Exp Dermatol* 2007; 32: 439–41.

Describes the ELISpot technique of diagnosing autoimmune progesterone dermatitis.

Estrogen dermatitis

Kumar A, Georgouras KE. *Australas J Dermatol* 1999; 40: 96–8.

A case report comparing progesterone dermatitis and estrogen dermatitis, as well as useful information on the technique and interpretation of intradermal testing for both disorders.

Iatrogenic autoimmune progesterone dermatitis caused by 17 alpha-hydroxyprogesterone caproate for preterm labor prevention

Bandino JP, Thoppil J, Kennedy JS, Hivnor CM. *Cutis* 2011; 88: 241–3.

A 30-year-old woman, gravida 2, para 1, developed autoimmune progesterone dermatitis 4 days after her third injection of 17- α -hydroxyprogesterone caproate (17P), presenting as an urticarial exanthema. Direct immunofluorescence was negative. The injections were discontinued and lesions resolved within 7 days.

The use of progestational agents, most recently 17P, to reduce preterm labor for patients at risk may result in more cases of autoimmune progesterone dermatitis being recognized.

First-Line Therapies

• Gonadotropin-releasing hormone agonists	A
• Tamoxifen	D
• Oral contraceptive pill	E
• Oral corticosteroids	E
• Potent topical corticosteroids	E
• Antihistamines	E

Recurrent anaphylaxis in menstruating women. Treatment with a luteinizing hormone-releasing hormone agonist – a preliminary

report

Slater JE, Raphael G, Cutler GB, Loriaux DL, Meggs WJ, Kaliner M. *Obstet Gynecol* 1987; 70: 542–6.

A double-blind, placebo-controlled crossover study of four women with cyclic anaphylaxis associated with progesterone secretion. Two of the subjects experienced dramatic reduction in the severity and number of attacks while receiving an investigational luteinizing hormone-releasing agonist imbzl-D-his⁶-pro⁹-NEt-LHRH, 4 µg/kg/day for 4 months. Liaison with a gynecologic endocrinologist may help in the selection of an appropriate GnRH agonist and estrogen combination of therapies.

Autoimmune progesterone dermatitis: a diagnosis easily missed

Toms-Whittle L, John L, Griffiths D, Buckley D. *Clin Exp Dermatol* 2010; 36: 378–80.

Successful treatment with intranasal buserelin 150 µg thrice daily. Symptoms recurred after cessation of buserelin after the maximum licensed period of 6 months, and consideration is being given to continuing it off-license with osteoprophylaxis.

Autoimmune progesterone dermatitis

Cocuroccia B, Gisondi P, Gubinelli E, Girolomoni G. *Gynecol Endocrinol* 2006; 22: 54–6.

Treatment with tamoxifen 20 mg daily produced complete and durable clearing of the eruption after 3 months.

A case of autoimmune progesterone dermatitis in an adolescent female

Kakarla N, Zurawin RK. *J Pediatr Adolesc Gynecol* 2006; 19: 125–9.

A case report describing a patient with no prior exogenous hormone exposure who cleared on oral contraceptive therapy. For patients naïve to exogenous progesterone, an oral contraceptive pill is considered to be first-line therapy (the preparation used contained 30 µg of ethinyl estradiol and 0.15 mg of levonorgestrel).

Autoimmune progesterone dermatitis

Anderson RH. *Cutis* 1984; 33: 490–1.

A case successfully treated with prednisolone 20 mg/day for 10 days during menstruation. The dosage of prednisolone was reduced slowly over several cycles, and the patient was eventually managed

on topical corticosteroids only.

Autoimmune progesterone dermatitis associated with infertility treatment

Jenkins J, Geng A, Robinson-Bostom L. J Am Acad Dermatol 2008; 58: 353–5.

Oral contraceptives and GnRH agonists were contraindicated in this patient undergoing treatment for infertility. The limited disease was well controlled with halobetasol propionate 0.05% cream.

Autoimmune progesterone dermatitis. Case report with histologic overlap of erythema multiforme and urticaria

Walling HW, Scupham RK. Int Soc Dermatol 2008; 47: 380–2.

Durable improvement on cetirizine 10 mg every morning and hydroxyzine 10 mg at bedtime taken on the days of the menstrual cycle previously associated with skin eruptions.

Second-Line Therapies

• Conjugated estrogens	E
• Danazol	E
• Azathioprine	E
• Progesterone desensitization	D

Autoimmune progesterone anaphylaxis

Bemaniah MH, Gharagozlu M, Farashahi MH, Nabavi M, Shirkhoda Z. Iran J Allergy Asthma Immunol 2007; 6: 97–9.

A case report of a patient with perimenstrual urticaria associated with angioedema and respiratory symptoms, all of which improved on conjugated estrogen 0.625 mg once daily.

Autoimmune progesterone dermatitis: effective prophylactic

treatment with danazol

Shahar E, Bergman R, Pollack S. *Int J Dermatol* 1997; 36: 708–11.

Successful prophylactic treatment with danazol in two patients at a dose of 200 mg twice daily, starting 1 to 2 days before menstruation and continuing for 3 days thereafter.

Case 2. Diagnosis: erythema multiforme as a presentation of autoimmune progesterone dermatitis

Warin AP. *Clin Exp Dermatol* 2001; 26: 107–8.

Successful treatment with azathioprine 100 mg daily.

Autoimmune progesterone dermatitis: clinical presentation and management with progesterone desensitization for successful in vitro fertilization

Prieto-Garcia A, Sloane DE, Gargiulo AR, Feldweg AM, Castells M. *Fertil Steril* 2011; 95: 1121.e9–13.

Six patients with documented autoimmune progesterone dermatitis were desensitized by a rapid 8- or 10-step protocol, receiving escalating intravaginal progesterone suppositories. The initial dose of intravaginal progesterone was either 0.05 or 0.1 mg. The same dose was repeated for a total of two to three doses, before being increased by a factor of 10. This pattern was completed for a total of 8 to 10 doses. Intravaginal suppositories were administered every 20 minutes. One of the patients received an oral protocol. Four patients achieved desensitization. Three patients received successful IVF subsequently.

Iatrogenic autoimmune progesterone dermatitis treated with a novel intramuscular progesterone desensitization protocol

Hill JL, Carr TF. *J Allergy Clin Immunol Pract* 2013; 1: 537–8.

A single case of a patient desensitized with an intramuscular progesterone protocol.

Autoimmune progesterone dermatitis

Soloman M, Itsekson A, Lev-Sagie A. *Curr Derm Rep* 2013; 2: 258–63.

Authors' description of their own protocol for both diagnosis and desensitization. For desensitization, they suggest monthly intradermal progesterone injections, commencing with 0.04 mL of 50 mg/mL progesterone, doubled each month for a total of 3 months.

Third-Line Therapy

• Bilateral oophorectomy

E

Autoimmune progesterone dermatitis: treatment with oophorectomy

Medeiros S, Rodrigues-Alves R, Costa M, Afonso A, Rodrigues A, Cardoso J. Clin Exp Dermatol 2010; 35: e12–3.

Bilateral oophorectomy was curative in this case of autoimmune progesterone dermatitis that was unresponsive to oral corticosteroids and GnRH agonist.

Bacillary angiomatosis

Lucy J. Thomas, and Richard C.D. Staughton

First described in 1983, bacillary angiomatosis (BA) is a vasculoproliferative disorder caused by the *intraerythrocytic* bacteria *Bartonella henselae* and *Bartonella quintana* (previously *Rochalimaea* spp.). It typically presents in profoundly immunocompromised patients (e.g., advanced HIV infection, posttransplant or during cytotoxic chemotherapy), although the incidence in patients receiving newer biologic therapies is unknown. Cutaneous lesions can be superficial, cherry-red, round papules with an eroded surface, similar to pyogenic granulomas; violaceous, lichenoid plaques; or deep

subcutaneous nodules. Single lesions have been reported in immunocompetent patients at inoculation sites, whereas in the immunocompromised the entire body surface may be affected. Lesions can be mistaken for Kaposi sarcoma or in-transit metastatic amelanotic melanoma because of the highly vascular and erosive nature of the lesions. In advanced HIV deep fungal infection (e.g., cryptococcosis and histoplasmosis) should also be considered. Patients with extracutaneous disease may or may not have skin signs and can present with vomiting, abdominal pain, and deranged liver function (peliosis hepatis) or pancytopenia and splenomegaly (peliosis splenis). Fever, lymphadenopathy, night sweats, endocarditis, blindness, and anemia can also be present.

B. henselae is transmitted through a cat scratch or bite and can also result in a localized skin papule and regional lymphadenitis known as *cat scratch disease*. *B. quintana* is transmitted by the human body louse and also causes trench fever (fever, headache, dizziness, and shin pain). Localized cutaneous lesions virtually identical to BA and typically in immunocompetent individuals are seen in verruga peruana, which occurs in Peru, Ecuador, and Colombia due to *B. bacilliformis*, which is transmitted by sandflies. Preceding acute infection known as *Oroya fever/Carrion disease* results in massive hemolytic anemia with >85% mortality if untreated.

Management Strategy

Prompt diagnosis is essential to prevent dissemination, which can be fatal. Clinical suspicion should be aroused in the context of a low CD4 lymphocyte count (<100) or other immunosuppression, especially with a history of exposure to cats (>35% harbor *B. henselae*) or body lice (*B. quintana*). Treatment is determined by species, clinical course, and immunologic status.

The response of bacillary angiomatosis to antibiotic treatment is usually dramatic, in contrast to cat scratch disease. Due to antiinflammatory and antiangiogenic effects *erythromycin* is our first-line therapy at a dose of 500 mg four times daily, but *doxycycline* 100 mg twice daily is also consistently successful. In severe or complicated disease either of these drugs combined with rifampicin 300 mg twice daily has been advocated and intravenous treatment may be required. Treatment should be continued for 3 months where there is only skin disease and 4 months where there is bone/visceral

involvement. Should relapse occur on these regimens, long-term prophylaxis with erythromycin or doxycycline may be indicated. However, in practice highly active antiretroviral therapy (HAART) should reverse the immunocompromised state, making long-term antibiotic therapy less necessary. The patient should be evaluated for parenchymal and osseous disease before treatment and warned that a Jarisch–Herxheimer reaction may occur after the first few doses of antibiotic.

In the case of verruga peruana oral rifampicin at a dose of 10 mg/kg/day for 2 to 3 weeks achieved a cure in over 93% of patients. Streptomycin (15–20 mg/kg/day for 2–3 weeks) has a reported cure rate of 56% and is therefore considered second line.

In the absence of randomized clinical trials, treatment is guided by anecdotal experience, retrospective cohort studies/case series, and microbiologic susceptibility data. A wide variety of therapeutic agents are mentioned in the literature, but there is a lack of correlation between the in vitro and in vivo drug susceptibility of *Bartonella* spp., which reduces the usefulness of laboratory data. The picture is clouded further by the different response of *Bartonella* spp. to drugs in each of the diseases it causes.

Specific Investigations

- Full blood count, liver function tests, HIV serology, and CD4 lymphocyte count
- Biopsy and Warthin–Starry stains/electron microscopy
- Prolonged culture of blood and biopsy tissue
- Polymerase chain reaction (PCR) of biopsy material
- Serology – indirect fluorescence assay

Multiple investigations are frequently required to confirm infection. Culture of the fastidious gram-negative rods of *Bartonella* spp. is extremely difficult, requiring special media and prolonged incubation of up to 45 days; it is invariably negative if antibiotics have been given. Skin biopsy is the essential diagnostic tool and shows a characteristic lobular proliferation of capillaries and venules with swollen endothelial cells containing clumps of bacteria. *Bartonella* spp. can also be visualized using the Warthin–Starry silver stains or electron microscopy and PCR can confirm the species. Reliance on serology in the immunosuppressed is hazardous, but the Centers for

Disease Control (CDC) definition of a positive test is an indirect fluorescence assay (IFA) titer >1:64.

Bacillary angiomatosis and bacillary peliosis in patients infected with human immunodeficiency virus: clinical characteristics in a case–control study

Mohle-Boetani JC, Koehler JE, Berger TG, LeBoit PE, Kemper CA, Reingold AL, et al. Clin Infect Dis 1996; 22: 794–800.

Forty-two cases were compared with 84 matched controls and the distinguishing clinical characteristics were evaluated. Significant differences included the presence of anemia (hematocrit <0.36), raised alkaline phosphatase and aspartate aminotransferase levels, and a low CD4 lymphocyte count (median being 21/mm³ compared with 186/mm³ in controls). Clinical signs included fever, abdominal pain, and lymphadenopathy.

Bacillary angiomatosis in immunocompromised patients

Gasquet S, Maurin M, Brouqui P, Lepidi H, Raoult D. AIDS 1998; 12: 1793–803.

Diagnosis remains mainly based on histologic appearance. On hematoxylin and eosin stains the appearance can be highly variable and so Warthin–Starry stains are essential to visualize the bacillus and confirm the diagnosis.

Laboratory diagnosis of *Bartonella* infections

Agan BK, Dolan MJ. Clin Lab Med 2002; 22: 937–62.

Culture methods have improved, but are still prolonged. Serologic testing for *B. henselae* has become the cornerstone for diagnosis in the immunocompetent patient. Ideal antigens for enzyme immunoassays have yet to be clearly identified. PCR currently offers the ability to establish the diagnosis when other tests fail.

Culture of *Bartonella quintana* and *Bartonella henselae* from human samples: a 5-year experience (1993–1998)

La Scola B, Raoult D. J Clin Microbiol 1999; 37: 1899–905.

In the large number of samples cultured, seven patients were diagnosed with bacillary angiomatosis. PCR was 100% sensitive in diagnosing these cases, in contrast to culture, which isolated *Bartonella* spp. from only three specimens. Serology was of no value, being positive in only one patient.

Rapid identification and differentiation of *Bartonella* species using a single step PCR assay

Jensen WA, Fall MZ, Rooney J, Kordick DL, Breitschwerdt EB. J Clin Microbiol 2000; 38: 1717–22.

The single-step assay described provided a simple and rapid means of identifying *Bartonella* spp.

First-Line Therapies

• Erythromycin	C
• Doxycycline	C
• Rifampicin	C

Pathogenicity and treatment of *Bartonella* infections

Angelakis E, Raoult D. Int J Antimicrob Agents 2014; 44: 16–25.

An excellent review of existing data and treatment recommendations for all *Bartonella* infections based on pathogenicity. A table clearly summarizes the various organisms, disease manifestations, and current treatment regimens (including doses and durations).

Treatment outcomes of human bartonellosis: a systematic review and meta-analysis

Prutsky G, Domecq JP, Mori L, Bebeko S, Matzumura M, Sabouni A, et al. Int J Infect Dis 2013; 17: e811–9.

This systematic review of treatment regimens for *B. henselae*, *B. quintana*, and *B. bacilliformis* identified only two randomized controlled trials analyzing the treatment of cat scratch disease and chronic bacteremia along with seven observational studies. With

respect to BA they concluded that erythromycin might be better than other antibiotics but there was no statistically significant difference compared with doxycycline.

Molecular diagnosis of deep nodular bacillary angiomatosis and monitoring of therapeutic success

Schlupen E-M, Schirren CG, Hoegl L, Schaller M, Volkenandt M. Br J Dermatol 1997; 136: 747–51.

An HIV-positive man presented with a 10-month history of bacillary angiomatosis on his ankle and was treated with erythromycin 500 mg four times daily. The swabs became negative on PCR at 12 weeks, at which point treatment was successfully stopped.

Clarithromycin therapy for bacillary peliosis did not prevent bacillary angiomatosis

Mukunda BN, West BC, Shekar R. Clin Infect Dis 1998; 27: 658.

A patient with AIDS presented with bacillary peliosis and was initially treated for a presumed *Mycobacterium avium intracellulare* complex infection with clarithromycin, ciprofloxacin, and rifabutin. He continued to be febrile and represented 15 days later with bacillary angiomatosis. This swiftly responded to doxycycline, which was continued for 6 weeks.

AIDS commentary: bacillary angiomatosis and bacillary peliosis in patients infected with human immunodeficiency virus

Koehler JE, Tappero JW. Clin Infect Dis 1993; 17: 612–4.

This review article refers to 50 patients whose lesions and symptoms responded to erythromycin or doxycycline therapy.

Molecular epidemiology of *Bartonella* infections in patients with bacillary angiomatosis-peliosis

Koehler JE, Sanchez MA, Garrido CS, Whitfeld MJ, Chen FM, Berger TG, et al. N Engl J Med 1997; 337: 1876–83.

A case–control study of 49 patients (92% HIV positive) in whom macrolides, doxycycline, tetracycline, and rifampin were found to be effective. This was in contrast to patients treated with trimethoprim–sulfamethoxazole, ciprofloxacin, penicillins, and cephalosporins in whom *Bartonella* spp. could be isolated on PCR or culture.

Bacillary angiomatosis: presentation of six patients, some with

unusual features

Schwartz RA, Nychay SG, Janniger CK, Lambert WC. Br J Dermatol 1997; 136: 60–5.

This article describes a variety of successful treatment regimens, including tetracycline and ciprofloxacin.

Although rifampicin has activity in vitro, its efficacy when used alone has not yet been established and so it is recommended in combination with either erythromycin or doxycycline for severely ill patients or where there is neurologic involvement (doxycycline has good central nervous system [CNS] penetration). Rifampicin monotherapy is, however, effective in the treatment of verruga peruana (B. bacilliformis).

Second-Line Therapies

• Azithromycin	C
• Clarithromycin	C
• Streptomycin	D

MICs of 28 antibiotic compounds for 14 *Bartonella* (formerly *Rochalimaea*) isolates

Maurin M, Gasquet S, Ducco C, Raoult D. Antimicrob Agents Chemother 1995; 39: 2387–91.

The newer macrolides were highly effective in preventing bacterial growth with MIC 90s of 0.03 µg/mL for azithromycin and clarithromycin. Erythromycin, doxycycline, and rifampin all had MIC 90s of 0.25 µg/mL.

Recommendations for the treatment of human infections caused by *Bartonella* species

Rolain JM, Brouqui P, Koehler JE, Maguina C, Dolan MJ, Raoult D. Antimicrob Agents Chemother 2004; 48: 1921–33.

A good review article. Although erythromycin and azithromycin are the authors' first-line treatments for bacillary angiomatosis, their use has been based on case series and case reports rather than on controlled clinical trials.

Bartonellosis (Carrion's disease) in the modern era

Maguina C, Garcia PJ, Gotuzzo E, Cordero L, Spach DH. Clin Infect Dis 2001; 33: 772–9.

Case series of patients with verruga peruana who demonstrated a good response to treatment with rifampicin (80%) and streptomycin (56%).

Third-Line Therapies

• Gentamicin	E
• Third- and fourth-generation cephalosporins	E

Lack of bactericidal effect of antibiotics except aminoglycosides on *Bartonella (Rochalimaea) henselae*

Musso D, Drancourt M, Raoult D. J Antimicrob Chemother 1995; 36: 101–8.

Aminoglycosides display in vitro bactericidal activity against *Bartonella* spp. and as such warrant further clinical investigation. For culture-positive *Bartonella* endocarditis, doxycycline for 6 weeks plus intravenous gentamicin for the first 14 days are recommended.

Bacillary angiomatosis in a pregnant patient with acquired immunodeficiency syndrome

Riley LE, Tuomala RE. Obstet Gynecol 1992; 79: 818–9.

A pregnant patient was treated with a third-generation cephalosporin, ceftizoxime. However, there are inadequate data to recommend use at present.

Balanitis

Tia M. Pyle, and Warren R. Heymann

Balanitis is a general term for inflammation of the glans penis, which may also extend to the foreskin (prepuce). It may be seen in all age groups and occurs more frequently in the uncircumcised. Etiologies include inflammatory, infectious, and neoplastic disorders. All types of balanitis may be aggravated by poor hygiene, warmth, and friction. This chapter will focus on Zoon balanitis and balanitis xerotica obliterans (BXO, lichen sclerosus).

Balanitis plasmacellularis (Zoon balanitis interchangeably)

represents a nonvenereal, nonspecific, chronic inflammation of the glans penis occasionally extending to the foreskin. The presentation is almost exclusively in uncircumcised men past the second decade of life. The shiny, red, sharply demarcated patch is often asymptomatic, though symptoms of pruritus, dysuria, and pain may be reported. The evaluation for Zoon balanitis should include thorough history and clinical workup to exclude genital herpes, secondary syphilis, and other etiologies of penile lesions. Zoon balanitis can also be associated with dermatoses of the genital area such as erosive lichen planus, lichen sclerosus, and penile psoriasis as a type of reaction pattern.

Other differentials (allergic contact dermatitis, erythroplasia of Queyrat or Bowen disease of the glans penis, and pemphigus vulgaris) should be ruled out. Biopsy demonstrates an atrophic epidermis with diamond-shaped keratinocytes overlying a predominately plasma cell-rich, bandlike infiltrate in the papillary dermis. Complications may include fissuring and pain, phimosis (inability to retract the foreskin due to agglutination/scarring), and stenosis or obstruction of the urethral meatus; surgical correction of sequelae may be necessary.

Lichen sclerosus (BXO) is treated similarly to Zoon (plasma cell) balanitis. Lichen sclerosus is also of unclear etiology, although an autoimmune pathogenesis associated with other conditions such as autoimmune thyroid disease, alopecia areata, and vitiligo may be involved. Histopathology confirms the diagnosis of BXO. This condition may be underrecognized in boys. It is important to identify the disorder and have continued follow-up because of the 4% to 5% lifetime risk of developing a squamous cell carcinoma.

Management Strategy

Evaluation of a patient with balanitis should include chief complaint, history of present illness, past medical and surgical history, medications, allergies, and review of systems. Specific information should be sought regarding sexual habits (number of encounters, gender, and symptomatology of sexual partners) and alleviating or exacerbating factors. To identify potential allergens and/or irritants, the patient's genital hygiene practices and the use of oral and topical agents (condoms, spermicides, sexual-enhancing products, lubricants, etc.) should be sought. A complete mucocutaneous examination,

including extragenital sites, should be performed. The genital examination includes skin and soft tissue structures extending from the lower abdomen to the perianal skin/gluteal cleft. Examination findings should direct the acquisition of microbiologic studies (KOH preparation; bacterial, fungal, and viral cultures), biopsy (hematoxylin and eosin, direct immunofluorescence), and serologic studies. Treatment of balanitis is dictated by results of these investigations.

Patients with balanitis should be instructed about appropriate local hygiene care, including retraction of the foreskin before cleansing. The glans and shaft should be cleaned with plain water or normal saline twice daily and after sexual activity. Soap and topical products may be irritants or allergens and should be avoided. A bland emollient (plain white petrolatum or similar agent) applied twice daily will minimize friction and improve barrier function.

Medical therapy for balanitis is directed by etiology. Circumcision is indicated in refractory cases. Urethral meatotomy or meatoplasty, glans resurfacing, and other surgical procedures may be required for patients with significant anatomic distortion or compromised urinary function. Collaboration with urologic specialists is essential.

Specific Investigations

- KOH microscopy for fungi
- Tzanck smear or direct fluorescent antigen testing for herpes viruses
- Swab culture for bacteria, viruses, and fungi
- Biopsy for routine histopathology and direct immunofluorescence, if indicated
- Fasting blood glucose
- Urinalysis and urine glucose
- Serologic tests for syphilis, herpes virus, and human immunodeficiency virus
- Serologic tests for vesiculobullous diseases (systemic lupus erythematosus, pemphigus vulgaris, bullous pemphigoid, etc.)
- Patch testing

2013 European guideline for the management of balanoposthitis

Edwards S, Bunker C, Ziller F, van der Meijden W. Int J STD AIDS

2014; 25: 615–26.

Comprehensive review of the many causes of balanitis with specific recommendations for evaluation and management.

Zoon balanitis: a comprehensive review

Dayal S, Sahu P. Indian J Sex Transm Dis 2016; 37: 129–38.

A complete review of Zoon balanitis with history, differential diagnosis, and treatment.

Balanitis xerotica obliterans in children and adolescents: a literature review and clinical series

Celis S, Reed F, Murphy F, Adams S, Gillick J, Abdelhafeez A, et al. J Ped Urol 2014; 10: 34–9.

A literature review of the diagnosis, treatment, and management of children under the age of 18 who were diagnosed with balanitis xerotica obliterans.

Dermoscopy in plasma cell balanitis: its usefulness in diagnosis and follow-up

Corazza M, Virgili A, Minghetti S, Toni G, Borghi A. J Eur Acad Dermatol Venereol 2016; 30: 182–4.

A case report showing dermoscopy findings of a “rusty,” spatterlike pattern with vascular prominence before treatment. Resolution revealed a rich vascular pattern after 3 months of twice-daily treatment with fusidic acid 2% and betamethasone valerate 0.1% cream-fixed combination (FA/BM). The “rusty” pattern persisted after treatment.

First-Line Therapies

• Hygiene	B
• Emollients	B

Clinical features and management of recurrent balanitis: association with atopy and genital washing

Birley HD, Walker MM, Luzzi GA, Bell R, Taylor-Robinson D, Byrne M, et al. *Genitourin Med* 1993; 69: 400–3.

Forty-three patients with recurrent balanitis were evaluated. Thirty-one patients diagnosed with irritant contact dermatitis had a greater lifetime incidence of atopy and more frequent genital hygiene habit; 90% responded to conservative treatment, use of emollient creams, and restriction of soap use.

Second-Line Therapies

• Topical antifungals	B
• Topical corticosteroids	A
• Circumcision	B

Candida balanitis: risk factors

Lisboa C, Santos A, Dias C, Azevedo F, Pina-Vaz C, Rodrigues A. *J Eur Acad Dermatol Venereol* 2010; 24: 820–6.

A prospective cross-sectional study of 478 men who attended a sexually transmitted diseases clinic revealed *Candida* balanitis in 18%, more than 40% of whom had a concomitant cause of balanitis. *Candida albicans* was the most common isolate. *Candida* colonization and infection were associated with age greater than 60 years and diabetes mellitus in males aged 40 years or older.

Comparison of the efficacy and safety of oral fluconazole and topical clotrimazole in patients with candida balanitis

Sary A, Soeltz-Szoets J, Ziegler C, Kinghorn G, Roy R. *Sex Transm Infect* 1996; 72: 98–102.

A randomized, open-label, parallel-group, multicenter study evaluating the efficacy of a single oral fluconazole dose of 150 mg compared with clotrimazole applied twice daily for 7 days in 157 men with candidal balanitis. The single 150-mg fluconazole dose was comparable in efficacy to 7 days of topical clotrimazole.

Lichen sclerosis: review of the literature and current recommendations for management

Pugliese JM, Morey AF, Peterson AC. J Urol 2007; 178: 2268–76.

Extensive review of the literature. Goals for treatment include symptomatic relief, prevention of scarring/anatomic distortion, and prevention of malignant transformation. An algorithmic approach to medical and surgical management of lichen sclerosis is provided with topical corticosteroids as first-line treatment.

Prevention of malignant transformation has not been assessed in the literature to date in the authors' opinion.

British Association of Dermatologists' guidelines for the management of lichen sclerosis 2010

Neill SM, Lewis FM, Tatnall FM, Cox NH. Br J Dermatol 2010; 163: 672–82.

Evidence-based recommendations for the evaluation and treatment of lichen sclerosis in men, women, and children. Topical corticosteroids are the treatment of choice. Testosterone is no longer recommended. Topical and systemic retinoids have not shown efficacy in uncomplicated lichen sclerosis, although they may be beneficial in recalcitrant cases. Surgery is only recommended when scarring and destruction have occurred. Circumcision is highly effective; recurrences and koebnerization have been documented.

Systematic review and meta-analysis of randomized controlled trials on topical interventions for genital lichen sclerosis

Chi C, Kirtschig G, Baldo M, Lewis F, Wang S, Wojnarowska F. J Am Acad Dermatol 2012; 67: 305–12.

Topical clobetasol propionate 0.05% applied for 3 months and mometasone furoate 0.05% applied for 5 weeks were both superior to placebo. Pimecrolimus 1% cream and clobetasol propionate 0.05% cream after 12 weeks of application were both effective at relieving pruritus and burning; there were no significant differences between clobetasol propionate and pimecrolimus. No evidence was found

supporting the topical use of androgens and progesterone.

Conservative treatment of phimosis with fluticasone propionate 0.05%: a clinical study in 1185 boys

Zavras N, Christianakis E, Mpourikas D, Ereikat K. J Pediatr Urol 2009; 5: 181–5.

A prospective study of 1185 boys with suspected phimosis using fluticasone propionate cream 0.05% (class 5 corticosteroid) twice daily for 4 to 8 weeks yielded successful resolution (full retraction of foreskin) in 91.1%.

Plasma cell balanitis of Zoon: response to Trimovate cream

Tang A, David N, Horton LW. Int J STD AIDS 2001; 12: 75–8.

Ten patients with plasma cell balanitis treated with a topical mixture of oxytetracycline 3%, nystatin 100,000 U/g, and clobetasone butyrate 0.05% (Trimovate) for 3 to 12 weeks had complete resolution. Four required retreatment(s).

Lichen sclerosus of the male genitalia and urethra: surgical options and results in a multicenter international experience with 215 patients

Kulkarni S, Berbagli G, Kirpekar D, Mirri F, Lazzeri M. Eur Urol 2009; 55: 945–54.

A total of 215 males (age range 11–85 years) with lichen sclerosus limited to the foreskin and/or external urethral meatus underwent circumcision or urethral reconstructive surgery. Thirty-four patients with foreskin-limited lichen sclerosus underwent circumcision with 100% success rate and no recurrences at mean follow-up of 65 months. Urethral involvement required more extensive surgical intervention with lower rates of success.

Plasma cell balanitis: clinical and histopathological features – response to circumcision

Kumar B, Sharma R, Rajagopalan M, Radotra BD. Genitourin Med 1995; 71: 32–4.

Twenty-seven patients with plasma cell balanitis were cured with circumcision. There were no recurrences at 3-year follow-up.

Plasma cell balanitis: clinicopathologic study of 112 cases and treatment modalities

Kumar B, Narang T, Dass Radotra B, Gupta S. J Cutan Med Surg 2006; 10: 11–5.

A study of 112 males with plasma cell balanitis demonstrated complete resolution and no recurrence in the 85 who underwent circumcision. Twenty-two of 27 showed healing at 2 to 3 months with topical therapy (corticosteroids, corticosteroids–antifungal, or tacrolimus).

Third-Line Therapies

• Topical tacrolimus	B
• Topical pimecrolimus	A/E
• Imiquimod	E
• CO ₂ laser	C
• Erbium:YAG laser	B
• Photodynamic therapy	E
• Acitretin	A

Multicentre, phase II trial on the safety and efficacy of topical tacrolimus ointment for the treatment of lichen sclerosis

Hengge UR, Krause W, Hofmann H, Stadler R, Gross G, Meurer M, et al. Br J Dermatol 2006; 155: 1021–8.

Prospective, multicenter phase II study of tacrolimus 0.1% ointment in 84 patients (49 women, 32 men, 3 girls) with lichen sclerosis twice

daily for 16 weeks demonstrated clearance of clinical disease in 43% and partial resolution in 34% at 24 weeks. Maximal response occurred at 10 to 24 weeks. No gender difference in response to therapy was noted.

Safety and tolerability of adjuvant topical tacrolimus treatment in boys with lichen sclerosus: a prospective phase 2 study

Ebert AK, Rosch WH, Vogt T. Eur Urol 2008; 54: 932–7.

Twenty boys with biopsy-confirmed lichen sclerosus underwent circumcision followed by topical tacrolimus 0.1% ointment twice daily for 3 weeks. All completed treatment without adverse side effects and no evidence of clinical disease at follow-up. Topical tacrolimus without circumcision was not evaluated.

Plasma cell balanitis of Zoon treated with topical tacrolimus 0.1%: report of 3 cases

Roe E, Dalmau J, Peramiquel L, Perez M, Lopez-Lozano HE, Alomar A. J Eur Acad Dermatol Venereol 2007; 21: 284–5.

Three patients with Zoon balanitis refractory to topical corticosteroids, antifungals, and antibacterials responded favorably to tacrolimus 0.1% ointment twice daily within 3 to 4 weeks.

Topical tacrolimus: an effective therapy for Zoon balanitis

Santos-Juanes J, Sanchez del Rio J, Galache C, Soto J. Arch Dermatol 2004; 140: 1538–9.

Complete remission was reported in three patients with Zoon balanitis after using topical tacrolimus 0.1% cream or ointment twice daily for 3 to 5 weeks. Mild irritation was noted in one patient.

Pimecrolimus 1% cream in non-specific inflammatory recurrent balanitis

Georgala S, Gregoriou S, Georgala C, Papaioannou D, Befon A, Kalogeromitros D, et al. Dermatology 2007; 215: 209–12.

A randomized controlled study of 26 men with nonspecific balanitis used pimecrolimus cream twice daily for 7 days. Seven of 11 men in the treatment group and 1 of 11 in the control group were free of all symptoms and lesions at day 14. As-needed use for 90 days showed good response.

Two cases of Zoon's balanitis treated with pimecrolimus 1%

cream

Bardazzi F, Antonucci A, Savoia F, Balestri R. Int J Dermatol 2008; 47: 198–201.

Two cases of resistant Zoon balanitis were treated with topical pimecrolimus 1% cream twice daily for 2 months. One patient achieved complete clinical regression. One patient noted improvement with persistence of a hyperpigmented patch. Treatment was well tolerated. Neither relapsed at 9 to 10 months follow-up.

Although the use of calcineurin inhibitors appears to be effective for both BXO and Zoon balanitis, with continued use, surveillance for the development of squamous cell carcinoma (notably in BXO) is essential because of the theoretical possibility that these agents increase the risk of malignancy.

Zoon's balanitis treated with imiquimod 5% cream

Marconi B, Campanati A, Simonetti O, Savelli A, Conocchiari L, Santinelli A, et al. Eur J Dermatol 2010; 20: 134–5.

A case report of Zoon balanitis successfully treated with imiquimod 5% cream three times weekly for 12 weeks.

Ablative erbium:YAG laser treatment of idiopathic chronic inflammatory non-cicatricial balanoposthitis (Zoon's disease). A series of 20 patients with long-term outcome

Wollina U. J Cosmet Laser Ther 2010; 12: 120–3.

Ablative erbium:YAG laser treatment was used in 20 patients with Zoon balanitis with complete reepithelialization within 2 to 3 weeks in all patients.

Genital lichen sclerosis treated by carbon dioxide laser

Aynaud O, Plantier F. Eur J Dermatol 2010; 20: 387–8.

A report of four cases of penile lichen sclerosis successfully treated with CO₂ laser and a review of the literature on CO₂ laser treatment for genital lichen sclerosis.

Zoon's balanitis: presentation of 15 patients, five treated with a carbon dioxide laser

Retamar RA, Kien MC, Chouela EN. Int J Dermatol 2003; 42: 305–7.

Discussion of CO₂ laser treatment in five patients with Zoon balanitis with variable efficacy.

Zoon's balanitis successfully treated with photodynamic therapy: case report and literature review

Borgia F, Vaccaro M, Foti A, Giuffrida R, Cannavò S. Photodiagnosis Photodyn Ther 2016; 13: 347–9.

A patient with recalcitrant Zoon balanitis who refused circumcision was treated with 10% ALA in polyethylene glycol ointment under occlusion for 3 hours followed by diode red light at 630 nm at a distance of 50 mm from the skin surface for a total time of 8 minutes with a resulting light dose of 75 J/cm². Almost complete clearance was seen at 3 months' follow-up after a total of three treatments at 2-week intervals.

Acitretin for severe lichen sclerosus of male genitalia: a randomized, placebo controlled study

Ioannides D, Lazaridou E, Apalla Z, Sotiriou E, Gregoriou S, Rigopoulos D. J Urol. 2010; 183: 1395–9.

A randomized, double-blind, placebo-controlled study to evaluate the efficacy of a 35-mg daily dose of acitretin for 20 weeks compared with placebo in men with severe, recalcitrant lichen sclerosus. Of 49 patients completing the study, 24 of the 33 in the acitretin group had complete or partial resolution, whereas only 3 out of 16 in the control group responded. This study found acitretin to be safe and effective.

Basal cell carcinoma

James M. Spencer

Basal cell carcinoma (BCC) is a slow-growing, rarely metastasizing but destructive malignancy, originating in the epidermis. It most commonly arises in areas chronically exposed to ultraviolet (UV) light, especially the head and neck.

Management Strategy

BCC slowly but relentlessly grows larger and deeper, and therefore therapeutic intervention is geared toward complete eradication of all malignant cells. Local recurrence is the consequence of inadequate therapy. Complete eradication is especially important because recurrent tumors are often larger and more aggressive than the original, incompletely treated primary tumor. The therapy chosen should achieve tumor eradication with the maximal preservation of function and the optimal cosmetic result. Most often, therapy uses destructive techniques such as *cryotherapy* or *curettage and electrodesiccation (C&D)*; more complex tumors may be treated by *excisional surgery*, *Mohs surgery*, or *radiation therapy*. The decision about which therapy to use is best made by considering four factors: tumor size, location, histology, and history (recurrent vs. primary). The clinician should consider each of these four factors and decide whether the patient is high risk or low risk for each to determine whether to use a simple or complex therapeutic strategy.

Most BCCs are discovered as primary tumors when they are still less than 1 cm in diameter. Generally tumors smaller than 1 cm on the face and 2 cm on the body are low risk.

Histologic growth pattern is a separate risk factor. The cytology of BCC does not vary: that is, all BCCs have well-differentiated, relatively monomorphic cell populations. However, the pattern of growth is variable and makes a large difference in choosing therapy. One must consider whether the tumor has a circumscribed or a diffuse growth pattern. BCC most typically exhibits a circumscribed, cohesive growth pattern known as *nodular*. Nodular BCCs may show partial differentiation toward other structures, such as cystic or keratotic, but these variants are without therapeutic significance because the growth pattern is still nodular. Morpheaform, micronodular, infiltrating, and superficial BCCs are all variants that exhibit a diffuse growth pattern. These lesions are more likely to recur as a result of subclinical extension or more aggressive tumor behavior, or both. Unfortunately, all too often biopsy reports simply state “BCC,” with no information about the growth pattern. Inadequately treated nodular BCC often recurs with a more aggressive diffuse growth pattern, such as infiltrating or micronodular.

Location is also an important variable to consider when choosing

therapy. BCC tends to occur in chronically sun-exposed sites, especially the head and neck. Approximately 80% occur on the head and neck, and 25% occur on the nose. The central portion of the face, which has the highest incidence of BCC, contains the eyes, nose, and mouth, structures of functional and cosmetic importance highly vulnerable to the destructive effects of BCC, as well as the destructive effects of therapy directed against BCC. The center of the face extending onto the area around the ears defines a roughly H-shaped area known as the *H zone*. Tumors in this zone have the highest recurrence rate and thus deserve special therapeutic attention. This zone also contains the most vulnerable structures and has the highest rate of BCC occurrence. Tumors near the ear canal in the H zone are of special concern. Extension down the ear canal provides the tumor with access to the brain, and when there is evidence of ear canal invasion, particularly aggressive therapy is warranted.

Recurrent tumors are more difficult to treat than primary tumors and require more aggressive methods.

When confronted with a BCC, the clinician may wish to consider these four variables in the context of the individual patient. The patient's overall medical status, medical history, and age may influence the therapeutic decision-making.

Specific Investigation

- Biopsy with adequate dermal component

An adequate biopsy is critical in assessing the tumor. The tumor growth pattern is important information that is impossible to determine when only a superficial fragment is submitted to the laboratory. Deep shave, punch, incisional, or excisional biopsy can all give sufficient dermis for such an evaluation.

A number of noninvasive imaging technologies are being investigated to delineate tumor depth and extent preoperatively and thus guide treatment. These include confocal microscopy, infrared spectroscopy, and ultrasound, but these all remain experimental and are not part of routine care.

Rarely, a BCC may have been neglected and reached a size such that direct bony invasion has occurred. If this is strongly suspected, a preoperative computed tomography (CT) scan should be considered.

The possibility that patients with a BCC have an increased risk of

developing subsequent internal malignancies has been suggested over the years and remains controversial. At present there is no recommendation for extraordinary evaluation for internal malignancies.

Basal cell carcinoma and risk of subsequent malignancies: a cancer registry-based study in southwest England

Bower CP, Lear JT, Bygrave S, Etherington D, Harvey I, Archer CB. J Am Acad Dermatol 2000; 42: 988–91.

A cohort of 13,961 patients diagnosed with BCC between 1981 and 1988 were followed for additional malignancies. There was a significant increased risk of subsequent melanoma, but no increased risk for internal malignancies.

Further complicating the relationship of BCC to other cancers is the argument that vitamin D provides chemoprevention for some visceral cancers. Specifically, it has been theorized that elevated levels of vitamin D lower the incidence of a variety of tumors, including breast, colon, and prostate cancers. Because vitamin D is manufactured in the skin after exposure to UVB, it has been suggested that those with high UVB exposure should have a higher incidence of BCC but a lower incidence of breast, colon, and prostate cancers, among others.

Are patients with skin cancer at lower risk of developing colorectal or breast cancer?

Soerjomataram I, Louwman WJ, Lemmens VE, Coebergh JW, de Vries E. Am J Epidemiol 2008; 167: 1421–9.

Patients ($n = 26,916$) with skin cancer ($n = 4089$ squamous cell carcinoma, $n = 19,319$ BCC, and $n = 3508$ melanomas) from the Netherlands were identified during the years 1972 to 2002 and analyzed for their incidence of colorectal and breast cancers. Squamous cell carcinoma (SCC) and BCC of the head and neck only were associated with a lower incidence of colorectal cancer, but not breast cancer. Patients with melanoma had a higher incidence of breast cancer.

The effect of vitamin D on cancer incidence remains controversial.

First-Line Therapies

• Curettage and electrodesiccation	B
• Cryosurgery	B
• Excisional surgery	B
• Mohs micrographic surgery	B

Recurrence rates of treated basal cell carcinomas. Part 2: curettage–electrodesiccation

Silverman MK, Kopf AW, Grin CM, Bart RS, Levenstein MJ. J Dermatol Surg Oncol 1991; 17: 720–6.

This retrospective study of 2314 primary BCCs treated by C&D at a university dermatology clinic reports a 13.2% 5-year recurrence rate after C&D. Further analysis showed that size and location were important variables, with 5-year recurrence rates varying from 9.5% in low-risk locations to over 16.3% in high-risk sites. Similarly, 5-year recurrence rates ranged from 8.5% for tumors 0 to 5 mm in diameter to 19.8% for tumors 20 mm or more.

Long-term recurrence rates in previously untreated (primary) basal cell carcinoma: implications for patient follow-up

Rowe DE, Carroll RJ, Day CL. J Dermatol Surg Oncol 1989; 15: 315–28.

Reviewed literature since 1947 and reported a weighted average 5-year recurrence rate of 7.7% of primary BCCs treated with C&D.

Mohs surgery is the treatment of choice for recurrent (previously treated) basal cell carcinoma

Rowe DE, Carroll RJ, Day CL. J Dermatol Surg Oncol 1989; 15: 424–31.

Reports an almost 40% 5-year recurrence rate of recurrent tumors treated by C&D, emphasizing that this modality is not appropriate for recurrent tumors.

Extensive retrospective studies exist supporting the utility of this simple, rapid, and inexpensive method to treat BCC. However, prospective studies directly comparing C&D with other therapeutic modalities are lacking, and drawing conclusions from retrospective studies not controlled for size,

histology, location, and history makes comparisons impossible.

Cryosurgery of basal cell carcinoma: a study of 358 patients

Bernardeau K, Derancourt C, Cambie M, Salmon-Ehr V, Morel M, Cavenelle F, et al. *Ann Dermatol Venereol* 2000; 127: 175–9.

A retrospective study of 395 BCCs in 358 patients reports a 5-year recurrence rate of 9%, which is in line with other reports, but that the use of a cryoprobe or other temperature-sensing device made no difference to outcome.

A systematic review of treatment modalities for primary basal cell carcinomas

Thissen MR, Neumann MH, Schouten LJ. *Arch Dermatol* 1999; 135: 1177–83.

Meta-analysis of published studies evaluating therapeutic methods for treating BCC. Inclusion criteria were prospective studies of at least 50 patients with primary BCC and at least 5 years' follow-up. Four studies of cryosurgery filled these criteria, with recurrence rates ranging from 0% to 20.4%.

Several large retrospective reports indicate a greater than 95% cure rate with cryotherapy. The authors of such series generally recommend two freeze–thaw cycles to maximize cell death and the use of a cryoprobe to assess tissue temperature achieved: –50°C is generally regarded as sufficiently cytotoxic.

Surgical margins for basal cell carcinoma

Wolf DJ, Zitelli JA. *Arch Dermatol* 1987; 123: 340–4.

Detailed histologic examination after excision with various margins revealed that for BCC <1 cm in diameter in low-risk areas, a surgical margin of 4 mm of normal-appearing skin around the tumor gave a 98% histologic cure rate.

Morpheaform basal-cell epitheliomas: a study of subclinical extensions in a series of 51 cases

Salasche SJ, Amonette RA. *J Dermatol Surg Oncol* 1981; 7: 387–94.

The average subclinical extension of morpheaform BCC is 7 mm, so a 4-mm margin would be inadequate.

Use the 4-mm margin for primary nodular BCC <1 cm in diameter. Larger tumors, diffuse growth pattern tumors, and recurrent tumors require larger margins or intraoperative histologic control.

Efficacy of curettage before excision in clearing surgical margins of nonmelanoma skin cancer

Chiller K, Passaro D, McCalmont T, Vin-Christian K. Arch Dermatol 2000; 136: 1327–32.

Preoperative curettage to better delineate surgical margins produced a statistically significant reduction in positive margins after surgical excision, suggesting the utility of curettage immediately before surgical excision.

Long-term recurrence rates in previously untreated (primary) basal cell carcinoma: implications for patient follow-up

Rowe DE, Carroll RJ, Day CL. J Dermatol Surg Oncol 1989; 15: 315–28.

Retrospective analysis of the literature since 1947 reports a weighted average 5-year recurrence rate of 1% when primary BCCs are treated using the Mohs technique.

Mohs surgery is the treatment of choice for recurrent (previously treated) basal cell carcinoma

Rowe DE, Carroll RJ, Day CL. J Dermatol Surg Oncol 1989; 15: 424–31.

Retrospective analysis of the literature since 1947 reports weighted average 5-year recurrence rate of 5.6% when recurrent BCCs are treated using the Mohs technique.

Both this and the previous study are retrospective rather than prospective, and thus direct comparison with other therapeutic modalities is difficult. However, it is most likely that the Mohs technique was used for higher-risk tumors, whereas simple methods such as C&D or cryosurgery are used for low-risk lesions, so the superior results utilizing the Mohs technique may be greater than these numbers would indicate.

Surgical excision versus Mohs micrographic surgery for basal cell carcinoma of the face: a randomized clinical trial with 10 year follow up

van Loo E, Mosterd K, Krekels GA, Roozeboom MH, Ostertag JU, Dirksen CD, et al. Eur J Cancer 2014; 50: 3011–20.

For many years, the evidence for the utility of Mohs surgery has consisted of retrospective case series. In a randomized prospective study 408 high-risk facial BCCs and 204 recurrent facial BCCs were submitted to conventional surgery or Mohs surgery. At 10-year follow-up, the recurrence rate for Mohs surgery was 4.4%, whereas for conventional surgery it was 12.2%. For recurrent facial BCC, Mohs

surgery produced 3.9% recurrence rate versus 13.55% for conventional surgery. This study suggests Mohs surgery produced superior cure rates for both primary high-risk BCC and facial recurrent BCC.

Second-Line Therapy

• Radiation therapy	B
---------------------	----------

Basal cell carcinoma of the face: surgery or radiotherapy? Results of a randomized study

Avril MF, Auperin A, Margulis A, Gerbaulet A, Duvillard P, Benhamou E, et al. Br J Cancer 1997; 76: 100–6.

A randomized trial in which 347 primary BCCs <4 cm in size were assigned to surgical excision or radiotherapy (RT). The 4-year recurrence rate was 0.7% for surgical excision and 7.5% for RT. More significantly, cosmesis as judged by the patient and blinded judges was significantly better in the surgery group than in the RT group.

This is a significant result because RT is often recommended as an option for those patients who wish to avoid a scar.

Therapeutic ionizing radiation and the incidence of basal cell carcinoma and squamous cell carcinoma

The New Hampshire Skin Cancer Study Group. Lichter MD, Karagas MR, Mott LA, Spencer SK, Stukel TA, Greenberg ER. Arch Dermatol 2000; 136: 1007–11.

There is a statistically significant increased risk of the development of BCC in the exposure window after therapeutic RT. The development of subsequent tumors is a significant possible side effect.

Radiation therapy is an effective, albeit expensive and time-consuming, option for patients unable or unwilling to undergo surgery. Generally, 3000 to 5000 cGy are given in 6 to 20 fractionated doses, so therapy may take weeks. Cure rates have repeatedly been reported to be in excess of 90%. BCCs with perineural invasion have a very high local recurrence rate, and

postoperative radiation is a wise precaution.

Third-Line Therapies

• Intralesional interferon	B
• Retinoids	D
• Topical imiquimod	A
• Photodynamic therapy	A
• Topical 5-fluorouracil	A
• CO ₂ laser	D
• PEG–interleukin 2	D
• NSAIDs	D
• Ingenol mebutate	D
• Vismodegib	A
• Intralesional interleukin	D
• Systemic chemotherapy	D

Intralesional recombinant interferon beta-1a in the treatment of basal cell carcinoma: results of an open-label multicenter study

Kowalzik L, Rogozinski T, Wimheuer R, Pilz J, Manske U, Scholz A, et al. *Eur J Dermatol* 2002; 12: 558–61.

A total of 133 BCCs were treated with intralesional interferon- β_{1a} 1 million units three times a week for 3 weeks. At 16 weeks' follow-up, 66.9% were clinically and biopsy clear. At 2-year follow-up, 4.5% of those that had cleared had recurred.

Alternative preparations of interferons have not been as successful as the α_{2a} preparation.

Treatment and prevention of basal cell carcinoma with oral isotretinoin

Peck GL, DiGiovanna JJ, Sarnoff DS, Gross EG, Butkus D, Olsen TG, et al. *J Am Acad Dermatol* 1988; 19: 176–85.

Twelve patients with multiple BCCs from varying causes were treated with high-dose oral isotretinoin (mean daily dosage 3.1 mg/kg/day) for a mean of 8 months. Of the 270 tumors monitored in these patients, only 8% underwent complete clinical and histologic regression.

Topical tretinoin treatment in basal cell carcinoma

Brenner S, Wolf R, Dascalu DI. *J Dermatol Surg Oncol* 1993; 19: 264–6.

Four lesions (single patient) were treated with 0.05% topical tretinoin twice a day for 3 weeks, followed by a 3-week rest, and a second treatment cycle. Short-term clinical and histologic evaluation showed initial clearance in all four lesions, but all four recurred within 9 months.

Topical treatment of basal cell carcinoma with tazarotene: a clinicopathological study on a large series of cases

Bianchi L, Orlandi A, Campione E, Angeloni C, Costanzo A, Spagnoli LG, et al. *Br J Dermatol* 2004; 151: 148–56.

A total of 154 small superficial and nodular BCCs were treated daily for 24 weeks with topical tazarotene. At the end of the treatment period, 70.8% of the lesions showed evidence of regression, but only 30.5% actually resolved clinically.

Retinoids, either systemically or topically, have not shown great efficacy in the treatment of BCC. However, retinoids definitely have an effective role in

the chemoprevention of future BCCs in high-risk patients.

Imiquimod 5% cream for the treatment of superficial basal cell carcinoma: results from two phase III, randomized, vehicle-controlled studies

Geisse J, Caro I, Lindholm J, Golitz L, Stampone P, Owens M. J Am Acad Dermatol 2004; 50: 722–33.

This paper reports results of 724 subjects who applied the cream daily, 5 to 7 days a week for 6 weeks. Twelve weeks after the treatment period, the area of the tumor was excised and examined histologically. The excised area was tumor free in 82% of the five times a week group and 79% of the seven times a week group.

Open study of the efficacy and mechanism of action of topical imiquimod in basal cell carcinoma

Vidal D, Matias-Guiu X, Alomar A. Clin Exp Dermatol 2004; 29: 518–25.

Fifty-five BCCs measuring more than 8 mm in diameter with superficial, nodular, or infiltrative histologic growth patterns were treated daily, either three times a week for 8 weeks or five times a week for 5 weeks. Punch biopsies were taken 6 weeks after therapy, and patients were followed clinically for 2 years: 4/4 (100%) superficial BCCs, 7/8 (88%) nodular BCCs, and 30/43 (70%) infiltrating BCCs were tumor free after therapy.

This product upregulates interferons α and γ , and interleukin 12, among other cytokines. It seems to be reasonably effective for superficial BCCs, but less so for other histologic growth patterns.

Photodynamic therapy for the treatment of basal cell carcinoma

Wilson BD, Mang TS, Stoll H, Jones C, Cooper M, Dougherty TJ. Arch Dermatol 1992; 128: 1597–601.

A total of 151 BCCs in 37 patients were treated with Photofrin, a systemic photosensitizer that preferentially accumulates in tumors, followed by exposure to 630 nm laser light. Overall, complete response rate by clinical observation at 3 months was 88%.

These authors noted that failures tended to be in high-risk areas such as the nose and high-risk histologic variants (morpheaform). Photofrin is a systemic photosensitizer, and some degree of cutaneous and ocular photosensitivity may last up to 4 to 6 weeks. A variety of other systemic photosensitizers are currently under investigation.

Photodynamic therapy of multiple nonmelanoma skin cancers with verteporfin and red light-emitting diodes: two year results evaluating tumor response and cosmetic outcomes

Lui H, Hobbs L, Tope WD, Lee PK, Elmetts C, Provost N, et al. Arch Dermatol 2004; 140: 26–32.

Fifty-four patients with 421 nonmelanoma skin cancers, including superficial BCC, nodular BCC, and SCC in situ, were treated with intravenous verteporfin followed by varying doses of red light. Treated areas were biopsied 6 months after treatment, and patients were followed clinically for 2 years. At the highest light dose, 93% of treated tumors were clear on biopsy, and 95% were clinically clear at 2-year follow-up.

Like Photofrin, verteporfin is an intravenous medication but has the advantage that patients are photosensitive for only 3 to 5 days.

Five year follow-up of a randomized prospective trial of topical methyl aminolevulinate photodynamic therapy vs. surgery for nodular basal cell carcinoma

Rhodes LE, de Rie MA, Leifsdottir R, Yu RC, Bachmann I, Goulden V, et al. Arch Dermatol 2007; 143: 1131–6.

Fifty-three nodular BCCs were treated with two to four sessions of mALA photodynamic therapy (PDT), and 52 nodular BCCs were treated by surgical excision. At 5-year follow-up there was a 14% recurrence rate in the PDT group versus 4% in the surgical excision group. However, the cosmetic outcome was rated higher in the PDT group than in the excision group.

Multiple sessions with topical mALA give a lower cure rate but a better cosmetic outcome than surgical excision.

Topical PDT with δ -aminolevulinic acid (ALA) and its methylated derivative (mALA) has become more popular and is commonly used in Europe. Surgical excision remains the gold standard to which other therapies must be compared. Comparison of different therapeutic modalities has been hard because few randomized prospective comparative trials have been performed. One such trial with 5-year follow-up has been completed comparing PDT with mALA to conventional surgical excision.

Treatment of basal cell carcinoma of the skin with 5-fluorouracil ointment. A 10 year follow-up study

Reymann F. Dermatologica 1979; 158: 368–72.

Ninety-five BCCs were treated with 5% 5-FU ointment. At 10-year

follow-up there was a 21.4% recurrence rate.

Fluorouracil paste treatment of thin basal cell carcinomas

Epstein E. Arch Dermatol 1985; 121: 207–13.

Forty-four thin BCCs were treated with 25% 5-FU in petrolatum under occlusion for 3 weeks with weekly dressing changes. The 5-year recurrence rate was 21%.

These older papers suggested that topical 5-FU is not a good option for BCC. However, two more recent papers suggest this area may deserve a second look.

5% 5-fluorouracil cream for the treatment of small superficial basal cell carcinoma: efficacy, tolerability, cosmetic outcome, and patient satisfaction

Gross K, Kircik L, Kricorian G. Dermatol Surg 2007; 33: 433–9.

Thirty-one superficial BCCs were treated with 5% 5-FU BID for up to 12 weeks. Three weeks after stopping therapy the area of the tumor was excised, which revealed 90% of the treated lesions to be tumor free; 10% had residual tumor.

Can the carbon dioxide laser completely ablate basal cell carcinomas? A histologic study

Horlock N, Grobbelaar AO, Gault DT. Br J Plastic Surg 2000; 53: 286–93.

Use of the continuous-wave CO₂ laser to destroy BCCs was examined by postlaser excision and histologic check. Superficial BCCs of the trunk could be reliably ablated, but nodular and infiltrating (a diffuse growth pattern) could not reliably be treated by this method.

Effect of perilesional injections of PEG–interleukin-2 from one dose a week to four doses a week

Kaplan B, Moy RL. Dermatol Surg 2000; 26: 1037–40.

Intralesional injection of interleukin-2 (3000–120,000 IU in one to four weekly doses) in varying doses from one dose a week to four doses a week was given to eight patients with 12 BCCs. A complete response was seen in 8 of the 12 (66%) tumors.

PEP005 (ingenol mebutate) gel for the topical treatment of superficial basal cell carcinoma: results of a randomized phase IIa trial

Siller G, Rosen R, Freeman M, Welburn P, Katsamas J, Ogbourne SM. *Australas J Dermatol* 2010; 51: 99–105.

Application of 0.05% ingenol mebutate gel on days 1 and 2 resulted in the highest clearance both clinically and histologically. This study was designed to examine the safety and efficacy of topic ingenol mebutate. They report a favorable safety profile and 71% tumor clearance rate. Further studies are needed for optimal dosage to treat superficial BCC.

The pulsed dye laser for the treatment of basal cell carcinoma

Ballard CJ, Rivas MP, McLeod MP, Choudhary S, Elgart GW, Nouri K. *Lasers Med Sci* 2011; 26: 641–4.

Nine biopsy-proven BCCs, were treated with the PDL (585-nm wavelength, a single 450- μ s pulse, 7-mm spot size, and 9.0 J/cm² energy) with a 4-mm border of normal skin were treated. A deep shave biopsy with histological examination occurred 4 weeks after the laser treatment. On histology, 5/9 (55.6%) sites demonstrated no evidence of BCC; however, 4/9 (44.4%) sites showed residual BCC

Pulsed dye laser as a novel non-surgical treatment for basal cell carcinomas: response and follow up 12–21 months after treatment

Konnikov N, Avram M, Jarell A, Tannous Z. *Lasers Surg Med* 2011; 43: 72–8.

Fourteen patients with 20 biopsy-proven BCCs on the trunk and extremities (8–35mm in diameter) were treated with four consecutive PDL treatments at 3–4 week intervals. A 4-mm margin of clinically normal skin was also treated. Complete clinical response was seen with 19 of 20 treated BCCs, regardless of size and histologic subtype. All remaining 19 BCCs were followed between 12 and 21 months (median=18 months) after the last PDL treatment. Of these 19 BCCs, only one recurred at 17 months follow up. The remaining 18 BCCs did not show any clinical signs of residual or recurrent tumor at 12–21 months follow-up.

Pulsed dye laser has emerged as a potential treatment for BCC. Treatment is not standardized, but most trials have utilized four treatments at high fluence. Success rates in case series range from 90% to 65% clear for low-risk tumors with short follow-up generally under 2 years.

Hedgehog pathway inhibitor therapy for locally advanced and

metastatic basal cell carcinoma: a systematic review and pooled analysis of interventional studies

Jacobsen AA, Aldahan AS, Hughes OB, Shah VV, Strasswimmer J. JAMA Dermatol 2016; 152: 816–24.

A review of 8 pooled articles included 744 total patients with 704 patients clinically evaluable. Sonidegib did not yield enough publications for a formal analysis. Objective response to vismodegib for locally advanced BCC had a weighted average of 64.7%; complete response averaged 31.1%. Objective response for metastatic BCC was 33.6% complete response averaged 3.9% Median duration of therapy was 35.8 weeks. Vismodegib was identified to have a significant, consistent effect on the median duration of therapy of locally advanced and metastatic BCC. While metastatic BCC responses are superior to any traditional approach, the response rate for laBCC might be considered in the context of other standard treatment options including surgery and radiation therapy.

A phase II, randomized, double-blind study of sonidegib in patients with advanced basal cell carcinoma

Dummer R, Guminski A, Gutzmer R, Dirix L, Lewis KD, Combemale P, et al. J Am Acad Dermatol 2016; 75: 113–25.

Mutations in the sonic hedgehog pathway have been shown to occur in 90% of BCCs. Essential to this pathway is the protein smoothened, and two inhibitors of this protein are now available. The first and best studied is vismodegib. In a meta-analysis of eight studies, pooled data showed locally advanced BCC had a 64.7% objective partial response, whereas 31.3% were completely clear. For metastatic BCC, there was a 33.6% objective partial response and a 3.9% complete clearance rate.

Sonidegib has less evidence for analysis. One paper examined two different doses in locally advanced and metastatic BCC. A dose of 200 mg was given to 79 patients with locally advanced and 13 with metastatic BCC. At this dose for locally advanced BCC, the objective partial response rate was 57.6% and the complete clearance rate was 4.5%. For metastatic BCC, there was a 7.7% objective partial response. At a dose of 800 mg per day, locally advanced BCC showed a 43.8% objective partial response and a 1.6% complete clearance rate. For metastatic BCC there was a 17.4% objective partial response rate.

Becker nevus

Michael P. Loosemore, Adisbeth Morales-Burgos, Elnaz F. Firoz, Bahar F. Firoz, and Leonard H. Goldberg

Becker nevus, also called *pigmented hairy epidermal nevus*, is a cutaneous hamartoma that may have increased epidermal (melanocyte), dermal (smooth muscle), and appendageal (hair follicle) components. Classically, Becker nevus is first noticed around puberty on the shoulders and chest in males, but may be congenital, involve any area of the body, and occur in women. The prevalence in postpubertal males is approximated to be 0.5%, or 1 in 200.

Management Strategy

Becker nevus is usually asymptomatic and may come to the attention of a physician for cosmetic or diagnostic purposes. It is important to examine the patient for developmental abnormalities that may accompany Becker nevus and occur within the spectrum of *Becker nevus syndrome*, one of several epidermal nevus syndromes. Reported associations include:

- Cutaneous
 - Acneiform eruptions
 - Hypohidrosis
 - Lichen planus
 - Localized lipoatrophy
 - Localized scleroderma
 - Polythelia (supernumerary nipples)
 - Psoriasiform dermatitis
 - Unilateral breast hypoplasia
 - Osteoma cutis
- Musculoskeletal
 - Limb asymmetry
 - Pectus excavatum or carinatum
 - Scoliosis, including other vertebral defects

Associations of Becker nevus with cutaneous malignancies have been reported. Both basal cell carcinoma and intraepithelial squamous cell carcinoma (Bowen disease) have been described separately in two young women without significant risk factors (i.e., photodamage, papillomavirus infection, arsenic exposure). Although melanoma has been described in patients with Becker nevus, the risk of malignant transformation of the nevus itself appears to be very low. Enhanced screening for melanoma is likely unnecessary.

Traditional *surgical* approaches to remove Becker nevus are either unsuccessful or result in significant scarring. *Laser* technology offers the clinician a means to reduce both the pigmentation and the hypertrichosis often seen in Becker nevus, and therefore may improve the cosmetic appearance of the lesion. Management of asymptomatic benign lesions should comprise diagnosis confirmation and fully evaluating for any associated pathology.

Becker's nevus syndrome revisited

Danarti R, König A, Salhi A, Bittar M, Happle R. J Am Acad Dermatol

2004; 51: 965–9.

A review of ipsilateral breast hypoplasia, other cutaneous anomalies, musculoskeletal abnormalities, and maxillofacial findings that may be observed in Becker nevus syndrome. The concept of paradominant inheritance is presented to explain occasional familial aggregation in this syndrome.

Becker nevus syndrome

Happle R, Koopman RJ. Am J Med Genet 1997; 68: 357–61.

Proposes term *Becker nevus syndrome* to describe association of Becker nevus with developmental defects such as unilateral breast hypoplasia and other cutaneous, muscular, or skeletal defects in 23 cases.

Becker's nevus and malignant melanoma

Fehr B, Panizzon RG, Schnyder UW. Dermatologica 1991; 182: 77–80.

Report of nine patients with Becker nevus and malignant melanoma. Five melanomas were on the same body site as the Becker nevus, but only one arose within the nevus itself.

A case of Becker's nevus with osteoma cutis

Park SB, Song BH, Park EJ, Kwon IH, Kim KH, Kim KJ. Ann Dermatol 2011; 23 (Suppl 2): S247–9.

An 18-year-old female was reported to have osteoma cutis accompanying her Becker nevus.

Specific Investigations

- The diagnosis of Becker nevus can be made on clinical examination. Although skin biopsy is diagnostic, it is often unnecessary. Familial Becker nevus has been regularly reported, so it is prudent to inquire about other family members, especially same-sex siblings.
- In some instances, differentiating between large congenital melanocytic nevus and Becker nevus may be difficult. Dermoscopy may help in equivocal cases. Reticulated pigment network, focal hypopigmentation, furrow hypopigmentation, hair follicles, perifollicular hypopigmentation, and vessels are the main dermoscopic features of Becker nevus.

Familial Becker's nevus

Fretzin DF, Whitney D. J Am Acad Dermatol 1985; 12: 589–90.

The first two published cases of familial Becker nevus.

Dermoscopic features of congenital melanocytic nevus and Becker nevus in an adult male population: an analysis with a 10-fold magnification

Ingordo V, Iannazzone SS, Cusano F, Naldi L. Dermatology 2006; 212: 354–60.

Assessed the use of optical dermoscopy with 10-fold magnification in differentiating between large congenital melanocytic nevus and Becker nevus.

First-Line Therapies

Treatment requested by patients can be divided into two components:

- Reduction of hyperpigmentation
- Removal of excess hair

Reduction of hyperpigmentation

• Erbium:YAG laser	C
• Long-pulse alexandrite laser	D
• Erbium-doped fiber laser (Fraxel)	D
• Q-switched ruby laser (QSRL)	D

Becker's naevus: a comparative study between erbium:YAG and Q-switched neodymium:YAG; clinical and histopathological findings

Trelles MA, Allones I, Moreno-Arias GA, Vélez M. Br J Dermatol 2005; 152: 308–13.

Twenty-two patients with Becker nevi were studied, 11 with each laser. Both erbium:YAG and Nd:YAG safely treated the lesions. For pigment removal, one pass with erbium:YAG was superior to three treatment sessions with Nd:YAG.

Treatment of Becker's nevi with a long-pulse alexandrite laser

Choi JE, Kim JW, Seo SH, Son SW, Ahn HH, Kye YC. *Dermatol Surg* 2009; 35: 1105–8.

Eleven Korean patients with Becker nevi and skin types III to V were treated with the 755-nm long-pulse alexandrite laser with a spot size of 15 to 18 mm, fluence of 20 to 25 J/cm², a pulse duration of 3 ms, and no cooling spray. Two patients had an excellent response, five good, and four a fair response. There was one case of partial hypertrophic scarring, and some patients had mild hypopigmentation; all outcomes were noted to be cosmetically acceptable.

Fractional resurfacing: a new therapeutic modality for Becker's nevus

Glaich AS, Goldberg LH, Dai T, Kunishige JH, Friedman PM. *Arch Dermatol* 2007; 143: 1488–90.

Two male patients with Becker nevi were treated with the 1550-nm wavelength erbium-doped fiber laser between 6 and 10 mJ at 4-week intervals and between five and six treatment sessions. Greater than 75% of the pigment had faded by 1 month in both patients. There was no improvement in hypertrichosis.

Q-switched ruby laser treatment of tattoos and benign pigmented skin lesions: a critical review

Raulin C, Schönermark MP, Greve B, Werner S. *Ann Plast Surg* 1998; 41: 555–65.

This review recommends 3 to 10 treatments at monthly intervals with Q-switched ruby laser at fluences between 7 and 20 J/cm² for hyperpigmentation. Although Q-switched ruby laser for long-term removal of associated hypertrichosis is not recommended, long-pulsed (755 nm) alexandrite laser has produced promising results.

The removal of cutaneous pigmented lesions with the Q-switched ruby laser and the Q-switched neodymium: yttrium-aluminum-garnet laser. A comparative study

Tse Y, Levine VJ, McClain SA, Ashinoff R. J Dermatol Surg Oncol 1994; 20: 795–800.

An area of Becker nevus was anesthetized and bisected, and each half treated with either Q-switched ruby laser or Q-switched (QS) Nd:YAG at 532 nm. Clinical lightening occurred in 63% and 43% of the lesion, respectively, at fluences of 8.4 and 2.8 J/cm². Q-switched ruby laser caused intraoperative pain, whereas QSNd:YAG caused postoperative discomfort.

Formation of fibrosis after nonablative and ablative fractional laser therapy

Wind BS, Meesters AA, Kroon MW, Beek JF, van der Veen JP, van der Wal AC, et al. Dermatol Surg 2012; 38: 437–42.

Eighteen patients with pigment disorders were randomized to either a nonablative 1550-nm fractional laser at 15 mJ/microbeam with 14% to 20% coverage (patients with erythema dyschromicum perstans and postinflammatory hyperpigmentation) or an ablative 10,600-nm fractional laser at 10 mJ/microbeam with 35% to 35% coverage (Becker nevi) and treated for three to five sessions. Biopsies were performed 3 months after the last treatment to assess fibrosis formation. Patients treated with nonablative fractional laser did not exhibit any fibrosis, whereas 50% of patients treated using ablative fractional laser showed fibrosis.

The ruby laser in the normal or long-pulsed mode has been used for laser epilation. A common side effect is hypopigmentation of adjacent skin, which can be used when treating hypertrichosis of a Becker nevus. Low-fluence hair removal has been reported to be effective as well, perhaps with fewer side effects.

Reduction of hypertrichosis

• Normal mode ruby laser

D

Treatment of a Becker's nevus using a 694-nm long-pulsed ruby laser

Nanni CA, Alster TS. Dermatol Surg 1998; 24: 1032–4.

A single case report that showed reduction in pigmentation and a 90% reduction in hair growth after three treatments with the long-pulsed ruby laser. Improvement was maintained for 10 months.

Hypertrichosis in Becker's nevus: effective low-fluence hair removal

Lapidoth M, Adatto M, Cohen S, Ben-Amitai D, Halachmi S. Lasers Med Sci 2014; 29: 191–3.

Fifteen patients treated with low-fluence, 808- to 810-nm diode laser had decreased hair growth at 6 and 12 months, without adverse effects.

Second-Line Therapy

Reduction of hyperpigmentation

• Frequency-doubled QSNd:YAG	D
------------------------------	----------

The Q-switched Nd:YAG laser operating at 532 nm has been shown to reduce pigmentation in Becker nevus, but does not appear to be as successful as the ruby laser.

Reduction of excess hair

• Electrolysis	E
----------------	----------

Electrolysis is a well-established method of epilation, but its use in removing hair from Becker nevus has not been described.

Third-Line Therapies

• Spironolactone	E
• Corrective camouflage	E

Congenital linear Becker's nevus, with underlying breast hypoplasia that spontaneously corrected during pregnancy: role of androgen receptors

Felton SJ, Al-Niaimi F, Thornton J, Lyon CC. J Clin Trials 2012; 2: 125.

The authors report a patient with congenital linear Becker nevus and breast hypoplasia. The Becker nevus was confirmed to have increased androgen receptors, and the breast hypoplasia improved when the patient became pregnant.

Becker's nevus with ipsilateral breast hypoplasia: improvement with spironolactone

Hoon Jung J, Chan Kim Y, Joon Park H, Woo Cinn Y. J Dermatol 2003; 30: 154–6.

The androgen receptor plays an important role in Becker nevus pathology, especially breast hypoplasia. This has been reported both to resolve during pregnancy and to improve with spironolactone treatment. Spironolactone, an antiandrogenic agent, was administered for the treatment of breast hypoplasia associated with Becker nevus in one case. After 1 month, breast enlargement was observed only in the hypoplastic breast.

Becker nevus is thought to be an androgen-dependent lesion, as it becomes more prominent after puberty, displays increased hairiness in males, and contains an increased number of androgen receptors and androgen-receptor messenger RNA compared with surrounding skin.

Corrective camouflage in pediatric dermatology

Tedeschi A, Dall'Oglio F, Micali G, Schwartz RA, Janniger CK. Cutis 2007; 79: 110–2.

Corrective camouflage using a variety of water-resistant and light to very opaque products was used in two patients with Becker nevi. Parents were satisfied with the cosmetic cover results. Corrective makeup may be a valid adjunctive therapy for patients undergoing

long-term treatments or in whom conventional therapy is ineffective.

Bed bugs

Whitney A. High, and Glen R. Needham

Human bed bugs (*Cimex lectularius*) are insects that require a blood meal to complete their life cycle, which is acquired by biting sleeping humans. The bite can elicit an allergic reaction, creating pruritic, erythematous papules that are often excoriated and even secondarily infected.

Management Strategy

Bed bug infestations have become more common with the eventual

resistance and subsequent banning of the use of dichlorodiphenyltrichloroethane (DDT).

Most bed bugs bite just before dawn, lying in close proximity to the sleeping quarters. Although the bite of a bed bug is painless, an allergic reaction may ensue in some individuals, resulting in a skin lesion. Bed bug bites tends to occur on exposed surfaces, such as the extremities or head/neck. The insect will not typically venture beneath bedding or bed clothes. A linear arrangement to the bites is common.

The insect does not reside or lay eggs upon humans, and hence, treatment focuses upon *detection and eradication of the household infestation*. *Insecticides, growth-regulating agents, and destructive modalities* may be employed to kill adults, progeny, and eggs. Many authorities believe that safe and successful eradication requires professional assistance.

Use of insecticides in the United States is regulated by the Environmental Protection Agency. The extended residual effect of DDT resulted in environmental damage; ultimately its use was banned. Resistance, first to DDT, and later to malathion, may be an issue with its reemergence as a scourge. More recently, pyrethroids (e.g., deltamethrin) have been utilized in controlling bed bug infestations, but again, resistance has emerged.

There is great interest in the use of temperature extremes to eradicate infestations. *Steam* may be utilized to sterilize a mattress or similar materials for which insecticides are inappropriate, but a target temperature of 160°F to 180°F must be reached over the entirety of the surface.

Commercial *whole room/whole home heating*, using propane heaters and fans to develop convective cycles, exist. Most of these systems achieve a target temperature of around 113°F, held for 15 to 60 minutes. Although this temperature is less than the thermal death point of bed bugs (118°F), such treatments are often successful, presumably due to powerful convection currents that desiccate the insects. Other comparatively simplistic measures, such as impermeable mattress covers, are also widely employed.

The manipulation of insect pheromones is gaining interest, as bed bugs use pheromones to aggregate for mating and to increase local humidity and avoid desiccation. Ergot blocking of this pheromone signaling, which may have disastrous effects upon a bed bug colony.

Treatment of bed bug bites among humans is directed at symptoms. Skin lesions are due to an allergic reaction to the saliva

leaked during feeding. Sensitization is not universal, and some individuals will not react.

Symptomatic bed bug bites often produce an erythematous wheal, followed by a firm, reddish papule, sometimes with a small central hemorrhagic punctum. Papulonecrotic and bullous forms have been described. Bites are often pruritic and are usually present on surfaces exposed during sleep, such as the head, neck, arms, legs, and shoulders. Bites are treated in a symptomatic fashion, with *potent topical steroids* and *antihistamines*.

The position of the U.S. Centers for Disease Control and Prevention (CDC), and the bulk of other experts, is that, as of yet, there is no clear evidence of successful transmission of a bloodborne pathogen via bed bug bites. Additional laboratory testing beyond bacterial culture of superinfected bites is not recommended.

A widely recognized contributing factor to the “epidemic” of bed bugs is travel. Hotels and other shared lodging facilities, regardless of cleanliness or cost, may be infested, and it is possible to bring an infestation home after a stay in infested lodgings.

An inspection of lodging facilities upon check-in is important. Luggage should be kept closed, or even sealed in plastic bags, to then be left at the destination upon departing. Use of dressers and bureaus at a hotel is discouraged. Metal luggage stands are preferable to wooden ones.

The re-emergence of the bed bug as a nuisance pest: implications of resistance to the pyrethroid insecticides

Davies TG, Field LM, Williamson MS. Med Vet Entomol 2012; 26: 241–54.

Resistance of bed bugs to insecticides is contributing to its resurgence as a pest. Reports of increasing resistance to pyrethroids exist throughout the world. The authors of this review report deltamethrin resistance in colonies obtained from more than 20 cities in the United States.

Insecticide resistance among bed bugs may be mediated by genetic mutations on target proteins, by overexpression of detoxifying enzymes, or by thickening of the insect cuticle, with reduced insecticide penetration. The existence of multiple pathways of resistance bodes ominously for ever-increasing problems with eradication of infestations.

Acute illnesses associated with insecticides used to control bed bugs – seven states, 2003–2010

Centers for Disease Control and Prevention (CDC), MMWR 2011; 60: 1269–74.

Although subject to concerns of overreporting or underreporting, the CDC recently detailed 111 illnesses over the span of 2003 to 2010, including one fatality, that were attributed to excessive and/or inappropriate use of insecticides for bed bugs. The authors encourage persons with bed bug infestations to seek the services of a certified exterminator; strict adherence is necessary with regard to product instructions and warnings.

Use of consumer-grade, indoor “foggers” or “bombs” for bed bugs is discouraged by experts because often they only scatter the bed bugs over a larger area. Silica gel or diatomaceous earth may be used as a less toxic (but also less effective) alternative that kills via dehydration. There is no effective “repellant” for bed bugs.

Identification of the airborne aggregation pheromone of the common bed bug, *Cimex lectularius*

Siljander E, Gries R, Khaskin G, Gries G. J Chem Ecol 2008; 34: 708–18.

Adult males, virgin adult females, and juvenile bed bugs respond to an airborne aggregation pheromone. The authors suggest that purposeful manipulation of this aggregation pheromone might be useful for control devices, such as traps.

Bed bugs reproduce via traumatic insemination, and females have structural adaptations to deal with this insult, whereas males have no such adaptations. Young males secrete pheromones to discourage other adult males from destructive same-sex copulation, and this represents another avenue of potential susceptibility.

Bedbugs as vectors for drug-resistant bacteria

Lowe CF, Romney MG. Emerg Infect Dis 2011; 17: 1132–4.

<https://dx.doi.org/10.3201/eid1706.101978>.

A recent report from Canada demonstrated that bed bugs may be capable of transmitting methicillin-resistant *Staphylococcus aureus* within an impoverished community.

Bedbugs

Kolb A, Needham GR, Neyman KM, High WA. Dermatol Ther 2009; 22: 347–52.

In this review article the authors instruct that, upon returning home, immediate inspection of luggage and other belongings aids in the discovery of bed bugs or eggs in the midst of transport. Unpacking in the garage and/or vacuuming the exterior, or even the interior, of bags, with immediate disposal of the vacuum bag itself in a sealed plastic bag, may be of benefit in preventing undesired translocation.

Specific Investigations

- Visualization of the bed bug by inspection, traps, or trained dogs
- Skin biopsy

The eggs, adults, and nymphal stages of the organism may be visualized with the human eye. Therefore when bed bug bites are suspected clinically, an appropriate starting point in investigation is simply careful inspection of sleeping quarters. Other techniques to detect infestation include simple taping of bed legs with sticky tape, placing bed posts in isolating devices or traps (either homemade or purchased), or trained dogs.

Visual inspection

Visual inspections should begin around the bed area. Adult bed bugs are 5 to 7 mm in length and vary in color from light brown to dark brown or even violaceous if they have recently fed. Nymphs are smaller and are often clearer in appearance, again unless having fed. Eggs are about 1 mm long, ovoid with an operculum, and are sticky, adhering to surfaces in small aggregates.

In addition to simply detecting the organism, there should be a search for fecal smears or flecks of blood upon the bed linens and upon the edges of the mattress and box springs. Bed bugs, even adults, may fit within extraordinarily narrow cracks and crevices in furniture and walls, behind peeling wallpaper, and even behind switch plates. If a credit card can be inserted into a crevice, then it may also host bed bugs!

Lastly, when populations of bed bugs are particularly dense, a pungent but sweet odor, likened to coriander or cut cilantro, may permeate an infested room or even an entire house.

Canine inspection

Dogs have been successfully trained to detect the odor of bed bugs. The training protocol of the commercial kennels is proprietary, and the exact odor the dogs are detecting is unknown.

Bed bug traps

Bed bugs are attracted to humans via a combination of heat, carbon dioxide exhalation, and perhaps other detectable scents, such as human body volatiles, such as aldehydes and sulcatone.

Using this information, two commercial bed bug trapping devices have been marketed, and plans to build a homemade trap (using a cat feeding bowl, dry ice, and a Thermos vessel) have been widely published.

The principle in all these devices is to attract bugs coupled with a “pitfall area” into which the bed bugs fall and cannot escape, or sticky material that entraps the organisms.

Other monitoring devices

A recently marketed device (Climbup Interceptor) consists of two nested plastic bowls, one inside the other, into which the feet of the bed may be placed. Bugs migrating either into the bed or away from the bed are entrapped between the bowls. Along these same lines, inverted duct tape may be placed, sticky side out, upon the legs of the bed to entrap bed bugs as they migrate across it.

Effectiveness of bed bug monitors for detecting and trapping bed bugs in apartments

Wang C, Tsai WT, Cooper R, White J. J Econ Entomol 2011; 104: 274–8.

A comparison was made of several bed bug monitoring devices, including the CDC3000, NightWatch, and a homemade dry ice trap, and a passive monitor (the Climbup Interceptor), without attractants, was used for estimating the bed bug numbers before and after placing active monitors. In occupied apartments, the relative effectiveness of the active monitors was as follows: dry ice trap > CDC3000 >

NightWatch. In lightly infested apartments, the Interceptor (operated for 7 days) trapped a similar number of bed bugs as the dry ice trap (operated for 1 day) and trapped more bed bugs than CDC3000 and NightWatch (operated for 1 day). The authors concluded that all the

monitors were effective tools in detecting early bed bug infestations and evaluating the results of bed bug control programs.

Ability of bed bug-detecting canines to locate live bed bugs and viable bed bug eggs

Pfiester M, Koehler PG, Pereira RM. J Econ Entomol 2008; 101: 1389–96.

The authors examined dogs trained to locate bed bugs by smell. Under test conditions they were able to discriminate bed bugs from other insects with a 97.5% positive indication rate (correct indication of bed bugs when present) and with zero false positives (incorrect indication of bed bugs when not present). They were able to discriminate live bed bugs and viable bed bug eggs from dead bed bugs, cast skins, and feces, with a 95% positive indication rate and a 3% false-positive rate on bed bug feces. In experimentally contrived “hotel rooms,” canines were 98% accurate in locating live bed bugs.

Skin biopsy

The histology of bed bug bites is nonspecific and similar to that of many other insect and arthropod assault reactions and includes a perivascular infiltrate of lymphocytes, histiocytes, eosinophils, and mast cells within the upper dermis, perhaps with dermal edema and/or extravasated erythrocytes.

Bullous reactions to bedbug bites reflect cutaneous vasculitis

deShazo RD, Feldlaufer MF, Mihm MC Jr, Goddard J. Am J Med 2012; 125: 688–94.

The authors examined “severe” cutaneous reactions, termed *bullous or complex reactions*, to bed bug bites and concluded the phenomenon is not rare. Of 357 photographs of bed bug bites posted on the Internet, 6% were bullous. Histopathologic evaluation of bullous reactions showed a polymorphous picture with histologic evidence of an urticarial-like reaction early on that rapidly developed into a hybrid leukocytoclastic vasculitis, similar to the dermal vasculitis in patients with Churg–Strauss disease.

First-Line Therapies

• Identify and eradicate the infestation	A
• Control symptoms associated with the bites using antihistamines, topical steroids, and in rare cases oral steroids	E

Toxicity and potential utility of ivermectin and moxidectin as xenointoxicants against the common bed bug, *Cimex lectularius*

Sheele JM, Ridge GE. Parasitol Res 2016; 115: 3071–81.

<http://dx.doi.org/10.1007/s00436-016-5062-x>.

In a controlled laboratory experiment, laboratory-reared bed bugs were exposed to varying concentrations of ivermectin and moxidectin using a feeding apparatus. Exposure to ivermectin, more than moxidectin, resulted in long-term sequelae among the insects to include reduced fecundity, feeding difficulty, and incomplete molting, but this was not a clinical trial.

Although interest in a xenotoxicant approach persists, the authors speculated that if ivermectin were used in such a schema, it might require a daily dose of 0.2 mg/kg for a 20-day period, and the safety of such a regimen in humans is not yet well established.

Behçet disease

Samantha R. Pop, Maryam Liaqat, and Justin J. Green

Behçet disease (BD) is a chronic inflammatory disorder leading to systemic vasculitis characterized by oral aphthae (at least three episodes in a 12-month period), plus two of the following: genital aphthae, cutaneous lesions (erythema nodosum, pustulosis, acneiform lesions, and pseudofolliculitis), uveitis or retinal vasculitis,

or positive pathergy test. A strong correlation between BD and HLA-B51 is widely replicated in several studies. Arthritis, gastrointestinal, cardiac, and neurologic manifestations may also occur. Many regimens effective for recurrent aphthous stomatitis are used to treat the aphthae of BD (see chapter on aphthous stomatitis). Recently 32 different countries joined together to establish new international guidelines, and data from 2556 BD patients were used to create a new diagnostic scoring system. In 98% of the patients, oral aphthous ulcer was a feature.

Management Strategy

In the absence of multisystem disease, the severity and extent of the mucocutaneous manifestations direct the treatment strategy. First-line therapy for oral and genital aphthae is a *high-potency topical corticosteroid* in a gel or ointment formulation. Alternatively, *intralesional corticosteroids* (triamcinolone 5 mg/mL) can be used for major aphthae and severe minor aphthae. Other topical therapies accelerate healing or diminish the pain associated with oral aphthae. These include viscous *lidocaine* 2% to 5% applied directly to lesions, *amlexanox* 5% oral paste, *sucralfate*, *tetracycline suspension*, *topical pimecrolimus* cream, and *tacrolimus* 0.1% ointment.

Colchicine 0.6 mg three times daily combined with topical corticosteroid therapy is efficacious in mucocutaneous disease. *Dapsone* 100 to 200 mg daily is also effective, but requires more frequent laboratory follow-up. The newer agent, apremilast 30 mg twice a day, for oral lesions has been noted to be beneficial in reducing mean numbers of ulcers and associated pain.

Those patients who fail the more conservative approaches or have severe mucocutaneous disease may require aggressive therapy. *Thalidomide* 100 to 300 mg daily (pediatric dose varies from 1 mg/kg/week to 1 mg/kg daily) is more effective than low-dose *methotrexate* 7.5 to 20 mg/week for severe disease. *Prednisone* taper begun at 1 mg/kg daily can be used for severe mucocutaneous flares, but rebound is a possible complication.

Systemic *interferon (IFN)- α_{2a}* and *anti-tumor necrosis factor (TNF)- α* therapies may be best suited for those with severe mucocutaneous lesions and nonocular systemic manifestations. *Etanercept* 50 mg weekly by subcutaneous injection or *infliximab* 5 mg/kg in single or

multiple intravenous infusions has been shown to be effective in patients with recalcitrant disease and may be used as monotherapy or as an adjunct to conventional immunosuppressive therapy. Notably, *infliximab* has demonstrated rapid therapeutic effect, which may be useful in patients with vision-threatening posterior uveitis. These patients should be screened for latent tuberculosis infection before initiating anti-TNF therapies. Patients with certain extracutaneous signs (e.g., uveitis, aneurysms) may warrant combination therapy with *prednisone* and an immunosuppressive agent such as *ciclosporin*, *azathioprine*, *chlorambucil*, or *cyclophosphamide*. Mucocutaneous disease alone rarely warrants this therapy; however, these agents have a beneficial effect on skin and mucous membrane lesions.

Specific Investigations

- Pathergy test optional
- Culture/polymerase chain reaction of aphthae to exclude herpes simplex virus
- Vitamins B₁, B₂, B₆, and B₁₂; folate, zinc, and iron levels
- Urinalysis
- HLA-B51
- Exclude inflammatory bowel disease

Behçet's syndrome: immunopathological and histopathological assessment of pathergy lesions is useful in diagnosis and follow-up

Jorizzo JL, Soloman AR, Cavallo T. Arch Pathol Lab Med 1985; 109: 747–51.

This method of pathergy testing may be more sensitive than standard techniques devoid of histologic study.

Behçet's disease and complex aphthosis

Ghate JV, Jorizzo JL. J Am Acad Dermatol 1999; 40: 1–18.

A review of investigations that should be carried out in a patient with complex aphthosis is presented.

Herpes simplex virus, nutritional deficiencies, neutropenia, lymphopenia, reactive arthritis, and inflammatory bowel disease may simulate the oral aphthae of BD.

Evaluation of current therapeutic strategies in Behçet's disease

Alexoudi I, Kapsimali V, Vaiopoulos A, Kanakis M, Vaiopoulos G. Clin Rheumatol 2011; 30: 157–63.

An excellent review and guide to treatment of all aspects of BD.

Interventions for the management of oral ulcers in Behçet's disease

Taylor J, Glenny AM, Walsh T, Brocklehurst P, Riley P, Gorodkin R, et al. Cochrane Database Syst Rev 2014; 9: CD011018.

In this review, 15 trials ($n = 888$ randomized participants) were included, 13 were placebo controlled, and 3 were head to head (2 trials had more than two treatment arms). According to the authors, due to the heterogeneity of trials, including trial design, choice of intervention, and choice and timing of outcome measures, it was not possible to carry out a meta-analysis.

First-Line Therapies

• Topical/intralesional corticosteroid	B
• Tacrolimus ointment	A
• Pimecrolimus cream	A
• Amlexanox 5% paste	A
• Sucralfate	A
• Tetracycline suspension	D
• Chlorhexidine gluconate	D
• Colchicine	A
• Zinc sulfate	A

Management of Behçet's disease: a systematic literature review for the European League Against Rheumatism evidence-based recommendations for the management of Behçet's disease

Hatemi G, Silman A, Bang D, Bodaghi B, Chamberlian AM, Gul A, et al. *Ann Rheum Dis* 2009; 68: 1528–34.

In this systematic literature review from 1966 to 2006, systemic medications for BD were analyzed for treating different aspects of the disease.

The use of sucralfate suspension in the treatment of oral and genital ulceration of Behçet disease: a randomized, placebo-controlled, double-blind study

Alpsoy E, Er H, Durusoy C, Yilmaz E. *Arch Dermatol* 1999; 135: 529–32.

In this study, 40 patients with BD were included in this randomized, double-blind study, which compared 5 mL sucralfate suspension with placebo suspension used as an oral rinse for 1 to 2 minutes after routine oral care and before bed. Results showed sucralfate significantly decreased the mean frequency, healing time, and pain of oral ulcers in comparison with baseline.

A double-blind trial of colchicine in Behçet's syndrome

Yurdakul S, Mat C, Tuzun Y, Ozyazgan Y, Hamuryudan V, Uysal O, et al. *Arthritis Rheum* 2001; 44: 2686–92.

A prospective, double-blind, controlled trial of 116 patients treated with colchicine vs. placebo. Therapy with colchicine 1 to 2 mg daily was effective for arthritis and erythema nodosum. Orogenital aphthae were more responsive to treatment in females.

Oral zinc sulfate in the treatment of Behçet's disease: a double blind cross-over study

Sharquie KE, Najim RA, Al-Dori WS, Al-Hayani RK. *J Dermatol* 2006; 33: 541–6.

In a prospective, randomized, double-blind, controlled trial, 27 patients with mucocutaneous and/or joint disease and 30 healthy subjects matched for age and gender were treated with zinc sulfate vs. placebo. Zinc sulfate 100 mg three times daily was found to be effective in reducing disease severity, and no adverse effects were reported.

Patients with ocular, neurologic, cardiac, or other systemic manifestations

were excluded.

Pimecrolimus versus placebo in genital aphthous ulcers of Behçet's disease: a randomized double-blind controlled trial

Chams-Davatchi C, Barikbin B, Shahram F, Nadji A, Moghaddassi M, Yousefi M, et al. *Int J Rheum Dis* 2010; 13: 253–8.

This was a randomized, double-blind controlled trial of twice-daily topical pimecrolimus versus placebo in genital aphthous ulcers in patients with BD. There was a significant decrease in healing time with pimecrolimus and slight improvement of pain.

Second-Line Therapies

• Dapsone	A
• Thalidomide	A
• Methotrexate	E
• Systemic corticosteroid	B

Dapsone in Behçet's disease: a double-blind, placebo-controlled, cross-over study

Sharquie KE, Najim RA, Abu-Raghif AR. *J Dermatol* 2002; 29: 267–79.

Randomized, double-blind, placebo-controlled, crossover trial of 20 patients treated with either dapsone 100 mg daily or placebo. There was a significant reduction of orogenital ulcers and other cutaneous manifestations in the dapsone group.

Vitamin E 800 IU daily may reduce the hemolysis induced by dapsone. Other studies have confirmed the utility of dapsone for mucocutaneous BD.

Thalidomide in the treatment of the mucocutaneous lesions of Behçet syndrome: a randomized, double-blind, placebo-

controlled trial

Hamuryudan V, Mat C, Saip S, Ozyazgan Y, Siva A, Yurdakul S, et al. *Ann Intern Med* 1998; 128: 443–50.

A randomized, double-blind, controlled trial of 96 males evaluated thalidomide 100 mg daily vs. 300 mg daily vs. placebo for 24 weeks. Both thalidomide dosages led to a significant suppression of oral ulcers at 4 weeks, and genital ulcers and follicular lesions at 8 weeks. Complete responses were observed in 11% of patients treated with thalidomide.

Low-dose weekly methotrexate for unusual neutrophilic vascular reactions: cutaneous polyarteritis nodosa and Behçet's disease

Jorizzo JL, White WL, Wise CM, Zanolli MD, Sherertz EF. *J Am Acad Dermatol* 1991; 24: 973–8.

Two female patients with oral and genital aphthae, pyoderma gangrenosum-like lesions, and cutaneous pustular vasculitic lesions cleared with methotrexate 15 to 20 mg/week.

Practical treatment recommendations for pharmacotherapy of Behçet's syndrome

Yazici H, Barnes CG. *Drugs* 1991; 42: 796–804.

Intravenous pulse methylprednisolone 1 g on 3 alternate days, or 1 mg/kg daily of prednisone for several weeks with subsequent taper, is recommended for severe or life-threatening major ulcerations.

Third-Line Therapies

• IFN- α_{2a}	A
• Isotretinoin	E
• Ciclosporin	A
• Azathioprine	A
• Cyclophosphamide	E
• Chlorambucil	D
• Minocycline	C
• Penicillin	B
• Prostaglandin E ₁	D
• Rebamipide	A
• Etanercept	A
• Infliximab	D
• Adsorption apheresis	E
• Azithromycin	D
• Oral contraceptives	E
• Nicotine patch	D
• Mycophenolate sodium	C
• Lenalidomide	E
• Apremilast	A

Successful treatment of Behçet's disease with lenalidomide

Green J, Upjohn E, McMormack C, Zeldis J, Prince HM. Br J Dermatol 2008; 158: 197–8.

A case report of improvement of oral ulceration and lethargy in Behçet disease with lenalidomide (10 mg/day).

Of note the patient tolerated the medication well; however, the patient did develop a deep vein thrombosis, which can be independently associated with lenalidomide or BD.

Interferon alfa-2a in the treatment of Behçet disease: a randomized placebo-controlled and double-blind study

Alpsoy E, Durusoy C, Yilmaz E, Ozgurel Y, Ermis O, Yazar S, et al. Arch Dermatol 2002; 138: 467–71.

A randomized, double-blinded, placebo-controlled trial of 23 patients receiving interferon- α_{2a} 6×10^6 IU, subcutaneously three times a week. After 3 months, 15 of 23 patients demonstrated improvement in oral, genital, and papulopustular lesions.

Interferon-alpha treatment of Behçet's disease

O'Duffy JD, Calamia K, Cohen S, Goronzy JJ, Herman D, Jorizzo J, et al. J Rheumatol 1998; 25: 1938–44.

Seven patients underwent daily subcutaneous injections of 3 million units of interferon- α_{2a} . This open trial reported a substantial reduction in mucocutaneous lesions and joint disease. Flulike symptoms, leukopenia, psoriasis, seizure, hyperthyroidism, and psychosis were side effects reported.

Systemic isotretinoin in the treatment of a Behçet's patient with arthritic symptoms and acne lesions

Akyol M, Dogan S, Kaptanoglu E, Ozcelik S. Clin Exp Rheumatol 2002; 20: S55.

A patient with oral ulcers, acne lesions, and arthritis was treated with 6 months of isotretinoin (total dosage 120 mg/kg). The patient experienced complete resolution of his acne and arthritis and reduced severity of oral ulcers, controlled with only topical treatment.

Double-masked trial of cyclosporine versus colchicine and long-

term open study of cyclosporine in Behçet's disease

Masuda K, Nakajima A, Urayama A, Nakae K, Kogure M, Inaba G. Lancet 1989; 1: 1093–6.

Ciclosporin (10 mg/kg) was more effective than colchicine (1 mg/kg) in reducing the number and frequency of oral aphthae and cutaneous lesions (erythema nodosum-like, subcutaneous thrombophlebitis, and folliculitis-like lesions).

Several case reports and open studies corroborate these findings. Note higher doses of ciclosporin used in this study.

Cyclosporine in Behçet's disease: results in 16 patients after 24 months of therapy

Pacor ML, Biasi D, Lunardi C, Cortina P, Caramaschi P, Girelli D, et al. Clin Rheumatol 1994; 13: 224–7.

Sixteen subjects with BD received 5 mg/kg ciclosporin daily for 24 months. A marked improvement of the symptoms was observed after 3 months of therapy, and 14 out of 16 patients obtained a complete clinical remission. Two patients dropped out of the study because of anemia and renal dysfunction, which returned to normal when ciclosporin was withdrawn.

A controlled trial of azathioprine in Behçet's syndrome

Yazici H, Pazarli H, Barnes CG, Tüzün Y, Ozyazgan Y, Silman A, et al. N Engl J Med 1990; 322: 281–5.

A randomized, controlled, double-blind trial of azathioprine 2.5 mg/kg daily vs. placebo in patients with BD resulted in prevention and decreased frequency of ocular disease. The prevalence of oral ulcers and the incidence of genital ulcers were diminished in the azathioprine group.

High-dose cyclophosphamide without stem cell rescue for the treatment of refractory Behçet's disease

Henderson CF, Brodsky RA, Jones RJ, Levine SM. Semin Arthritis Rheum 2011; 41: 301–4.

In this case report, two patients with refractory BD were successfully treated with cyclophosphamide 200 mg/kg intravenously divided over 4 days with disease-free remission lasting 18 to 24 months. Both patients had a transient pancytopenia, and one suffered episodes of pneumonia and *Clostridium difficile* colitis.

Long-lasting remission of Behçet's disease after chlorambucil therapy

Abdalla MI, Bahgat NE. Br J Ophthalmol 1973; 57: 706–11.

Remission of aphthae was achieved in all seven patients treated with oral chlorambucil and corticosteroids, but only in a minority of patients treated with corticosteroids alone.

Streptococcal infection in the pathogenesis of Behçet's disease and clinical effects of minocycline on the disease symptoms

Kaneko F, Oyama N, Nishibu A. Yonsei Med J 1997; 38: 444–54.

In 11 patients treated with minocycline 100 mg daily the frequency of cutaneous symptoms was reduced by 10% for oral aphthae and by 100% for perifolliculitis.

Oral prostaglandin E₁ as a therapeutic modality for leg ulcers in Behçet's disease

Takeuchi A, Hashimoto T. Int J Clin Pharm Res 1987; 7: 283–9.

In five patients, leg ulcers began to regranulate within 2 weeks of using oral prostaglandin E₁ 15 to 30 µg daily.

Efficacy of rebamipide as adjunctive therapy in the treatment of recurrent oral aphthous ulcers in patients with Behçet's disease

Matsuda T, Ohno S, Hirohata S, Miyanaga Y, Ujihara H, Inaba G, et al. Drugs R&D 2003; 4: 19–28.

A multicenter, randomized, double-blind, placebo-controlled prospective study of rebamipide 300 mg/day plus usual therapy ($n = 19$) vs. placebo plus usual therapy ($n = 16$) showed moderate-to-marked improvement of oral aphthae and pain in 65% of the treatment group vs. 36% in the placebo group.

Rebamipide is not available in U.S. however is available in many countries world wide and other uses include treatment for recurrent aphthous ulcers.

Short-term trial of etanercept in Behçet's disease: a double blind, placebo controlled study

Melikoglu M, Fresko I, Mat C, Ozyazgan Y, Gogus F, Yurdakul S, et al. J Rheumatol 2005; 32: 98–105.

A randomized, double-blind, controlled trial of 40 BD patients who received either etanercept 25 mg or placebo subcutaneously twice a

week for 4 weeks. Etanercept was found to be effective in suppressing oral ulcers, nodular lesions, and papulopustular lesions.

Infliximab treatment for ocular and extraocular manifestations of Behçet's disease

Accorinti M, Pirraglia MP, Paroli MP, Priori R, Conti F, Pivetti-Pezzi P. *Jpn J Ophthalmol* 2007; 51: 191–6.

Twelve patients with BD and uveitis refractory to conventional immunosuppressive therapy were given infliximab (5 mg/kg at 0 and 2 weeks, then monthly for 4–6 months and quarterly 1–2 months thereafter). After a median 15-month follow-up, 11 of the 12 showed a significant reduction in the number of ocular relapses, as well as fewer extraocular manifestations, resulting in less systemic corticosteroid use. One patient stopped treatment after 2 months because of the development of pulmonary tuberculosis.

Anti-TNF agents for Behçet's disease: analysis of published data on 369 patients

Arida A, Fragiadaki K, Giavri E, Sfikakis P. *Semin Arthritis Rheum* 2011; 41: 61–70.

In this evidence-based review of the literature regarding anti-TNF agents in BD, the authors concluded that there is enough evidence to suggest that TNF blockade should be considered in patients with severe or resistant disease.

Treatment of Behçet's disease with granulocyte and monocyte adsorption apheresis

Kanekura T, Gushi A, Fukumaru S, Fukumaru S, Sakamoto R, Kawahara K, et al. *J Am Acad Dermatol* 2004; 51: S83–7.

A report of successful treatment of orogenital ulceration in two patients who underwent five and eight treatments each.

Clinical and immunologic effects of azithromycin in Behçet's disease

Mumcu G, Ergun T, Elbir Y, Eksioglu-Demiralp E, Yavuz S, Atalay T, et al. *J Oral Pathol Med* 2005; 34: 13–6.

In eight patients treated with azithromycin 500 mg three times per week for 4 weeks, faster healing times of preexisting oral ulcers, as well as complete resolution of folliculitic lesions, were observed.

Effect of prophylactic benzathine penicillin on mucocutaneous symptoms of Behçet's disease

Calguneri M, Ertenli I, Kiraz S, Erman M, Celik I. *Dermatology* 1996; 192: 125–8.

A prospective, randomized trial with 60 patients revealed statistically significant reduction in frequency and duration of oral aphthae and erythema nodosum–like lesions and the frequency of genital aphthae with the addition of benzathine penicillin 1.2 million units every 3 weeks to colchicine vs. colchicine monotherapy.

This study was apparently nonblinded and not placebo controlled.

Behçet's disease: remission of patient symptoms after oral contraceptive therapy

Oh SH, Kwon JY, Lee JH, Hand EC, Bang D. *Clin Exp Dermatol* 2009; 34: e88–90.

In this case report, a patient with BD had clearing of erythema nodosum and oral and genital ulcers with the administration of oral contraceptives. Upon discontinuation of the oral contraceptive the symptoms returned; however, with readministration the symptoms resolved.

Nicotine-patch therapy of mucocutaneous lesions of Behçet's disease: a case series

Ciancio G, Colina M, La Corte R, Lo Monaco A, De Leonardis F, Trotta F, et al. *Rheumatology* 2010; 49: 501–4.

This case report demonstrated improvement of mucocutaneous lesions with nicotine replacement in ex-smokers with BD.

This cannot be extrapolated to nonsmokers; however, it represents an interesting therapeutic consideration in those patients who are trying to quit smoking.

Mycophenolate sodium in the treatment of mucocutaneous Behçet's disease

Köse O, Simşek I, Pay S. *Int J Dermatol* 2011; 50: 895–6.

In this open, prospective trial mycophenolate sodium was effective in treating 10 patients with refractory mucocutaneous BD without major complications.

Apremilast for Behçet's syndrome—a phase 2, placebo-controlled study

Hatemi G, Melikoglu M, Tunc R, Korkmaz C, Turgut Ozturk B, Mat C, et al. N Engl J Med 2015; 372: 1510–18.

In this phase II, multicenter, placebo-controlled study, 111 patients received 30 mg of apremilast twice daily or placebo for 12 weeks followed by a 12-week extension phase in which the placebo group was switched to apremilast with a 28-day posttreatment observation phase. The mean number of ulcers per patient was significantly lower in the apremilast group than in the placebo group, and the mean reduction in pain from baseline was greater with apremilast than placebo.

This study was not long enough or large enough to assess long-term efficacy.

Apremilast, a phosphodiesterase-4 inhibitor, appears to be promising as an effective treatment of oral ulcers in BD.

Bioterrorism

*Cody R. Thornton, and Boris D. Lushniak**

Bioterrorism is defined as the use of viruses, bacteria, fungi, or toxins from living organisms to produce death or disease in humans, animals, or plants. The diseases that are of greatest concern are smallpox, anthrax, tularemia, plague, the hemorrhagic fevers, and botulism (which has no cutaneous features and will not be further discussed here). Several of the conditions discussed, including smallpox, pneumonic plague, and viral hemorrhagic fevers, are contagious to caregivers, so appropriate care must be taken to prevent the further transmission of disease.

Smallpox

After a worldwide vaccination campaign, the last natural case occurred in Somalia in 1977, and by 1980 the World Health Assembly declared smallpox eradicated. The virus now remains stored in secure laboratory facilities in the United States and Russia.

Smallpox is a highly stable virus, spread by direct contact, short distance (6 feet) aerosol exposure, or, in rare cases, through fomites. The incubation period ranges from 7 to 19 days, followed by a prodrome of 2 to 4 days, which includes high fever (101–104°F), prostration, malaise, and myalgias. After the prodrome, an exanthem appears with a mostly centrifugal distribution. Lesions progress in a synchronous fashion from macule (day 0–1), to papule (day 2–3), to deep tense umbilicated vesicle (day 3–5), to deep round tense pustule (day 6–12), to crust formation (day 13–20), to crust separation (day 21–28), and resulting depressed scars. Complications of smallpox

include sepsis and toxemia, encephalitis, and blindness.

The differential diagnosis for smallpox includes varicella and disseminated herpes simplex or zoster; molluscum contagiosum; erythema multiforme; pustular drug eruption; purpura fulminans; hand, foot, and mouth disease; and monkeypox. Varicella has a relatively benign prodrome, with more superficial lesions in a centripetal distribution with asynchronous evolution and crusting in 4 to 7 days.

Smallpox vaccination with the scarification technique using the live vaccinia virus can cause adverse reactions in those vaccinated as well as their close contacts. Contraindications to nonemergency vaccination include immunodeficiency states, immunomodulating medications, allergic reactions, pregnancy, cardiovascular diseases, and epidermal-disrupting diseases such as atopic dermatitis, pemphigus, or Darier disease in vaccine recipients or family members. Localized skin reactions include a robust primary reaction at the site, autoinoculation or contact transmission of the vaccinia, and ocular vaccinia. Generalized skin reactions with systemic symptoms can also occur, including generalized vaccinia (distant site viremic spread), erythema multiforme major, progressive vaccinia (progressive necrosis at the site), and eczema vaccinatum (localized or systemic dissemination) as seen in those with atopic dermatitis or other skin diseases. Other adverse reactions of vaccination include postvaccinial encephalopathy and encephalomyelitis and myopericarditis. A new-generation vaccine given by the subcutaneous route, a nonreplicating attenuated modified *vaccinia* ankara (Imvamune), has been investigated, and adverse reactions seem to be minimized and may be used in atopics. This new vaccine is stockpiled in the U.S. Strategic National Stockpile but would require investigational new drug or emergency use authorization protocols.

Management Strategy

The management of smallpox includes the recognition, diagnosis, and isolation of index cases; notification of public health authorities; *vaccination*; treatment; supportive care of the cases; and vaccination and isolation of those who were in contact with the cases. Although there is no specific treatment for smallpox, several investigational antiviral candidates are undergoing study for both treatment of

disease and for adverse events associated with vaccination. *Vaccinia immune globulin* is also available from the CDC to treat specific adverse events. In an outbreak scenario a “ring vaccination” strategy, as used in the eradication program, would be used initially whereby the case would be vaccinated, as well as those exposed to the case and those exposed to the exposed, in an expanding ring fashion. Vaccination should be effective in limiting the disease if given within 3 to 4 days of exposure.

Specific Investigations

- Tzanck smear
- Direct fluorescent antibody testing for varicella zoster virus (VZV) and herpes simplex virus (HSV)
- Polymerase chain reaction (PCR) for VZV, vaccinia, variola, other orthopox viruses (monkeypox)
- Electron microscopy
- Orthopox virus culture
- Serology

Laboratory diagnosis to differentiate smallpox, vaccinia, and other vesicular/pustular illnesses

Besser JM, Crouch NA, Sullivan M. J Lab Clin Med 2003; 142: 246–51.

Patients who are at risk should have laboratory testing to include electron microscopy, PCR, orthopox virus culture, and variola serology performed at designated laboratories. Tzanck smears and real-time PCR assays for HSV and VZV can be performed at standard reference laboratories.

Cutaneous manifestations of category A bioweapons

Aquino LL, Wu JJ. J Am Acad Dermatol 2011; 65: 1213.e1–15.

Reviews the diagnosis and treatment of diseases caused by potential biowarfare agents that produce cutaneous manifestations and provides information regarding reporting and containment of possible bioterrorism-related diseases.

Clinical management of potential bioterrorism-related conditions

Adalja AA, Toner E, Inglesby TV. N Engl J Med 2015; 372: 954–62.

The purpose of this review is to highlight clinically useful issues

and management of deliberate infection with several pathogens of greatest bioweapons concern. Because most of these conditions can occur naturally, suspicion for bioterrorism depends on clinicians being alert to unusual patterns, such as unexplained clusters of infection.

Development and experience with an algorithm to evaluate suspected smallpox cases in the United States, 2002–2004

Seward JF, Galil K, Damon I, Norton SA, Rotz L, Schmid S, et al. Clin Infect Dis 2004; 39: 1477–83.

Diagnostic criteria and a CDC algorithm to evaluate and manage suspected cases of smallpox. Three categories (i.e., low, moderate, or high risk of actually having smallpox) dictate subsequent diagnostic strategies. Specific variola laboratory testing is reserved for high-risk persons. An interactive version of the algorithm is available online at <http://www.bt.cdc.gov/agent/smallpox/diagnosis/riskalgorithm/index>.

First-Line Therapies

Suspected cases

• Isolation—negative-pressure room	A
• Respiratory and contact isolation	A
• Vaccination of early-stage patients	A
• Maintenance of hydration and adequate nutrition	A

Vaccination reactions

• Vaccinia immune globulin	D
• Idoxuridine for corneal lesions	D
• Antivirals	E

Countermeasures and vaccination against terrorism using smallpox: pre-event and post-event smallpox vaccination and its contraindications

Sato H. *Environ Health Prev Med* 2011; 16: 281–9.

Core components of the public health management of a terrorist attack using smallpox are vaccination (ring vaccination and mass vaccination); adverse event monitoring; confirmed and suspected smallpox case management; contact management; identifying, tracing, and monitoring contacts; and quarantine.

Inactivation of poxviruses by upper-room UVC light in a simulated hospital room environment

McDevitt JJ, Milton DK, Rudnick SN, First MW. *PLoS ONE* 2008; 3: e3186.

A reduction in airborne *Vaccinia* concentrations can be obtained by combining UV light, upper-room 254-nm germicidal UVC, with air mixing using a conventional ceiling fan. Although the greatest risk for an aerosol attack with smallpox is during the winter, protective measures using UVC would be best suited during winter due to the increased survival at baseline and greater UVC susceptibility of *Vaccinia* under winter conditions.

Vaccinia virus infection after sexual contact with a military smallpox vaccinee

Morb Mortal Wkly Rep 2010; 59: 773–5.

Health care providers should consider vaccinia virus infection in the differentials of clinically compatible genital lesions (conjugal transfer vaccinia).

Progressive vaccinia in a military smallpox vaccinee: United States, 2009

MMWR Morb Mortal Wkly Rep 2009; 58: 532–6.

This report summarizes the patient's clinical course and medical management. This is the first confirmed case of progressive vaccinia in the United States since 1987. Therapy included imiquimod, VIG, oral and topical ST-246 (a smallpox drug candidate with antiorthopox activity inhibiting virus maturation), and oral CMX001 (a lipid conjugate of cidofovir) under emergency investigational new drug protocols.

Household transmission of vaccinia virus from contact with a military smallpox vaccinee: Illinois and Indiana, 2007

MMWR Morb Mortal Wkly Rep 2007; 56: 478–81.

This case highlights the need for clinicians to maintain a high index of suspicion when evaluating recently vaccinated patients and their family members with vesiculopustular rash. This is the first eczema vaccinatum case reported in the United States since 1988. Therapy included cidofovir, VIG, and oral ST-246 under emergency investigational new drug protocols.

A randomized, double-blind, dose-finding phase II study to evaluate immunogenicity and safety of the third generation smallpox vaccine candidate Imvamune

von Krempelhuber A, Vollmar J, Pokorny R, Rapp P, Wulff N, Petzold B, et al. Vaccine 2010; 28: 1209–16.

Imvamune is a modified *Vaccinia* ankara–based virus that is being developed as a safer third-generation smallpox vaccine, especially in those for whom traditional smallpox vaccines are contraindicated, such as the immunocompromised and those with eczema or dermatitis. Imvamune has displayed a favorable safety profile, with local reactions as the most frequent observation.

Smallpox vaccine, ACAM2000: sites and duration of viral shedding and effect of povidone iodine on scarification site shedding and immune response

Pittman PR, Garman PM, Kim SH, Schmader TJ, Nieding WJ, Pike JG, et al. Vaccine 2015; 33: 2990–6.

Counter to current dogma, this study showed that VACV continues to shed from the vaccination site after the scab separates. The use of povidone iodine in addition to a semipermeable dressing may reduce the rates of autoinoculation and contact transmission originating from the vaccination site in smallpox-vaccinated individuals.

Adverse events following smallpox vaccination with ACAM2000 in a military population

Beachkofsky TM, Carrizales SC, Bidinger JJ, Hrncir DE, Whittemore DE, Hivnor CM. Arch Dermatol 2010; 146: 656–61.

Presentation of the first confirmed case of generalized vaccinia after immunization with the second-generation smallpox vaccine ACAM2000. In addition, there is a description of seven cases of

benign, acral, papulovesicular eruptions thought to be associated with ACAM2000 administration.

Clinical efficacy of intramuscular Vaccinia immune globulin: a literature review

Hopkins RJ, Lane JM. Clin Infect Dis 2004; 39: 819–26.

Vaccinia immune globulin (VIG) reduces the morbidity and mortality associated with progressive vaccinia (vaccinia necrosum) and eczema vaccinatum. Indications for treatment include generalized vaccinia, progressive vaccinia, eczema vaccinatum, and some accidental implantations. The use of intramuscular administration of VIG to prevent smallpox in contacts of patients with documented cases is also discussed.

Pregnancy discovered after smallpox vaccination: is vaccinia immune globulin appropriate?

Napolitano PG, Ryan MA, Grabenstein JD. Am J Obstet Gynecol 2004; 191: 1863–7.

VIG is not approved for use in fetal vaccinia complications, and a risk of teratogenicity from mercury in the thimerosal preservative has been cited. Fetal vaccinia is a rare complication of smallpox vaccination during pregnancy, and although some have suggested that therapeutic treatment with VIG can prevent fetal vaccinia, VIG should only be given if a pregnant woman develops a condition in which VIG is indicated (e.g., eczema vaccinatum, progressive vaccinia, or serious generalized vaccinia).

A prospective study of the incidence of myocarditis/pericarditis and new onset cardiac symptoms following smallpox and influenza vaccination

Engler RJ, Nelson MR, Collins LC Jr, Spooner C, Hemann BA, Gibbs BT, et al. PLoS One 2015; 10: e0118283.

Passive surveillance significantly underestimates the true incidence of myocarditis/pericarditis after smallpox immunization. A postsmallpox incidence rate was more than 200 times higher than the presmallpox background population surveillance rate of myocarditis/pericarditis (RR 214, 95% CI 65–558). Active safety surveillance is needed to identify adverse events that are not well understood or previously recognized.

Traditional smallpox vaccination with reduced risk of inadvertent contact spread by administration of povidone iodine ointment

Hammarlund E, Lewis MW, Hanifin JM, Simpson EL, Carlson NE, Slifka MK. Vaccine 2008; 26: 430–9.

This ointment rapidly inactivated virus on the skin without reducing neutralizing antibody titers or antiviral T-cell responses. Moreover, there was no delay in healing/eschar separation after povidone iodine application.

Second-Line Therapies

• Penicillinase-resistant antibiotics for secondary skin infection	D
• Local treatments—manage like a “burn patient”	C
• Idoxuridine (topical) treatment of corneal lesions	C
• Efficacy is probable in view of use in vaccinia (see earlier).	

Third-Line Therapies

• Cidofovir plus VIG plus drug candidates ST-246 or CMX001 (see vaccination reactions)	D
• Cidofovir	E
• Cidofovir plus VIG	E
• Imvamune	E
• Brincidofovir	E

Severe eczema vaccinatum in a household contact of a smallpox vaccinee

Vora S, Damon I, Fulginiti V, Weber SG, Kahana M, Stein SL, et al. Clin Infect Dis 2008; 46: 1555–61.

A 28-month-old child with refractory atopic dermatitis developed severe eczema vaccinatum after exposure to his father, a U.S. military member who had recently received smallpox vaccine. In this first confirmed case of eczema vaccinatum in the United States related to smallpox vaccination since routine vaccination was discontinued in 1972, the child was treated with intravenous *Vaccinia* immune

globulin, used for the first time in a pediatric patient, cidofovir, and ST-246, an investigational drug being studied for orthopoxvirus infection.

Cidofovir in the treatment of poxvirus infections

De Clercq E. Antiviral Res 2002; 55: 1–13.

Experimental use of cidofovir in poxvirus infections.

Cutaneous infections of mice with vaccinia or cowpox viruses and efficacy of cidofovir

Quenelle DC, Collins DJ, Kern ER. Antiviral Res 2004; 63: 33–40.

In hairless mice, 5% topical cidofovir was more effective than systemic treatment at reducing virus titers in skin, lung, kidney, and spleen.

Repeated high-dose (5×10^8 TCID₅₀) toxicity study of a third generation smallpox vaccine (Imvamune) in New Zealand white rabbits

Tree JA, Hall G, Rees P, Vipond J, Funnell SG, Roberts AD. Hum Vaccin Immunother 2016; 12: 1795–801.

Subcutaneous injection of two high-doses of Imvamune to rabbits was well tolerated, producing only minor changes at the site of administration.

The efficacy and pharmacokinetics of brincidofovir for the treatment of lethal rabbitpox virus infection: a model of smallpox disease

Trost LC, Rose ML, Khouri J, Keilholz L, Long J, Godin SJ, et al. Antiviral Res 2015; 117: 115–21.

Observation of a dose-dependent increase in survival occurred in all brincidofovir (BCV)-treatment groups demonstrating the activity of BCV in the rabbitpox model of smallpox and the feasibility of scaling doses efficacious in the model to a proposed human dose and regimen for treatment of smallpox.

Anthrax

Anthrax is caused by spores from the gram-positive, nonmotile *Bacillus anthracis*. Farm workers or processors of wool, hair, or hides

are at risk. After a livestock vaccination campaign in the 1950s, anthrax became a very rare disease in the United States, with only 409 cases (of which 18 were inhalational and the remainder cutaneous) described from 1951 to 2000. In 2001 anthrax spores were disseminated in a bioterrorist incident through the U.S. mail system resulting in 11 inhalational cases (5 deaths) and 11 cutaneous cases.

Cutaneous anthrax is the form most commonly encountered in naturally occurring cases. A nontender pruritic macule and then papule develops 1 to 12 days after skin exposure and inoculation of spores (see the figure). Within 48 hours this lesion develops into a vesicle or bulla, which then ruptures, forming a depressed, black, necrotic ulcer (black eschar) within an edematous, erythematous plaque. The greatest concern in a bioterrorist event would be inhalational anthrax, which can occur from 1 to over 40 days after exposure. The initial prodrome is a viral-like illness with myalgias, fatigue, and fever followed by hypoxia and dyspnea (with evidence of radiographic mediastinal widening) and respiratory failure. After the initial infection the spores produce toxins that do not respond to antibiotics. Historically inhalation anthrax resulted in a high fatality rate.

The diagnosis of any form of anthrax, especially in nonrural areas, requires a high index of suspicion and would mandate a notification of public health authorities. The varied differential diagnosis of cutaneous anthrax includes insect bite, brown recluse spider bite, tularemia, the *tache noir* of rickettsial diseases, ecthyma gangrenosum, staphylococcal or streptococcal ecthyma, cat scratch disease, orf, and other conditions with eschar or an ulceroglandular presentation.

Management Strategy

Universal precautions should be maintained in evaluating a patient with suspected cutaneous anthrax. *Ciprofloxacin* and *doxycycline* are the mainstays of therapy. The need for postexposure prophylaxis with antibiotics would be determined by public health officials based upon the epidemiologic investigation and the likelihood of exposure to spores. The duration of treatment and postexposure prophylaxis may be up to 60 days.

The vaccine, anthrax vaccine adsorbed (AVA), induces immunity to a protein in the toxins. The regimen consists of six injections at 0, 2, and 4 weeks, followed by doses at 6, 12, and 18 months plus annual

boosters. Vaccination is only indicated for at-risk laboratory workers, select emergency responders, and military personnel. In combination with antibiotics, postexposure vaccination may be effective in preventing disease after exposure to *B. anthracis* spores.

Specific Investigations

- Culture and Gram stain of tissue, blood, or other fluids
- For cutaneous anthrax, use a Dacron or rayon swab (not cotton) to swab the vesicle, ulcer, or eschar edge
- Punch biopsy fixed in formalin from a papule or vesicular lesion and including adjacent skin
- Biopsies should be taken from both vesicle and eschar, if present
- A photograph, digital image, or diagram indicating the site of each biopsy in relation to the lesion
- Immunohistochemical assays
- Serology (available through CDC)
- PCR assay

Cutaneous manifestations of category A bioweapons

Aquino LL, Wu JJ. J Am Acad Dermatol 2011; 65: 1213.e1–15.

Reviews diagnosis, treatment, reporting, and containment of diseases caused by potential biowarfare agents that produce cutaneous manifestations.

Severe systemic *Bacillus anthracis* infection in an intravenous drug user

Veitch J, Kansara A, Bailey D, Kustos I. BMJ Case Rep 2014; 2014: pii: bcr2013201921.

Summarization of the steps in diagnosis and the management options, including extensive surgical debridement and a prolonged course of combination antibiotic therapy, in patients presenting with systemic *Bacillus anthracis* infection.

Anthrax infection

Sweeney DA, Hicks CW, Cui X, Li Y, Eichacker PQ. Am J Respir Crit Care Med 2011; 184: 1333–41.

Clues to anthrax infection include history of exposure to herbivore animal products, heroin use, or clustering of patients with similar

respiratory symptoms suggesting a bioterrorist event. This review summarizes the microbiology, pathogenesis, diagnosis, and management of anthrax.

An overview of anthrax infection including the recently identified form of disease in injection drug users

Hicks CW, Sweeney DA, Cui X, Li Y, Eichacker PQ. Intensive Care Med 2012; 38: 1092–104.

Patients with gastrointestinal, inhalational, or injectional anthrax may have advanced infection at presentation that can be highly lethal. Once anthrax is suspected, the diagnosis can usually be made with Gram stain and culture from blood or tissue followed by confirmatory testing (e.g., PCR).

Application of r-PFE hyperimmune sera for concurrent detection of *Bacillus anthracis*, *Yersinia pestis* and staphylococcal enterotoxin B

Balakrishna K, Tuteja U, Murali HS, Batra HV. J Appl Microbiol 2014; 116: 1465–73.

Evaluate the potential of an intergeneric multidomain recombinant chimeric protein for the simultaneous detection of *Bacillus anthracis*, *Yersinia pestis*, and staphylococcal enterotoxin B.

First-Line Therapies

• Raxibacumab—human monoclonal antibody	D
• Ciprofloxacin	D
• Doxycycline	D

Oral antibiotics are used for cutaneous anthrax below the head and neck if systemic symptoms and malignant edema are absent. If they are present, intravenous antibiotics are used.

Anthrax prevention and treatment: utility of therapy combining antibiotic plus vaccine

Klinman DM, Yamamoto M, Tross D, Tomaru K. Expert Opin Biol

Ther 2009; 9: 1477–86.

For the foreseeable future, vaccination will rely on first- and second-generation vaccines coadministered with immune adjuvants. Optimal postexposure treatment of immunologically naive individuals should include a combination of vaccine plus antibiotic therapy.

Raxibacumab [treatment of inhalation anthrax]

Mazumdar S. mABs 2009; 1: 531–8.

Raxibacumab (ABthrax) is a human IgG1 monoclonal antibody against *Bacillus anthracis* and protective antigen approved through the U.S. Food and Drug Administration's (FDA) animal efficacy rule, better known as the *animal rule pathway*.

Second-Line Therapies

• Amoxicillin	D
• Penicillin	D
• Chloramphenicol	D
• Clindamycin	D
• Systemic corticosteroids for treatment of edema	E

Amoxicillin for postexposure inhalational anthrax in pediatrics: rationale for dosing recommendations

Alexander JJ, Colangelo PM, Cooper CK, Roberts R, Rodriguez WJ, Murphy MD. *Pediatr Infect Dis J* 2008; 27: 955–7.

Covers dosage considerations and dosing intervals for postexposure inhalational anthrax.

Third-Line Therapies

• Macrolides	E
• Aminoglycosides	E
• Chloroquine—experimental	E
• Combination MAb—experimental	E

Combinations of monoclonal antibodies to anthrax toxin manifest new properties in neutralization assays

Pohl MA, Rivera J, Nakouzi A, Chow SK, Casadevall A. Infect Immun 2013; 81: 1880–8.

Although no single MAb to LF provided significant toxin neutralization, LF-immunized mice were completely protected from infection with *B. anthracis* strain Sterne, which suggested that a polyclonal response is required for effective toxin neutralization. A combination of multiple MAbs may provide the most effective form of passive immunotherapy, with the caveat that these may demonstrate emergent properties with regard to protective efficacy.

A dual-purpose protein ligand for effective therapy and sensitive diagnosis of anthrax

Vuyisich M, Gnanakaran S, Lovchik JA, Lyons CR, Gupta G. Protein J 2008; 27: 292–302.

Article reports the design of a bivalent protein ligand with dual use in therapy and diagnosis of anthrax caused by *Bacillus anthracis*.

Prophylaxis

• Vaccination	A
• Antibiotics	A

Use of anthrax vaccine in the U.S.: recommendations of the Advisory Committee on Immunization Practices (ACIP)

Wright JG, Quinn CP, Shadomy S, Messonnier N. MMWR 2010; 59: 1–30.

This statement (1) provides updated information on anthrax epidemiology; (2) summarizes the evidence regarding the effectiveness and efficacy, immunogenicity, and safety of AVA; (3) provides recommendations for preevent and preexposure use of AVA; and (4) provides recommendations for postexposure use of AVA.

A short course of antibiotic treatment is effective in preventing death from experimental inhalational anthrax after discontinuing antibiotics

Vietri NJ, Purcell BK, Tobery SA, Rasmussen SL, Leffel EK, Twenhafel NA, et al. J Infect Dis 2009; 199: 336–41.

In the treatment of inhalational anthrax, the prolonged course of antibiotics required to achieve prophylaxis may not be necessary to prevent anthrax that results from the germination of retained spores after the discontinuation of antibiotics.

Comprehensive analysis and selection of anthrax vaccine adsorbed immune correlates of protection in rhesus macaques

Chen L, Schiffer JM, Dalton S, Sabourin CL, Niemuth NA, Plikaytis BD, et al. Vaccine Immunol 2014; 21: 1512–20.

The anti-PA IgG levels at the time of challenge (last) were the most accurate single measure for determining the probability of survival against inhalation anthrax in rhesus macaques completing a 3-i.m. priming series of AVA. In the absence of a last anti-PA IgG

measurement concurrent with aerosol exposure, the month-7 anti-PA IgG and TNA responses to 3-i.m. priming are suitable alternative correlates of protection.

Tularemia

Tularemia is caused by the very infectious (as few as 10–50 organisms can cause disease) gram-negative coccobacillus *Francisella tularensis*, found in rodents, rabbits, and hares. Exposure can occur through insect bites (usually infected ticks or deerflies), handling of infected animal carcasses, eating or drinking contaminated food or water, or through inhalation. Symptoms can appear 1 to 14 days after exposure, and person-to-person transmission is not seen. Inhalational (pneumonic) tularemia would most likely be the chief concern in a bioterrorist event. It starts abruptly as a flulike illness or atypical pneumonia with fever, chills, headaches, sore throat, and myalgia. Pulmonary symptoms can include a dry cough and pleuritic chest pain and, if untreated, can escalate to severe bronchopneumonia, hemoptysis, and respiratory failure, with marked hilar lymphadenitis.

Ulceroglandular tularemia presents with a painful papule at the site of inoculation. The papule progresses to a pustule and then to a tender ulcer with eschar formation. Regional lymph nodes become enlarged and tender (buboes), usually within a few days after the appearance of the papule. Oculoglandular tularemia presents with conjunctival ulcerations and purulent conjunctivitis, periorbital edema, and nodules of the conjunctivae, along with tender preauricular or cervical lymphadenopathy. Glandular tularemia is marked by lymphadenopathy with no ulcer formation.

Oropharyngeal tularemia presents with gastrointestinal symptoms, stomatitis, and exudative pharyngitis or tonsillitis, sometimes with ulceration and pronounced cervical or retropharyngeal lymphadenopathy

The varied clinical manifestations of tularemia may show exanthems, which may be macular, papular, papulovesicular, pustular, or petechial, and are most prominent on the face and extremities. Erythema nodosum, erythema multiforme, and Sweet syndrome have also been described.

Although a high level of suspicion would be necessary, ulceroglandular or oculoglandular disease has a rather straightforward presentation. However, pneumonic tularemia has variable pulmonary symptoms.

Management Strategy

The organism can be cultured and detected in secretions, exudates, or biopsy specimens by direct fluorescent antibody or immunohistochemical techniques. Antigen detection assays, polymerase chain reaction (PCR), enzyme-linked immunoassays (ELISA), and other specialized techniques may be used. Serum antibody titers could be helpful, but not until 10 days into the disease course.

For severe disease, parenteral therapy is indicated. *Streptomycin* has been used successfully for many years for tularemia, but it is not widely available and has been replaced by gentamicin. Streptomycin is ototoxic and nephrotoxic to patients, and if administered to pregnant women can cause fetal hearing loss and kidney damage. Oral *ciprofloxacin* and *doxycycline* have proven effective in the treatment of tularemia. There is no vaccine currently available.

Specific Investigations

- Gram stain

- Culture
- Serology — agglutination and ELISA testing
- Direct fluorescent antibody and immunohistochemistry
- PCR

Ultrasound of lymph nodes. Clinical and laboratory findings of tularemia: a retrospective analysis

Koç S, Duygu F, Söğüt E, Gürbüzler L, Eyibilen A, Aladağ I. Kulak Burun Bogaz Ihtis Derg 2012; 22: 26–31.

Aims to define demographic characteristics and clinical and laboratory findings of the patients with tularemia and to assess the treatment outcomes. Tularemia should be differentiated from upper respiratory tract infections and cervical lymphadenopathy.

WHO guidelines on tularaemia

WHO/CDS/EPR. Geneva: World Health Organization, 2007.

This text provides comprehensive data about tularemia, epidemiology, clinical expression, laboratory diagnostics, and treatment considerations.

Evaluation of clinical and sonographic features in 55 children with tularemia

Oz F, Eksioglu A, Tanır G, Bayhan G, Metin Ö, Teke TA. Vector Borne Zoonotic Dis 2014; 14: 571–5.

Sonographic findings may be useful in the evaluation and staging of lymphadenopathy.

First-Line Therapies

• Streptomycin	B
• Gentamicin	B
• Ciprofloxacin for uncomplicated disease	C

Second-Line Therapies

• Doxycycline	D
• Chloramphenicol	D

Tularemia: current diagnosis and treatment options

Hepburn MJ, Simpson AJ. Expert Rev Anti Infect Ther 2008; 6: 231–40.

This review focuses on the utility of culture, PCR, and serologic testing for tularemia. In addition, it reviews the evidence to support different therapeutic options for tularemia, highlighting both the most effective supporting evidence for therapeutic recommendations and gaps in current knowledge.

Evaluation of tularaemia courses: a multicentre study from Turkey

Erdem H, Ozturk-Engin D, Yesilyurt M, Karabay O, Elaldi N, Celebi G, et al. Clin Microbiol Infect 2014; 20: O1042–51.

Cervical lymphadenomegaly was the most common clinical sign, and granulomatous inflammation of lymph nodes was the most common histopathologic finding. The most common complication of oropharyngeal tularemia was lymph node suppuration. Hence, the differential diagnosis of tuberculosis is an important concern for tularemia patients. The most commonly used antibiotics were streptomycin and doxycycline.

Tularemia in children: evaluation of clinical, laboratory and therapeutic features of 27 tularemia cases

Kaya A, Deveci K, Uysal IO, Güven AS, Demir M, Uysal EB, et al. Turk J Pediatr 2012; 54: 105–12.

Streptomycin should be the first-line antibiotic in the treatment of pediatric tularemia cases.

Plague

Plague, caused by the gram-negative bacillus *Yersinia pestis*, is a disease of rodents and their fleas. Bubonic plague usually occurs after a bite and begins with fever and flulike symptoms. Then swollen, tender lymph nodes (buboes) develop near the site of the infected bite, most often in the cervical, axillary, femoral, or inguinal areas. Vesicles, pustules, eschars, or ulcerations can appear at the site of the bite. Without antibiotic treatment, secondary pneumonia or septicemia may follow. Highly contagious pneumonic plague can be primary and spread from person to person (or even cat to person) or may develop secondarily from bubonic or septicemic plague. One to 6 days after exposure, patients with pneumonic plague present with fever, headache, weakness, gastrointestinal symptoms, and rapidly developing pneumonia with dyspnea, chest pain, productive cough, and hemoptysis, and can progress to respiratory failure and sepsis.

Management Strategy

Early diagnosis mandates a high level of suspicion. Diagnostic tools include antigen detection, immunoassays, immunostaining, and PCR. Cultures and staining of sputum, blood, or lymph node aspirate will assist in the diagnosis. Cases should be reported immediately to public health authorities. Drainage and secretion precautions are indicated for buboes, and strict respiratory isolation and respiratory droplet precautions are mandatory for the first 48 hours of therapy of pneumonic plague. Postexposure prophylactic treatment of at-risk contacts is mandatory.

Streptomycin is the drug of choice for plague but has limited availability. It is ototoxic and nephrotoxic, and if administered to pregnant women can cause fetal hearing loss and kidney damage. *Gentamicin* is also used for plague and is favored in pregnancy. *Doxycycline*, *ciprofloxacin*, and *chloramphenicol* can also be used in treatment. All are highly effective if used early. Vaccines are not available.

Specific Investigations

- Gram stain and culture of sputum and fluid from buboes

- Serology
- PCR

Sentinel laboratory guidelines for suspected agent of bioterrorism: *Yersinia pestis*

American Society for Microbiology, Washington DC, 2009.
Comprehensive guide to *Yersinia pestis*.

Detection of *Yersinia pestis* using real-time PCR in patients with suspected bubonic plague

Riehm JM, Rahalison L, Scholz HC, Thoma B, Pfeffer M, Razanakoto LM, et al. Mol Cell Probes 2011; 25: 8–12.

The best real-time PCR assay was the 5'-nuclease assay targeting the plasminogen activator gene (*pla*), which was positive in 120 cases. In conclusion, the 5'-nuclease assay targeting *pla* can be recommended as a diagnostic tool for establishing a presumptive diagnosis when bubonic plague is clinically suspected.

Outbreak of human pneumonic plague with dog-to-human and possible human-to-human transmission—Colorado, June-July 2014

Runfola JK, House J, Miller L, Colton L, Hite D, Hawley A, et al. MMWR Morb Mortal Wkly Rep 2015; 64: 429–34.

This outbreak highlights (1) the need to consider plague in the differential diagnosis of ill domestic animals, including dogs, in areas where plague is endemic; (2) the limitations of automated diagnostic systems for identifying rare bacteria such as *Y. pestis*; and (3) the potential for milder plague illness in patients taking antimicrobial agents. Hospital laboratorians should be aware of the limitations of automated identification systems, and clinicians should suspect plague in patients with clinically compatible symptoms from whom *Pseudomonas luteola* is isolated.

Bioterrorism: class A agents and their potential presentations in immunocompromised patients

Richard JL, Grimes DE. Clin J Oncol Nurs 2008; 12: 295–302.

The variable signs and symptoms that may be present in immunocompromised patients with cancer are discussed with a focus on assessment and early recognition of an outbreak. The availability

of vaccines and the implications for patients with cancer receiving these vaccines is also discussed.

First-Line Therapies

• Intramuscular streptomycin	A
• Intramuscular or intravenous gentamicin	A

In vitro efficacy of antibiotics commonly used to treat human plague against intracellular *Yersinia pestis*

Wendte JM, Ponnusamy D, Reiber D, Blair JL, Clinkenbeard KD. Antimicrob Agents Chemother 2011; 55: 3752–7.

Provides an understanding of the selection of antibiotics for prophylactic treatment in the case of a bioterrorism event with *Yersinia*.

Second-Line Therapies

• Doxycycline	C
• Ciprofloxacin	C

Third-Line Therapies

• Chloramphenicol	D
• Sulfonamides	D

Use of an in vitro pharmacodynamic model to derive a moxifloxacin regimen that optimizes kill of *Yersinia pestis* and prevents emergence of resistance

Louie A, Heine HS, VanScoy B, Eichas A, Files K, Fikes S, et al. Antimicrob Agents Chemother 2011; 55: 822–30.

The efficacies of simulated pharmacokinetic profiles for human 10-day clinical regimens of ampicillin, meropenem, moxifloxacin, ciprofloxacin, and gentamicin were compared with the gold standard, streptomycin.

Viral hemorrhagic fevers

The viral hemorrhagic fevers are caused by viruses of four distinct families: arenaviruses, filoviruses, bunyaviruses, and flaviviruses. They are all RNA viruses and are found in animal or insect hosts that can infect humans. In some cases human-to-human spread through bodily fluids is possible as in Ebola, Marburg, Lassa, and Crimean-Congo hemorrhagic fevers. The mode of transmission, clinical course, and mortality of these illnesses vary with the specific virus involved, but each is capable of causing a hemorrhagic fever syndrome. Symptoms include fever, fatigue, dizziness, myalgias, exhaustion, vomiting, diarrhea, and hemorrhagic manifestations, such as hemorrhagic or purpuric skin lesions, epistaxis, hematemesis, hemoptysis, blood in stools, multiple organ failure, hypotension, and shock.

Management Strategy

As a result of the outbreak of Ebola in West Africa from 2014 to 2015 there have been significant updates to the scientific literature,

specifically on Ebola virus. However, many of the same foundational requirements for detection and case management remain, including a high index of suspicion for patients presenting with a febrile illness and hemorrhagic manifestations and strict infection control practices for provider safety. Atypical presentations are possible and include asymptomatic cases. Cases, even suspect ones, should be reported immediately to public health authorities. Because of the high risk to close contacts, including health care workers, strict *universal precautions, appropriate barrier protection, and isolation* should be instituted. Contacts of suspected cases must be closely monitored. Care depends largely on availability of appropriate resources and treatment facilities and still remains primarily supportive. Ribavirin may be effective in Lassa fever or hemorrhagic fever with renal syndrome. Diagnostic tests are only available through select federal labs. Vaccines are available only for yellow fever and Argentine hemorrhagic fever; nonlicensed vaccines are currently developed for Ebola.

Specific Investigations

- Antigen detection by antigen-capture ELISA
- IgM antibody detection by antibody-capture ELISA
- Reverse transcriptase PCR
- Viral isolation is of limited value because it requires a biosafety level 4 laboratory

Clinical presentation, biochemical, and haematological parameters and their association with outcome in patients with Ebola virus disease: an observational cohort study

Hunt L, Gupta-Wright A. Lancet Infect Dis 2015; 15: 1292–9.

Ebola virus disease (EVD) is associated with a high prevalence of hematologic and biochemical abnormalities, even in mild disease and in the absence of gastrointestinal symptoms. Clinical care that targets hypovolemia, electrolyte disturbance, and acute kidney injury is likely to reduce historically high case fatality rates.

Clinical illness and outcomes in patients with Ebola in Sierra Leone

Schieffelin JS, Shaffer JG, Goba A, Gbakie M, Gire SK, Colubri A, et al.

N Engl J Med 2014; 371: 2092–100.

A study of 106 EVD-positive patients in Sierra Leone showed that the incubation period was estimated to be 6 to 12 days and the case fatality rate was 74%. Common findings at presentation included fever, headache, weakness, dizziness, diarrhea, abdominal pain, and vomiting. Clinical and laboratory factors at presentation that were associated with a fatal outcome included fever, weakness, dizziness, diarrhea, and elevated levels of blood urea nitrogen, aspartate aminotransferase, and creatinine. Exploratory analyses indicated that patients under the age of 21 years had a lower case fatality rate than those over the age of 45 years, and patients presenting with fewer than 100,000 EBOV copies per milliliter had a lower case fatality rate than those with 10 million EBOV copies per milliliter or more.

Confronting Ebola as a sexually transmitted infection

Fischer WA 2nd, Wohl DA. Clin Infect Dis 2016; 62: 1272–6.

Medical care of survivors must consider that Ebola virus persists in genital fluids and can be sexually transmitted, along with the potential for lingering virus in other body compartments to permit recrudescence of EVD. Authors provide a review of the epidemiology, pathophysiology, clinical presentation, diagnosis, treatment, and complications of HFRS.

Prognostic indicators for Ebola patient survival

Crowe SJ, Maenner MJ, Kuah S, Erickson BR, Coffee M, Knust B, et al. Emerg Infect Dis 2016; 22: 217–23.

Viral load in the first Ebola virus–positive blood sample was inversely associated with survival: 52 (87%) of 60 patients with a Ct of >24 survived and 20 (22%) of 91 with a Ct of <24 survived. Ct values may be useful for clinicians making treatment decisions or managing patient or family expectations.

First-Line Therapies

• Supportive care (fluid replacement, electrolyte management)	A
• Intravenous ribavirin (Lassa)	C
• Renal replacement therapy	D
• Antibiotic treatment	C

Severe Ebola virus disease with vascular leakage and multiorgan failure: treatment of a patient in intensive care

Wolf T, Kann G. Lancet 2015; 385: 1428–35.

The effective treatment of vascular leakage and multiorgan failure by combination of ventilatory support, antibiotic treatment, and renal replacement therapy can sustain a patient with severe EVD until virologic remission. FX06 could potentially be a valuable agent in contribution to supportive therapy.

Review of the literature and proposed guidelines for the use of oral ribavirin as postexposure prophylaxis for Lassa fever

Bausch DG, Hadi CM, Khan SH, Lertora JJ. Clin Infect Dis 2010; 51: 1435–41.

Recommend oral ribavirin postexposure prophylaxis for Lassa fever exclusively for definitive high-risk exposures. These guidelines may also serve for exposure to other hemorrhagic fever viruses susceptible to ribavirin.

Second-Line Therapies

• Convalescent plasma	B
• Ventilatory support (given appropriate infection control/ICU setting)	C
• Vaccine development	E

Protective monotherapy against lethal Ebola virus infection by a potently neutralizing antibody

Corti D, Misasi J, Mulangu S, Stanley DA, Kanekiyo M, Wollen S, et al. Science 2016; 351: 1339–42.

Monoclonal antibodies (mAbs) isolated from a survivor neutralize

recent and previous outbreak variants of Ebola virus and mediate antibody-dependent, cell-mediated cytotoxicity in vitro. Strikingly, monotherapy with mAb114 protected macaques when given as late as 5 days after challenge. Treatment with a single human mAb suggests that a simplified therapeutic strategy for human Ebola infection may be possible.

Update: management of patients with suspected viral hemorrhagic fever – United States

MMRW 1995; 44; 475–9.

CDC guidelines for the management of suspected cases of viral hemorrhagic fever.

Efficacy and effectiveness of an rVSV-vectored vaccine in preventing Ebola virus disease: final results from the Guinea ring vaccination, open-label, cluster-randomised trial

Henao-Restrepo AM, Camacho A, Longini IM, Watson CH, Edmunds WJ, Egger M, et al. Lancet 2017; 389: 505–18.

Study results add weight to the interim assessment that rVSV-ZEBOV offers substantial protection against Ebola virus disease, with no cases among vaccinated individuals from day 10 after vaccination in both randomised and non-randomised clusters.

Discovery of an antibody for pan-ebolavirus therapy

Furuyama W, Marzi A. Sci Rep 2016; 6: 20514.

Report on the generation of an Ebola virus glycoprotein-specific monoclonal antibody that effectively inhibits cellular entry of representative isolates of all known Ebola virus species in vitro and shows its protective efficacy in mouse models of Ebola virus infections.

Bites and stings

Dirk M. Elston

This chapter presents strategies for the prevention and management of bites and stings and their complications.

Management Strategy

Bite reactions

DEET is effective for prevention of bites from a broad range of arthropods. Picaridin is effective against mosquitoes. Permethrin can be used on fabric. A veterinarian should be consulted about flea infestation in pets. Antivenin is available for many arachnid toxins, but most respond to rest, ice, and elevation.

If prevention fails, second-line treatments aim to improve pruritus. *Topical antipruritics*, such as 1/4% camphor and menthol, and *topical anesthetics*, such as pramoxine and lidocaine, can be helpful. For persistent bite reactions, topical or intralesional corticosteroids may be helpful.

Anaphylaxis

Individuals who experience anaphylaxis in response to stings should be referred to an allergist for *desensitization*. Rush desensitization is possible for those with life-threatening allergy. Patients with a history of anaphylaxis should also carry an *epinephrine autoinjector* (EpiPen).

Vectorborne disease

Most tickborne illness responds to *doxycycline*. For early Lyme disease, evidence suggests that a 10-day course is as effective as longer courses of antibiotic. Babesiosis responds to *clindamycin and quinine*, but *azithromycin* and *atovaquone* may be as effective with a lower incidence of side effects. *Atovaquone-proguanil* has been effective in refractory cases in immunocompromised patients.

Scorpion-related cardiomyopathy: clinical characteristics, pathophysiology, and treatment

Abroug F, Souheil E, Ouanes I, Dachraoui F, Fekih-Hassen M, Ouanes Besbes L. Clin Toxicol (Phila) 2015; 53: 511–8.

More than 1 million scorpion stings occur each year. Acute cardiogenic shock and pulmonary edema are the most severe complications, with a 0.27% lethality rate. Oxygen supplementation to maintain an oxygen saturation of 92% or more, continuous positive airway pressure, and dobutamine infusion improve outcomes.

Immunological aspects of the immune response induced by mosquito allergens

Cantillo JF, Fernández-Caldas E, Puerta L. *Int Arch Allergy Immunol* 2014; 165: 271–82.

The most common mosquito species implicated in allergic reactions belong to the genera *Aedes*, *Culex*, and *Anopheles*. Allergen-specific immunotherapy with mosquito extracts is capable of inducing a protective response with decreased production of immunoglobulin E (IgE) antibodies, increased IgG levels, and a reduction in the severity of both cutaneous and respiratory symptoms.

Anaphylaxis to insect stings

Golden DB. *Immunol Allergy Clin North Am* 2015; 35: 287–302.

Anaphylaxis to insect stings occurs in 3% of adults and can be fatal. The risk of a subsequent severe systemic reaction to a sting varies between 30% and 65% in adults with previous reactions, and serum tryptase level correlates with the risk. Venom immunotherapy is 75% to 98% effective in preventing anaphylaxis from stings.

Secondary cutaneous diphtheria due to the bite of a Thai centipede (*Scolopendra*)

Jüngling C, Sadowski C, Glitsch M, Vandersee S. *J Dtsch Dermatol Ges* 2014; 12: 1043–4.

Secondary infection, including cutaneous diphtheria, can follow arthropod bites and stings.

Scorpion stings in pregnant women: an analysis of 11 cases and review of literature

Kaplanoglu M, Helvacı MR. *Clin Exp Obstet Gynecol* 2015; 42: 228–30.

Although local pain, hyperemia, swelling, and itching were common, pregnancy complications were not.

Cutaneous and systemic mastocytosis in children: a risk factor for anaphylaxis?

Matito A, Carter M. *Curr Allergy Asthma Rep* 2015; 15: 22.

In contrast to adults, hymenoptera stings are an uncommon trigger of anaphylaxis in children with mastocytosis.

Unusual reactions to *Hymenoptera* stings: what should we keep in mind?

Mingomataj EÇ, Bakiri AH, Ibranjic A, Sturm GJ. *Clin Rev Allergy*

Immunol 2014; 47: 91–9.

Hemodynamic compromise of vital organs with hypoxia and hypovolemia, together with evidence of IgE sensitization, are indications for venom immunotherapy.

Recognition, treatment, and prevention of anaphylaxis

Moore LE, Kemp AM, Kemp SF. Immunol Allergy Clin North Am 2015; 35: 363–74.

Reactions to medications, foods, and insect stings cause most episodes of anaphylaxis. Treatment involves prompt administration of epinephrine and supportive care.

Centipede venom: recent discoveries and current state of knowledge

Undheim EA, Fry BG, King GF. Toxins (Basel) 2015; 7: 679–704.

Centipede venom proteins are highly diverse, with 61 distinct venom protein and peptide families, with little overlap with other animal venoms.

Specific Investigations

- CBC and fibrin split products after brown recluse spider bite
- Rickettsial immunofluorescence and immunoperoxidase
- Lyme serologic tests
- ELISA, PCR, and immunofluorescence for virus such as West Nile, Dengue, and Chikungunya

PCR assays can also be used to identify biting insects too small for conventional identification

IgE typing, skin testing, and basophil activation testing can be used to confirm the cause of anaphylaxis.

Tryptase levels can be used to predict severe reactions and in forensic investigations to confirm death from anaphylaxis. Expression of Th1 and Th2 trafficking can be used to follow the course of immunotherapy.

Venom immunotherapy: an updated review

Antolín-Amérigo D, Moreno Aguilar C, Vega A, Alvarez-Mon M. Curr Allergy Asthma Rep 2014; 14: 449.

In patients with negative serum IgE and skin prick testing, basophil activation tests are promising to guide therapy.

Expression of Th1, Th2, lymphocyte trafficking and activation markers on CD4+ T-cells of *Hymenoptera* allergic subjects and after venom immunotherapy

Cabrera CM, Urrea JM, Alfaya T, Roca Fde L, Feo-Brito F. Mol Immunol 2014; 62: 178–85.

A shift toward a Th1-type response characterized by an increase in IFN- γ levels is observed after venom immunotherapy.

New directions in diagnostic evaluation of insect allergy

Golden DB. Curr Opin Allergy Clin Immunol 2014; 14: 334–9.

Measurement of IgE to recombinant venom allergens can distinguish cross-sensitization from dual sensitization to honeybee and vespid venoms, helping to limit venom immunotherapy to a single venom.

Anaphylaxis to insect venom allergens: role of molecular diagnostics

Ollert M, Blank S. Curr Allergy Asthma Rep 2015; 15: 26.

Knowledge about the molecular composition of *Hymenoptera* venoms has increased and resulted in the ability to measure specific IgE in venom-allergic patients. Recombinant venom allergens are not available.

Advances in allergic skin disease, anaphylaxis, and hypersensitivity reactions to foods, drugs, and insects in 2014

Sicherer SH, Leung DY. J Allergy Clin Immunol 2015; 135: 357–67.

Baseline platelet-activating factor acetylhydrolase levels are promising as a marker to predict the severity of sting reactions.

First-Line Therapies

Prevention

• DEET	A
• Permethrin	A
• Picaridin	B
• Combinations of DEET and permethrin	A

Flea treatments for pets

• Lufenuron	A
• Fipronil	A
• Imidacloprid	A

Anaphylaxis

• Epinephrine	A
• Immunotherapy	A

Spider bites

• Rest, ice, and elevation	B
• Tetracycline or triamcinolone for brown recluse bites	C
• Antivenin for brown recluse bites	C
• Antivenin for black widow and red-black spider bites	A

Scorpion stings

• Antivenin for stings in Arizona	B
• Prazosin for Indian red scorpion stings	A

Arthropod borne infections

• Lyme borreliosis	
• Tetracycline	A
• Amoxicillin in children	A
• Intravenous ceftriaxone	A
• Rocky Mountain spotted fever	
• Doxycycline	A
• Human monocytic ehrlichiosis	
• Human anaplasmosis	
• Babesiosis	
• Azithromycin and atovaquone	A
• Quinine and clindamycin	A

Venom immunotherapy: an updated review

Antolín-Amérigo D, Moreno Aguilar C, Vega A, Alvarez-Mon M. Curr Allergy Asthma Rep 2014; 14: 449.

Venom immunotherapy is the most effective form of specific immunotherapy in use.

Mildly heated forceps: a useful instrument for easy and complete removal of ticks on the skin

Jang YH, Moon SY, Lee WJ, Lee SJ, Kim Do W. J Am Acad Dermatol 2014; 71: e199–200.

Heating of forceps has been used to enhance tick removal.

Mosquito repellents for travelers

Stanczyk NM, Behrens RH, Chen-Hussey V, Stewart SA, Logan JG. BMJ 2015; 350: h99.

Repellents have improved and provide sustained protection against insect bites and mosquito-borne disease.

Are we doing enough to promote the effective use of mosquito repellents?

Webb CE. Med J Aust 2015; 202: 128–9.

Despite their wide availability, mosquito repellents are often not used.

Are topical insect repellents effective against malaria in endemic populations? A systematic review and meta-analysis

Wilson AL, Chen-Hussey V, Logan JG, Lindsay SW. Malar J 2014; 13: 446.

Meta-analysis suggests that although topical repellents provide individual protection against mosquito bites, their ability to provide effective sustained protection against malaria in endemic populations did not reach statistical significance, suggesting continued need for malaria prophylaxis in long-term travelers and the need for other effective strategies to control the disease.

Second-Line Therapies

Repellents

• Botanicals	C
• Novel pyrethroids	C

Relief of pruritus

• Camphor and menthol	E
• Pramoxine	E
• Lidocaine	E
• Benzocaine	E
• Lidocaine/prilocaine	E

Treatment of bite and sting reactions

• Superpotent and potent topical corticosteroids	E
• For young children: mild-to-moderate–strength topical corticosteroids	E
• Local ice	C
• Local heat	C
• New immunotherapy agents	B
• Omalizumab for patients with adverse reactions to immunotherapy	C

Indian red scorpion stings

• Captopril	C
• Antivenin	D

Arthropodborne infections

• Babesiosis	
• Atovaquone-proguanil in immunosuppressed patients	C

Insecticide-treated clothes for the control of vector-borne diseases: a review on effectiveness and safety

Banks SD, Murray N, Wilder-Smith A, Logan JG. Med Vet Entomol 2014; 28 (Suppl 1): 14–25.

New microencapsulation technologies may prolong the activity of insecticides on clothing. These can help to overcome reduction in efficacy as a result of washing, ultraviolet light exposure, and normal wear and tear.

Persistently high estimates of late night, indoor exposure to malaria vectors despite high coverage of insecticide treated nets

Bayoh MN, Walker ED, Kosgei J, Ombok M, Olang GB, Githeko AK, et al. Parasit Vectors 2014; 7: 380.

Despite the use of impregnated nets, indoor bites continue at a high rate, suggesting the need for better agents.

Developing a preventive immunization approach against insect bite hypersensitivity using recombinant allergens: a pilot study

Jonsdottir S, Hamza E, Janda J, Rhyner C, Meinke A, Marti E, et al. Vet Immunol Immunopathol 2015; 166: 8–21.

Recombinant allergens for immunotherapy have been used successfully in horses.

Treatment with a combination of omalizumab and specific immunotherapy for severe anaphylaxis after a wasp sting

Palgan K, Bartuzi Z, Gotz-Zbikowska M. Int J Immunopathol Pharmacol 2014; 27: 109–12.

Venom immunotherapy may provoke immediate anaphylaxis, which can lead to treatment withdrawal. The antiimmunoglobulin (Ig) E monoclonal antibody omalizumab proved useful to allow resumption of immunotherapy.

Third-Line Therapies

Treatment of bites

• Intralesional corticosteroids	E
• Enhanced penetration topical antihistamines	B

Repellents

• Newer agents and botanicals	C
• New vaccines in development for vectorborne illness	C

Good performances but short lasting efficacy of Actellic 50 EC Indoor Residual Spraying (IRS) on malaria transmission in Benin, West Africa

Aïkpon R, Sèzonlin M, Tokponon F, Okè M, Oussou O, Oké-Agbo F, et al. *Parasit Vectors* 2014; 30: 256.

Pirimiphos methyl used for indoor residual spraying resulted in a significant reduction (94.25%) in bite rate and the entomologic inoculation rate (99.24% reduction).

A *Listeria monocytogenes*-based vaccine that secretes sand fly salivary protein LJM11 confers long-term protection against vector-transmitted *Leishmania major*

Abi Abdallah DS, Pavinski Bitar A, Oliveira F, Meneses C, Park JJ, Mendez S, et al. *Infect Immun* 2014; 82: 2736–45.

A sand fly salivary protein vaccine using an attenuated strain of *Listeria monocytogenes* shows promise for the prevention of leishmaniasis.

Ethosomes-based topical delivery system of antihistaminic drug for treatment of skin allergies

Goindi S, Dhatt B, Kaur A. *J Microencapsul* 2014; 31: 716–24.

An ethosome-based topical formulation of cetirizine dihydrochloride consisting of drug, phospholipon 90 G, and ethanol was effective in atopic dermatitis-related itching and could be of benefit for bite reactions.

Laboratory evaluation of citronella, picaridin, and DEET repellents against *Psorophora ciliata* and *Psorophora howardii*

Scott JM, Hossain T, Davidson C, Smith ML, Xue RD. J Am Mosq Control Assoc 2014; 30: 136–7.

Citronella-based repellents are less effective than standard chemical repellents.

Blastomycosis

Wanda Sonia Robles, and Mahreen Ameen

With permission from Lebwohl MG. Atlas of the Skin and Systemic Disease. Churchill Livingstone: Elsevier, 1995. Courtesy of Fabio Barbosa, MD.

Blastomycosis is a systemic, suppurative granulomatous infection caused by the thermally dimorphic fungus *Blastomyces dermatitidis*. It is acquired by inhalation of the conidia, which are transformed into the yeast form in the lungs. It is an endemic mycosis that is most prevalent in the North American continent, particularly in the states that border the Mississippi and Ohio rivers and the Great Lakes region. Cases have also been reported in Latin America, Africa, the

Middle East, and India. Consequently, the term *North American blastomycosis* is now obsolete. Point-source epidemics have been reported in endemic regions relating to recreational activities in wooded areas along waterways.

Blastomycosis is associated with a spectrum of disease ranging from subclinical infection to an acute or chronic pneumonia. Most cases are restricted to the respiratory system, and many are asymptomatic. Extrapulmonary infection occurs in 25% to 40% of cases and most commonly affects the skin. Cutaneous manifestations range from papules to verrucous and ulcerative lesions. The bones, genitourinary system, and central nervous system (CNS) may also be involved. Dissemination occurs more frequently in the immunocompromised, such as organ transplant recipients and those with HIV infection. The immunocompromised are at high risk of CNS involvement and adult respiratory distress syndrome. Their prognosis is poor and therefore they require aggressive management. There are also rare reports of primary cutaneous blastomycosis acquired after accidental inoculation, and in some cases infection has been self-limiting.

Management Strategy

In the immunocompetent individual, acute pulmonary blastomycosis may be mild and self-limiting. However, all diagnosed cases are treated in order to prevent extrapulmonary dissemination.

Itraconazole is the drug of choice for the treatment of non-CNS infection that is not life threatening. A loading dose of 200 mg three times daily for 3 days followed by 200 mg once or twice daily for 6 to 12 months is recommended. Serum itraconazole levels should be measured 2 weeks after commencement of treatment. Ketoconazole (400–800 mg daily) and fluconazole (400–800 mg daily) are second-line agents, as they have lower efficacy against *Blastomyces*. In addition, long-term treatment with ketoconazole is associated with adverse effects. The new-generation azoles, voriconazole and posaconazole, have demonstrated activity against *B. dermatitidis* in in vitro and animal studies. There have been reports of the successful use of voriconazole in the treatment of CNS blastomycosis.

Amphotericin B is the treatment of choice for those who fail on treatment with azoles, who have severe infection, the immunosuppressed, in pregnancy, and with CNS involvement. The

experience to date has been largely with the use of amphotericin B deoxycholate. Liposomal amphotericin B is recommended for CNS infection, as it achieves higher CNS penetration and is better tolerated with prolonged therapy. This is also recommended for severe lung disease. After an initial response with amphotericin B, step-down therapy to an azole is common practice.

Specific Investigations

- Direct microscopy
- Culture
- Histopathology
- Chest radiography
- Bone scanning (radionuclide bone scan/computed tomography/magnetic resonance imaging [CT/MRI])
- Serology for HIV infection (where relevant)

Definitive diagnosis of blastomycosis is based on the identification of characteristic thick-walled, broad-based budding yeasts by direct examination of tissue or the isolation of *Blastomyces* in culture. Specimens for direct microscopy in 10% KOH can be skin scrapings, pus from skin lesions, sputum, and biopsy tissue from any lesion suspicious of infection. Successful culture of sputum, tissue biopsy specimens, cerebrospinal fluid, or urine produces a white mold at 25°C on Sabouraud agar and a brown wrinkled colony at 37°C on blood agar. Histopathology of infected tissues reveals a pyogranulomatous response without caseation and pseudoepitheliomatous hyperplasia. A *Blastomyces* antigen assay is available to test urine, blood, and other fluids, but it is not always specific. Antibody assays are nonspecific and insensitive.

Cutaneous inoculation blastomycosis

Gray NA, Baddour LM. Clin Infect Dis 2002; 34: e44–9.

This article reports a case in a male adult that resulted from inoculation after being struck by a projectile while performing yard work. It also reviews 21 previous published cases of cutaneous inoculation. Skin lesions were associated with lymphadenopathy or lymphangitis in 65% of cases. Organisms were recovered from skin lesions by direct microscopy or culture. Fifty percent of cases occurred after exposure in a clinical setting (laboratory or morgue).

The median incubation period was only 2 weeks. One case was self-limiting, a further three were treated with surgery, and the remainder were successfully treated with the antifungals ketoconazole and itraconazole.

First-Line Therapies

• Itraconazole	B
• Amphotericin B	C

Blastomycosis

Castillo CG, Kauffman CA, Miceli MH. Infect Dis Clin North Am 2016; 30: 247–64.

This very good review advocates the use of itraconazole for either mild-to-moderate pulmonary or extrapulmonary infection and lipid formulation amphotericin B for cases of severe or life-threatening infection followed by step-down therapy with itraconazole.

Itraconazole therapy for blastomycosis and histoplasmosis

NIAID Mycoses Study Group; Dismukes WE, Badcher RW, Cloud JC, Kauffman CA, Chapman SW, George RB, et al. Am J Med 1992; 93: 489–97.

A prospective, nonrandomized, multicenter trial involving 48 patients with pulmonary or disseminated blastomycosis without CNS involvement. Patients were treated with itraconazole 200 to 400 mg/day for a median period of 6.2 months with a 90% cure rate (43/48). Treatment was very well tolerated, and there was no therapeutic advantage for patients treated with the higher dose.

Endemic blastomycosis in Mississippi: epidemiologic and clinical studies

Chapman SW, Lin AC, Hendricks KA, Nolan RL, Currier MM, Morris

KR, et al. *Semin Respir Infect* 1997; 12: 219–28.

This was a review of 326 confirmed cases of blastomycosis from Mississippi. There was involvement of lungs (91.4%), skin (18.1%), bone (4.3%), genitourinary system (1.8%), and CNS (1.2%). Skin or bone disease was associated with multiorgan involvement. A successful outcome without relapse was noted in 86.5% of amphotericin B deoxycholate–treated patients and in 81.7% of ketoconazole-treated patients. The relapse rate for ketoconazole-treated patients was higher than for amphotericin B–treated patients (14% and 3.9%, respectively).

Blastomycosis of the central nervous system: a multicenter review of diagnosis and treatment in the modern era

Bariola JR, Perry P, Pappas PG, Proia L, Shealey W, Wright PW, et al. *Clin Infect Dis* 2010; 50: 797–804.

A retrospective study of 22 patients with CNS infection treated with either amphotericin B deoxycholate or a lipid formulation of amphotericin B followed by a prolonged course of oral azole therapy (voriconazole, fluconazole, or itraconazole).

The most favorable outcomes were achieved with initial treatment with a lipid formulation of amphotericin B followed by a prolonged course of oral voriconazole.

Second-Line Therapies

• Ketoconazole	B
• Fluconazole	B
• Voriconazole	D
• Caspofungin	E
• Isavuconazole	E

Treatment of blastomycosis and histoplasmosis with ketoconazole. Results of a prospective randomized clinical trial
National Institute of Allergy and Infectious Diseases Mycoses Study Group; Dismukes WE, Cloud G, Bowles C. Ann Intern Med 1985; 103: 861–72.

This was a multicenter, prospective, randomized trial. Of 65 patients with blastomycosis treated for 6 months or more, high-dose ketoconazole (800 mg daily) was significantly more effective than low-dose ketoconazole (400 mg daily) (100% vs. 79% cure rate, $p=0.001$). Adverse effects occurred in 60% of patients and were more common in those treated at higher doses. Therefore the study group recommended that treatment should commence at the lower dose.

Despite its efficacy, ketoconazole is now rarely used because of its associated adverse effects as well as the availability of better-tolerated azoles.

Treatment of blastomycosis with fluconazole: a pilot study

The National Institute of Allergy and Infectious Disease Mycoses Study Group; Pappas PG, Bradsher RW, Chapman SW, Kauffman CA, Dine A, Cloud GA, et al. Clin Infect Dis 1995; 20: 267–71.

A multicenter, randomized, open-label, pilot study compared two doses of fluconazole (200 and 400 mg daily) for the treatment of non-life-threatening blastomycosis. The analysis data included 23 patients who were treated for a minimum 6-month period. There was a successful outcome in 65% of patients (15/23) with no relapse at follow-up at 7 months. Of those who responded, 62% (8/15) had received 200 mg daily and 70% (7/10) received 400 mg daily.

The results of this study were disappointing. However, fluconazole has excellent CNS penetration and may therefore have a better role in the treatment of CNS infection, although there are no studies to support this.

Treatment of blastomycosis with higher doses of fluconazole

The National Institute of Allergy and Infectious Disease Mycoses Study Group; Pappas PG, Bradsher RW, Kauffman CA, Cloud GA, Thomas CJ, Campbell GD Jr, et al. Clin Infect Dis 1997; 25: 200–5.

This multicenter, randomized, open-label study investigated the efficacy of high-dose fluconazole (400–800 mg daily) for the treatment of non-life-threatening blastomycosis. There was an 87% cure rate (34/39) after a mean treatment period of 8.9 months.

This study demonstrates a much higher efficacy for fluconazole at doses of 400 to 800 mg daily.

The role of voriconazole in the treatment of central nervous system blastomycosis

Ta M, Flowers SA, Rogers PD. Ann Pharmacother 2009; 43: 1696–700.

Seven cases of CNS blastomycosis successfully treated sequentially with amphotericin B followed by voriconazole are described.

Animal and human studies indicate that high concentrations of voriconazole can be achieved in the cerebrospinal fluid (CSF) and brain tissue. The authors suggest that voriconazole may be considered an azole option for either follow-up therapy after liposomal amphotericin B therapy or as salvage therapy in patients intolerant of amphotericin B or other azoles.

Voriconazole use for endemic fungal infections

Hage CA, Bowyer S, Tarvin SE, Helper D, Kleiman MB, Joseph Wheat L. Clin Infect Dis 2010; 50: 85–92.

Eight patients with blastomycosis either improved or remained stable with voriconazole therapy, although two subsequently relapsed. In these cases voriconazole was used as salvage therapy, particularly in patients who demonstrated intolerance to other

antifungal agents.

Treatment of chronic pulmonary blastomycosis with caspofungin

Mardini J, Nguyen B, Ghannoum M, Couture C, Lavergne V. J Med Microbiol 2011; 60: 1875–8.

This is a case report of chronic pulmonary blastomycosis successfully treated with caspofungin.

Echinocandins have not been recommended for the treatment of blastomycosis because of poor in vitro activity against Blastomyces dermatitidis and until now a lack of supporting clinical data.

Isavuconazole treatment of cryptococcosis and dimorphic mycoses

Thompson GR 3rd, Rendon A, Ribeiro Dos Santos R, Queiroz-Telles F, Ostrosky-Zeichner L, Azie N, et al. Clin Infect Dis. 2016; 63: 356–62.

An open-label, nonrandomized, phase III trial to evaluate efficacy and safety of isavuconazole in the management of invasive fungal infections.

Findings: well tolerated, clinical activity against endemic fungi, with safety profile similar to those observed in larger studies.

This drug is recommended as a valuable alternative to currently available agents.

Guidelines

Clinical practice guidelines for the management of blastomycosis: 2008 update by the Infectious Diseases Society of America

Infectious Diseases Society of America; Chapman SW, Dismukes WE, Proia LA, Bradsher RW, Pappas PG, Threlkeld MG, et al. Clin Infect Dis 2008; 46: 1801–12.

This updated evidence-based guideline replaces the previous guidelines published in 2000. Treatment is guided by the extent of infection, CNS involvement, and the immune state of the host. Previously, mild cases of pulmonary blastomycosis were managed conservatively, as they are sometimes self-limiting. However, with the advent and high efficacy of oral azoles, primarily itraconazole, most cases are now actively treated in order to prevent extrapulmonary spread and any risk of future reactivation.

- Itraconazole is the drug of choice for the treatment of mild-to-moderate pulmonary or disseminated infection. The recommended dose is an initial loading dose of 200 mg three times daily for 3 days, followed by 200 mg once or twice daily for 6 to 12 months. Serum levels should be measured after 2 weeks to ensure adequate drug exposure.
- Amphotericin B is the treatment of choice for those with severe pulmonary or disseminated infection and in the immunocompromised. Either the lipid formulation (3–5 mg/kg/day) or amphotericin deoxycholate (0.7–1 mg/kg/day) is given for 1 to 2 weeks or until improvement is noted. Itraconazole is then recommended as step-down therapy (loading dose and then 200 mg twice daily for 6–12 months, except in the immunocompromised, who require at least 12 months of treatment or until immunosuppression has been reversed).
- Liposomal amphotericin B at a dose of 5 mg/kg/day is the recommended treatment for CNS infection. Treatment should be given for 4 to 6 weeks followed by an oral azole (fluconazole 800 mg daily/itraconazole 200 mg two to three times daily/voriconazole 200–400 mg twice daily), which should be given for at least 12 months and until there is resolution of CSF abnormalities.
- Amphotericin B is the drug of choice for patients who have failed to respond to azole treatment.
- Amphotericin B is the only drug approved for the treatment of blastomycosis in pregnant women.

Blistering distal dactylitis

Irshad Zaki

Courtesy of Joseph Bikowski, MD.

Blistering distal dactylitis (BDD) is a superficial, tender, blistering

infection seen in childhood and the early teens. It is usually caused by group A β -hemolytic streptococci, although group B organisms, staphylococci, and more recently methicillin-resistant *Staphylococcus aureus* (MRSA) have also been implicated. The distal volar fat pads of the fingers are the most common site of infection, but involvement of the nail folds and toes can occasionally occur.

Management Strategy

BDD can cause considerable alarm to parents, as large tense blisters rapidly develop. Despite the absence of constitutional symptoms, patients usually seek help soon after the onset of the infection. The condition does not resolve spontaneously, but prompt treatment results in rapid improvement. *Blisters should be incised to release fluid*, which can vary from clear and watery to frank pus. Subsequent application of topical antibiotics can be helpful, but systemic treatment is usually also required. *Penicillin V* is the treatment of choice for streptococcal infection, but *erythromycin* is an effective alternative for patients allergic to penicillin. It is important to exclude MRSA or immunosuppression for resistant cases.

The differential diagnosis of the condition includes traumatic blisters, herpetic whitlow, staphylococcal bullous impetigo, and the Weber–Cockayne variant of epidermolysis bullosa.

Specific Investigations

- Gram stain of blister fluid
- Culture of blister fluid
- Swab of nasopharynx for bacteriology

A clinically recognizable streptococcal infection

Hays GC, Mullard JE. *Paediatrics* 1975; 56: 129–31.

First large series report describing 13 patients with BDD. Streptococci were found on culture of blister fluid in all cases, and gram-positive cocci were usually found on Gram staining. This report suggests a link with infection of the nasopharynx, but this has not been confirmed in other case reports.

Blistering distal dactylitis in an adult

Kollipara R, Downing C, Lee M, Guidry J, Robare-Stout S, Tyring S. J Cutan Med Surg 2015; 19: 397–9.

Although the majority of cases are in children over the age of 2, this has also been described in adults, particularly if immunosuppressed. Bacteriology should be considered for an isolated distal phalanx blister at any age.

First-Line Therapies

• Incision and drainage of blister	C
• Topical antibiotics	C
• Systemic penicillin	C

Is blistering distal dactylitis a variant of bullous impetigo?

Scheinfeld NS. Clin Exp Dermatol 2007; 32: 314–6.

Good review of literature and treatment. Confirms the importance of incision and drainage, adequate dressings, and the need to consider *S. aureus* as a cause if penicillin is ineffective.

Second-Line Therapies

• Systemic erythromycin	D
• Intravenous vancomycin	D

Blistering distal dactylitis: a manifestation of group A beta-haemolytic streptococcal infection

Schneider JA, Parlette HL. Arch Dermatol 1982; 118: 879–80.

Short report of the authors' personal experience, suggesting that

this is a relatively common problem. Systemic penicillin and erythromycin were both found to be effective. It is likely that many cases of BDD are wrongly diagnosed as bullous impetigo by clinicians not familiar with this disorder.

MRSA blistering distal dactylitis and review of reported cases

Fretzayas A, Moustaki M, Tsagris V, Brozou T, Nicolaidou P. *Pediatr Dermatol* 2011; 28: 433–5.

First report of BDD due to MRSA infection. This case highlights the importance of culture of blister fluid, as infection with this organism may increase in the future.

Third-Line Therapies

• Amoxicillin/clavulanic acid	D
• Conservative measures for herpetic whitlow	D

A review and report of blistering distal dactylitis due to *Staphylococcus aureus* in two HIV-positive men

Scheinfeld N. *Dermatol Online J* 2007; 13: 8.

S. aureus was found to be the etiologic agent in two HIV-positive patients. The condition improved after treatment with a proprietary mixture of amoxicillin trihydrate and clavulanate potassium. The report highlights that blisters may not always be present and that BDD may present with erosions.

Coexistent infections on a child's distal phalanx: blistering dactylitis and herpetic whitlow

Ney AC, English JC 3rd, Greer KE. *Cutis* 2002; 69: 46–8.

Consider comorbidity if BDD does not respond to antibiotics.

Body dysmorphic disorder (dermatologic nondisease)

Colin A. Morton

Synonyms: Dermatologic nondisease, Body dysmorphic disease, Dysmorphophobia.

Body dysmorphic disorder (BDD) is an alteration in perception of body image that causes preoccupation with a minimal or imagined defect in appearance. The preoccupation can be markedly excessive, causing clinically significant emotional distress and impairment in social, occupational, or other important areas of functioning. Preoccupations commonly involve the face and head, with skin and hair being the most frequent areas of concern. However, any area of the body may be involved. Dermatologic preoccupations are distressing, time consuming, and difficult or impossible for patients to resist. Insight is typically poor, and alterations in perception are often to delusional proportion. Most patients have ideas of reference, thinking that others take special notice or mock them for their perceived defect. Repetitive behaviors are present in almost all patients, such as excessive checking or grooming, innumerable consultations with dermatologists and plastic surgeons, constant need for reference and reassurance, and skin manipulations. Risk of suicidal ideation and attempts are high, affecting approximately one quarter of BDD patients.

Management Strategy

BDD is common in dermatologic settings, with prevalence estimated at 11.9%. Recognition of these patients is extremely important because they typically have psychiatric comorbidities, diminished quality of

life, and impairments in psychosocial and vocational function. They are usually poor candidates for cosmetic procedures. Dissatisfaction, anger, and even aggression directed toward the treating clinician have been reported. Patients with BDD often have associated psychiatric disorders, including major depression, substance abuse and dependence, social phobia, and obsessive-compulsive disorder (OCD). Recent studies have suggested abnormal brain network organization with magnetic resonance (MR) imaging, which may provide some biologic basis for the characteristic distortions in self-perception. The majority of these patients also have a personality disorder. Appropriate psychiatric treatment can result in a generally favorable outcome.

Typical body areas of preoccupation include:

- **Face.** Preoccupation with facial itching and burning or obsessive preoccupation with imagined acne, scars, wrinkles, pigmentation, oiliness, redness, paleness, facial vessels, and facial hair are common. Preoccupation with the nose, ears, and pore size is reported. Despite the fact that others usually do not see these minimal or nonexistent flaws, patients can spend hours in front of mirrors, preventing them from working or socializing.
- **Scalp.** Dysesthesias (burning or itch) and obsession with imagined hair loss are common.
- **Genital.** Genital size, scrotal, perineal, and perianal burning, as well as vulvar redness and burning are common symptoms. Preoccupation with sexually transmitted disease or neoplastic process is common. Symptoms can be incapacitating.

Hallmarks and Flags for Diagnosis of Body Dysmorphic Disorder

Patients presenting with extreme concern that appears out of proportion to their chief complaint accompanied by a paucity of objective physical findings should raise suspicion that BDD may be present. Obsession, rumination, and extreme psychological distress are striking features. These patients usually report dissatisfaction with previous physicians and describe poor outcomes from past medical and surgical interventions. Skin picking and related behaviors such as excessive tanning, excessive grooming, and relentless need for reassurance are characteristic. Attempts to correct their perceptions are inevitably futile because their perceptual distortions and

associated cognitions are deeply entrenched. It can be argued that the distorted perceptions are delusional, which, by definition, suggests that they are unresponsive to objective logic and persuasion. Patients often wear heavy makeup, hats, sunglasses, scarves, and other clothing to hide their imperfections and perceived ugliness.

Patients with BDD often make unusual and excessive requests for cosmetic procedures with the belief that the procedure will transform or fix their lives. Poor psychosocial functioning with difficulties in relationships, school, and work is almost always seen. Depression is frequently evident, and previous suicide attempts are not infrequent. Bear in mind that there have been instances of violent behavior toward treatment providers.

Clinical interactions and consultations with these patients are typically long, difficult, and emotionally draining. Regardless of the actual length of time spent with them, BDD patients often feel that they were not given adequate time and attention. As already stated, it is inadvisable to perform procedures on these patients because less than 10% will be satisfied with the results of medical or surgical interventions.

Serotonin selective reuptake inhibitors (SSRIs) and cognitive behavior psychotherapy remain the treatments of choice. Fluoxetine, fluvoxamine, and citalopram are the best-studied agents, but recent evidence suggests that all SSRIs are probably effective. Higher dosing regimens than those used for depression are usually required. For example, fluoxetine and citalopram should be titrated to 60 mg per day, and fluvoxamine should be increased to 300 mg per day at monthly intervals. Patients should receive a trial of 12 to 16 weeks before efficacy is assessed. If one agent fails, another should be substituted because some patients idiosyncratically respond more favorably to one agent over another. SSRIs appear to be more effective than antipsychotic agents despite the fact that BDD can involve severe distortions in self-perception to delusional proportion. Interestingly, only about 20% of patients will become free of their delusional thinking. However, the intrusiveness of the thoughts and distress will diminish sufficiently such that many patients will be able to resume some social and vocational functioning.

Table 31.1

Screening questions

1. How much do you currently think about your skin?
2. On an average day, how many hours do you spend thinking about your skin? Please add up all the time that your feature is on your mind and make your best estimate.
3. Do you feel your skin is ugly or very unattractive?
4. How noticeable do you think your skin is?
5. Does your skin currently cause you a lot of distress?
6. How many times a day do you usually check your skin, either in a mirror or by feeling it with your fingers?
7. How often do you feel anxious about your skin in social situations? Does it lead to you avoiding social situations?
8. Has your skin had an effect on dating or on an existing relationship?
9. Has your skin interfered with your ability to work or study, or your role as a homemaker?

(Adapted from Veale D, Ellison N, Werner TG, Dodhia R, Serfaty MA, Clarke A. Development of a cosmetic procedure screening questionnaire (COPSS) for body dysmorphic disorder. *J Plast Reconstr Aesthet Surg* 2012; 65: 530–2.)

Cognitive behavior therapy (CBT) is a reality-based, in-the-present therapy that specifically focuses on the affected individual's cognitions and associated emotional experiences. The key elements are known as *exposure*, *response prevention*, *perceptual retraining*, and *cognitive restructuring*. Exposure consists of having patients expose the perceived defect in social and work situations. Response prevention techniques help patients avoid performance of their repetitive behaviors such as avoidance of others, excessive camouflage, picking, hyperventilating, etc. Perceptual retraining involves the development of a more holistic positive view of appearance. Cognitive restructuring helps patients challenge and eventually change their erroneous beliefs about their appearance. Ideally, treatment of BDD should encompass both CBT and an SSRI.

To initiate treatment or referral, suggest to the patient in a gentle manner that they may have a body image disorder called BDD. Convey your concern regarding the amount of their time being

usurped by their preoccupation and their emotional distress. Psychiatric referral is preferable but often not feasible. Dermatologists are encouraged to align themselves, if possible, with mental health professionals who are experienced in treating this entity. Euphemisms for the psychiatric practitioner such as skin-emotion specialist may reduce the stigma of psychiatric referral and may increase patient acceptance. If referral is not possible, treating with an SSRI may be successful. If suicidal ideation or intent is present, immediate hospitalization is recommended.

Specific Investigations

- Assess for potential suicide risk; emergent referral and appropriate notification if active ideation or intent
- Assess for any evidence of physical or emotional abuse
- Assess for evidence of substance abuse
- Assess for concomitant underlying psychiatric disease (i.e., depression/anxiety/OCD/psychosis), and make an appropriate psychiatric referral
- Appropriately diagnose and acknowledge genuine skin disease (i.e., hair loss, acne, rosacea, psoriasis, eczema, keratosis pilaris, seborrheic keratoses, dyschromia) and offer legitimate therapies
- Investigate perceived skin changes appropriately to rule out atypical presentations of an underlying organic process if suspicion is present; perform bacterial, viral, fungal cultures, skin biopsy, serologies, and imaging studies when deemed appropriate

Depression, anxiety, anger, and somatic symptoms in patients with body dysmorphic disorder

Phillips KA, Siniscalchi JM, McElroy SL. *Psychiatr Q* 2004; 75: 309–20.

Seventy-five patients with BDD completed a symptom questionnaire assessing depression, anxiety, somatic/somatization, and anger-hostility. Compared with normal controls, BDD subjects had markedly elevated scores on all four scales, indicating severe distress and psychopathology. When treated with fluvoxamine, all symptoms significantly improved.

Quality of life for patients with body dysmorphic disorder

Phillips KA. J Nerv Ment Dis 2000; 188: 170–5.

This is the only published study looking at quality of life (QOL) in BDD patients. These patients were found to have a poorer mental health QOL than has been reported for patients with other severe illnesses such as type 2 diabetes, recent myocardial infarction, or depression. These findings highlight the dramatic impact of a nondisease.

Thirty-three cases of body dysmorphic disorder in children and adolescents

Albertini RS, Phillips KA. J Am Acad Child Adolesc Psychiatry 1999; 38: 453–9.

Thirty-three cases were examined. Onset was usually during adolescence but sometimes occurred in childhood. Earlier identification and treatment may avert unnecessary cosmetic and medical interventions as well as suicide.

Gender differences in body dysmorphic disorder

Phillips KA, Diaz S. J Nerv Ment Dis 1997; 185: 570–7.

This study looked at a large series of patients with DSM-IV–defined BDD and found that one quarter of patients had attempted suicide. Female patients with severe symptoms are at greater risk.

Suicide in dermatological patients

Cotterill JA, Cunliffe WJ. Br J Dermatol 1997; 137: 246–50.

Sixteen patients who had committed suicide are described. Most of these patients had acne or BDD. Females with facial complaints and men with facial scarring appeared more at risk for suicide. The authors relate these findings to the possible preventive benefits of early isotretinoin to prevent scarring in patients predisposed to BDD.

Diagnostic Aids

The Body Dysmorphic Disorder Symptom Scale: development and preliminary validation of a self-report scale of symptom specific dysfunction

Wilhelm S, Greenberg JL, Rosenfield E, Kasarskis I, Blashill AJ. Body Image 2016; 17: 82–7.

This report evaluates and compares the psychometric

characteristics of the BDD-SS (Body Dysmorphic Disorder Symptom Scale) in relation to other measures of BDD, body image, and depression in 99 adult participants diagnosed with BDD.

First-Line Therapies

• SSRIs	A
• Cognitive behavior therapy	B

Treating body dysmorphic disorder with medication: evidence, misconceptions, and a suggested approach

Phillips KA, Hollander E. Body Image 2008; 5: 13–27.

SSRIs are associated with improvement in core BDD symptoms, psychosocial functioning, QOL, suicidality, and other aspects of BDD.

Pharmacotherapy and psychotherapy for body dysmorphic disorder

Ipsier JC, Sander C, Stein DJ. Cochrane Database Syst Rev. 2009; 1: CD005332.

Supports efficacy of SSRIs.

A randomized placebo-controlled trial of fluoxetine in body dysmorphic disorder

Phillips KA, Albertini RS, Rasmussen SA. Arch Gen Psychiatry 2002; 59: 381–8.

This is the only placebo-controlled BDD pharmacotherapy study. In the 74 patients studied, fluoxetine was significantly more effective than placebo, with a response rate of 53% versus 18%.

Pharmacotherapy relapse prevention in body dysmorphic disorder: a double-blind, placebo-controlled trial

Phillips KA, Keshaviah A, Dougherty DD, Stout RL, Menard W, Wilhelm S. Am J Psychiatry 2016; 173: 887–95.

One hundred BDD subjects treated with citalopram for 14 weeks

with 81% response rate. Fifty-eight responders were treated with additional citalopram or placebo for 6 months. Placebo group was 40% versus 18% for citalopram. Study supports ongoing maintenance therapy.

An open label study of venlafaxine in body dysmorphic disorder

Allen A, Hadley SJ, Kaplan A, Simeon D, Friedberg J, Priday L, et al. *CNS Spectr* 2008; 13: 138–44.

Seventeen patients enrolled; 11 completed 12 to 16 weeks of venlafaxine at a minimum dose of 150 mg a day. All 11 patients significantly improved.

Clomipramine versus desipramine crossover trial in body dysmorphic disorder: selective efficacy of a serotonin reuptake inhibitor in imagined ugliness

Hollander E, Allen A, Kwon J, Mosovich S, Schmeidler J, Wong C. *Arch Gen Psychiatry* 1999; 56: 1033–9.

This double-blind, crossover study of 29 randomized patients found clomipramine (an SSRI) superior to desipramine (a non-SSRI tricyclic antidepressant).

Efficacy and safety of fluvoxamine in body dysmorphic disorder

Phillips KA, Dwight MM, McElroy SL. *J Clin Psychiatry* 1998; 59: 165–71.

Open-label study of fluvoxamine demonstrated good clinical response in 19 (63%) of 30 patients.

Delusional and response to open-label fluvoxamine in body dysmorphic disorder

Phillips KA, McElroy SL, Dwight MM, Eisen JL, Rasmussen SA. *J Clin Psychiatry* 2001; 62: 87–91.

Thirty patients with BDD were treated with fluvoxamine for 16 weeks in this open-label trial. Sixty-three percent of treated patients significantly improved. Important to note that both delusional and nondelusional patients responded similarly.

Change in psychosocial functioning and quality of life of patients with body dysmorphic disorder treated with fluoxetine: a placebo-controlled study

Phillips KA, Rasmussen SA. *Psychosomatics* 2004; 45: 438–44.

This was a 12-week, placebo-controlled study of psychosocial functioning and mental health–related QOL in 60 patients. At baseline, the patients had impaired psychosocial functioning and markedly poor mental health–related QOL. Significant decrease in the severity of BDD was demonstrated along with improvement in functioning and QOL.

Modular cognitive behavioral therapy for body dysmorphic disorder: a randomized controlled trial

Wihelm S, Phillips KA, Didie E, Buhlmann U, Greenberg JL, Fama JM, et al. *Behav Ther* 2014; 34: 314–27.

Thirty-six adults treated with 22 sessions of modular CBT. Eighty-one percent achieved significant improvement in BDD symptoms, and high levels of satisfaction with treatment were reported.

Cognitive-behavioral body image therapy for body dysmorphic disorder

Rosen JC, Reiter J, Orosan P. *J Consult Clin Psycho* 1995; 63: 263–9.

Exposure and response prevention was effective in 77% of 27 women treated with cognitive behavior group therapy for 8 weeks. Subjects in the treatment group improved more than those in the no-treatment waiting-list control group.

Body dysmorphic disorder: a cognitive behavioral model and pilot randomized controlled trial

Veale D, Gournay K, Dryden W, Boocock A, Shah F, Wilson R, et al. *Behav Res Ther* 1996; 34; 717–29.

Nineteen patients randomly assigned to CBT or a waiting-list control group. There was significantly greater improvement in BDD symptoms in the CBT group.

Second-Line Therapy

• Additional psychotropic agents and insight-oriented psychotherapy	D
---	----------

Treating body dysmorphic disorder with medication: evidence, misconceptions, and a suggested approach

Phillips KA, Hollander E. *Body Image* 2008; 5: 13–27.

Excellent review of alternative and concomitant psychotropic medications, including clomipramine, venlafaxine, buspirone, and pimozide.

An open study of buspirone augmentation of serotonin-reuptake inhibitors in body dysmorphic disorder

Phillips KA. *Psychopharmacol Bull* 1996; 32: 175–80.

Thirteen patients with DSM-IV BDD who had not responded or had responded only partially to an SSRI had buspirone added to the regimen. Six of these subjects (46%) improved. Three who decreased or discontinued buspirone experienced an increase in symptom severity.

Bowen disease and erythroplasia of Queyrat

Colin A. Morton

Bowen disease (in situ squamous cell carcinoma, in situ SCC) and erythroplasia of Queyrat (EQ) are forms of intraepidermal squamous cell carcinoma, with the latter located on the penis. The lesions typically present as well-demarcated, erythematous, hyperkeratotic plaques with an irregular border that are persistent and slowly

enlarging. Plaques of EQ develop on the glans or inner aspect of the foreskin and can be smooth or scaly/warty. Risk factors for the development of Bowen disease and EQ vary according to the site of disease, but include sun exposure, HPV (human papilloma virus) infection, arsenic exposure, radiation exposure, and HIV or other forms of immunosuppression.

Diagnosis

An initial diagnostic biopsy is recommended, especially for EQ and atypical presentations of Bowen, but many dermatologists will initiate treatment of typical Bowen disease on the basis of clinical diagnosis, aided by dermoscopy.

The specific dermoscopic criteria of Bowen's disease

Zalaudek I, Di Stefani A, Argenziano G. *J Eur Acad Dermatol Venereol* 2006; 20: 361–2. Dermoscopy can offer assistance in diagnosis with irregular clusters of coiled “glomerular vessels” together with a scaly surface characteristic, with small pigmented globules and/or homogeneous pigmentation present in pigmented variants.

Management Strategy

Therapy aims to cure disease by preventing progression to invasive SCC. SCC arises in only around 3% to 5% of typical Bowen disease but about 10% for EQ. Several treatment options are available, and evidence-based guidelines seek to balance efficacy, tolerability, and cosmesis as well as cost effectiveness. Partners of patients with EQ should be screened for other forms of intraepithelial neoplasia caused by HPV in the genital area.

British Association of Dermatologists' guidelines for the management of squamous cell carcinoma in situ (Bowen's disease) 2013

Morton CA, Birnie AJ, Eedy DJ. *Br J Dermatol* 2014; 170: 245–60.

Quality of evidence for reported treatments for Bowen disease and EQ was reviewed in detail. The strongest evidence was for topical photodynamic therapy (PDT), 5-fluorouracil, and imiquimod, as well

as cryotherapy. Nonsurgical options are increasingly used and offer advantages for large/multiple lesions. Surgical excision and curettage remain in common use, although with lower-quality evidence available. Treatment tolerability is a greater challenge for patients with EQ, but with a similar choice of therapy as for Bowen disease.

Direct surgical excision can be considered if a lesion is small and well defined, especially if there is doubt over possible invasive SCC. Lesion ablation may also be achieved with electrodesiccation and curettage or cryotherapy. Mohs micrographic surgery (MMS) is the surgical treatment of choice in severe/recurrent cases of EQ and indicated for certain sites (e.g., digital Bowen disease) where tissue-sparing benefits are important. Laser and radiotherapy have a more limited evidence base, with poor healing reported after radiotherapy. Several treatment combinations are also reported in the literature, but so far lack a substantial evidence base.

First-Line Therapies

• Photodynamic therapy	A
• Cryotherapy	A
• Standard excision	B
• Electrodesiccation and curettage	B

Interventions for cutaneous Bowen's disease

Bath-Hextall FJ, Matin RN, Wilkinson D, Leonardi-Bee J. Cochrane Database Syst Rev 2013; 6: CD007281.

Review of interventions for SCC in situ by the Cochrane Skin Group identified nine randomized controlled trials (RCTs), but noted limited data for surgery and topical cream therapies. MAL-PDT was shown to be an effective treatment, more efficacious than cryotherapy, but equivalent to topical 5-fluorouracil, whereas ALA-PDT achieved a higher clearance rate compared with 5-fluorouracil,

but with no difference in efficacy between 5-fluorouracil and cryotherapy.

Comparison of topical methyl aminolevulinate photodynamic therapy with cryotherapy or fluorouracil for treatment of squamous cell carcinoma in situ

Morton C, Horn M, Leman J, Tack B, Bedane C, Tjioe M, et al. Arch Dermatol 2006; 142: 729–35.

Complete response rates at 1 year were highest for methyl aminolevulinate PDT ($n = 96$) at 80% (two treatments spaced 1 week apart, with the methyl aminolevulinate applied for 3 hours before red light illumination) compared with cryotherapy ($n = 96$) at 67% (a minimum 20-second freeze/thaw cycle) and 5% 5-fluorouracil cream at 69% (4 weeks of treatment applied once a day for the first week then twice a day), although the three therapies were equivalent at 24 months. Cosmetic outcomes were best after methyl aminolevulinate PDT.

Given the smaller sample size of 30 lesions treated by 5-fluorouracil in this study where comparator was chosen by clinician's preference and more limited study data elsewhere, topical 5-fluorouracil has been overall considered a second-line therapy in this chapter.

European guidelines for photodynamic therapy. Part 1: treatment delivery and current indications – actinic keratoses, Bowen's disease, basal cell carcinoma

Morton CA, Szeimies RM, Sidoroff A, Braathen LR. J Eur Acad Dermatol Venereol 2013; 27: 536–44.

Review of the literature observing high efficacy (86% to 93%) of typical lesions of Bowen disease at 3 months after MAL-PDT with sustained clearance of 68% to 71%, equivalent to cryotherapy and topical 5-fluorouracil. PDT has been shown effective for large lesions over 3 cm in diameter, clearing 96%, as well as a tissue-sparing option for digital, subungual, and nipple lesions.

Methyl-aminolevulinate photodynamic therapy for the treatment of erythroplasia of Queyrat in 23 patients

Fai D, Romano I, Cassano N, Vena GA. J Dermatolog Treat 2012; 23: 330–2.

Nineteen patients obtained a complete clinical remission without any sign of recurrence over an average posttreatment period of 18

months, although local adverse reactions were common during treatment.

Bowen's disease involving the urethra

Yasuda M, Tamura A, Shimizu A, Takahashi A, Ishikawa O. J Dermatol 2005; 32: 210–3.

A case report highlighting the importance of early and definitive surgical treatment of EQ, recognizing the limited options when EQ extends to include the urethral meatus.

Comparison of cryotherapy with curettage in the treatment of Bowen's disease: a prospective study

Ahmed I, Berth-Jones J, Charles-Holmes S, O'Callaghan CJ, Ilchyshyn A. Br J Dermatol 2000; 143: 759–66.

Eighty lesions were randomized to two groups, cryotherapy ($n = 36$) or curettage ($n = 44$), and followed for a median of 2 years. Curettage produced comparable cure rates with more rapid healing, less pain, and fewer complications.

Second-Line Therapies

• 5-Fluorouracil	B
• Imiquimod 5%	B
• Mohs micrographic surgery	B

Topical treatment of Bowen's disease with 5-fluorouracil

Bargman H, Hochman J. J Cutan Med Surg 2003; 7: 101–5.

Only 2 of 26 biopsy-confirmed lesions recurred up to 10 years after treatment.

Imiquimod 5% cream monotherapy for cutaneous squamous cell carcinoma in situ (Bowen's disease): a randomized, double-blind, placebo-controlled trial

Patel GK, Goodwin R, Chawla M, Laidler P, Price PE, Finlay AY, et al. J Am Acad Dermatol 2006; 54: 1025–32.

Seventy-three percent of 31 patients achieved clinical remission with no recurrence at the 9-month follow-up.

Treatment of Bowen's disease with topical 5% imiquimod cream: retrospective study

Rosen T, Harting M, Gibson M. Dermatol Surg 2007; 33: 427–31.

Forty-two of 49 patients (86%) treated with 5% imiquimod cream once daily for a mean of 9 weeks achieved complete clinical remission at 1.5-year follow-up.

Erythroplasia of Queyrat treated with imiquimod 5% cream

Micali G, Nasca MR, De Pasquale R. J Am Acad Dermatol 2006; 55: 901–3.

Case report of an elderly man with EQ treated with 5% imiquimod with clinical and histologically confirmed cure.

Cutaneous squamous carcinoma in situ (Bowen's disease): treatment with Mohs micrographic surgery

Leibovitch I, Huilgol SC, Selva D, Richards S, Paver R. J Am Acad Dermatol 2005; 52: 997–1002.

A case series evaluating 270 cases of Bowen disease treated with MMS with 5-year follow-up demonstrating recurrence rates of approximately 6%. The majority of lesions treated were on the head and neck, and many were recurrent at the time of MMS.

Extensive Bowen's disease of the penile shaft treated with fresh tissue Mohs micrographic surgery in two separate operations

Moritz DL, Lynch WS. J Dermatol Surg Oncol 1991; 17: 374–8.

Third-Line Therapies

• Laser	C
• Radiotherapy	C

Bowen's disease treated by carbon dioxide laser. A series of 44 patients

Covadonga Martinez-Gonzalez M, del Pozo J, Paradela S, Fernández-Jorge B, Fernández-Torres R, Fonseca E. J Dermatolog Treat 2008; 19: 293–9.

A larger retrospective study that used a CO₂ laser in superpulsed mode (2 W/cm²) to treat SCC in situ in 44 patients reported clearance after one treatment in 86% of patients, with all but one of the remaining lesions cleared after a total of two to four treatments.

Radiation therapy for Bowen's disease of the skin

Lukas VanderSpek LA, Pond GR, Wells W, Tsang RW. Int J Radiat Oncol Biol Phys 2005; 63: 505–10.

Forty-four cases of Bowen disease treated with radiation therapy were reviewed, demonstrating remission in 42 patients, with three recurrences at a mean follow-up period of 2.5 years. A broad range of radiation schedules were used and compared for efficacy and safety. These demonstrated no significant differences between low- to medium- and high-dose radiation schedules on disease remission or recurrence.

Bullous pemphigoid

Sandra Peña, and Victoria P. Werth

Bullous pemphigoid (BP) is an autoimmune subepidermal blistering disease that mainly affects elderly patients, although childhood cases do occur. Subepidermal blistering is mediated by activation of complement and release of tissue-destructive proteases after IgG autoantibody complex formation with hemidesmosomal antigens BPAg1 (BP230) and BPAg2 (BP180 or collagen XVII). IgE autoantibodies to BPAg2 have also been identified in the majority of patients and have been shown to be pathogenic. The clinical

hallmarks of the eruption are tense bullae with either generalized or localized distribution; however, variants, including urticarial, vesicular, vegetative, erythrodermic, and nodularis, have been described. Pruritus associated with BP can be severe and adversely affect quality of life. Mucosal involvement with small blisters or erosions may exist in a minority of patients. Although there can be relapses and exacerbations, BP is generally self-limiting, with remission in most adults by 5 years, and more rapidly in children. Mortality can be high in patients with poor overall health and advanced age.

Management Strategy

The Cochrane Skin Group updated its review on the treatment of BP in 2011. The review focused on evidence from 10 randomized controlled trials (RCTs) to help guide physicians with treatment. Although the quality of evidence from the majority of the trials was limited by small sample size and lack of blinding, 2 of the 10 studies were large and included more than half of the participants in the review (July 2002, July 2009). The reviewers concluded that very potent topical steroids were effective and safe in the treatment of BP and that milder regimens are effective in moderate BP. Doses of prednisolone >0.75 mg/kg/day showed no added benefit over lower doses and had an increased incidence of adverse effects. The data also showed that topical clobetasol propionate 0.05% cream (40 g/day) was as effective as oral corticosteroids in controlling disease and associated with fewer side effects. These are the only recommendations with strong evidentiary support.

Patients with localized disease may be successfully treated with clobetasol propionate 0.05% or *intralesional corticosteroids*. Those with generalized disease in which topical therapy is not feasible can be treated with *prednisone*, 0.5 to 0.75 mg/kg/day, depending on disease severity and considering the overall health of the patient. The risks of both short- and long-term systemic corticosteroid therapy are well known and are heightened in the elderly patient population. Every effort should be made to find the minimum dosage of systemic corticosteroids required to suppress disease. With only a few exceptions, all elderly patients started on systemic corticosteroids should also start calcium, vitamin D, and bisphosphonate therapy. All patients on systemic corticosteroids should be screened for

tuberculosis and have their blood pressure and serum glucose levels followed closely.

Tetracycline combined with *nicotinamide* can be used for patients unable to tolerate or who have contraindications to corticosteroids. If gastrointestinal side effects manifest, *minocycline* may be substituted. Tetracycline alone has also been used in one case with success.

Azathioprine is a second-line alternative that may be used alone or as a corticosteroid-sparing agent in more severe disease. Due to genetic polymorphisms in the expression of thiopurine methyltransferase (TPMT), the enzyme that metabolizes azathioprine, a TPMT level before initiating treatment may assist the physician in appropriate dosing. *Azathioprine* has a slow onset of action and should be started in conjunction with corticosteroids during the acute stage. Patients usually respond within 3 to 4 weeks of initiation.

Mycophenolate mofetil, an immunosuppressant, is an effective corticosteroid-sparing agent in BP. It is generally well tolerated and does not carry the risk of liver toxicity seen with azathioprine.

Dapsone is particularly useful when histologic examination reveals a predominance of neutrophils. *Methotrexate* is another corticosteroid-sparing agent that may be useful in BP. It is given in a weekly, low-dosage protocol in a similar manner to psoriasis therapy.

For severe and refractory BP, a variety of immunosuppressive and immunomodulatory therapies have demonstrated efficacy, including *intravenous immunoglobulin*, *chlorambucil*, *pulsed intravenous corticosteroids*, *cyclophosphamide*, *ciclosporin*, *etanercept*, *rituximab*, *daclizumab*, and *omalizumab*.

An international consensus on the definition of end points and a disease severity measure for studies in BP was recently published and should allow for better comparisons between studies in the future (**Definitions and outcome measures for bullous pemphigoid: recommendations by an international panel of experts.** Murrel DF, Daniel BS, Joly P, Borradori L, Amagai M, Hashimoto T, et al. *J Am Acad Dermatol* 2012; 66: 479–85).

Specific Investigations

- Evaluation of medications to rule out drug-induced cases
- Consider patient age and overall medical condition for therapeutic decision-making

- Biopsy of intact bulla for histologic examination with hematoxylin and eosin
- Biopsy of perilesional skin for direct immunofluorescence (sent in Michel's transport medium)
- Consider BP180 (BPAg2) ELISA or indirect immunofluorescence on blood or blister fluid sample
- Consider fasting glucose screening
- Consider screening for antiphospholipid antibodies

Drug-induced pemphigoid: bullous and cicatricial

Vassileva S. Clin Dermatol 1998; 16: 379–87.

Many drugs have been recognized to induce BP, including furosemide, bumetanide, spironolactone, phenacetin, penicillins, ibuprofen, D-penicillamine, captopril, fluoxetine, β -adrenergic blockers, terbinafine, gabapentin, risperidone, and PUVA.

Prediction of survival for patients with bullous pemphigoid: a prospective study

Joly P, Benichou J, Lok C, Hellot MF, Saiag P, Tancrede-Bohin E, et al. Arch Dermatol 2005; 141: 691–8.

The only prospective trial evaluating factors that influence survival in 341 BP patients found that increasing age and poor overall health were direct predictors of mortality. They showed that disease activity had no correlation with mortality.

Increased frequency of diabetes mellitus in patients with bullous pemphigoid: a case–control study

Chuang TY, Korkij W, Soltani K, Clayman J, Cook J. J Am Acad Dermatol 1984; 6: 1099–102.

The prevalence of diabetes mellitus before administration of systemic corticosteroids was significantly higher in patients with BP (20%) than in controls (2.5%).

Bullous pemphigoid and comorbidities: a case-control study in Portuguese patients

Teixeira VB, Cabral R, Brites MM, Vieira R, Figueiredo A. An Bras Dermatol 2014; 89: 274–8

The prevalence of at least one neurologic disease was significantly higher in BP cases before the diagnosis of BP compared with that of

controls. Researchers did not find any significant associations between BP and malignancy or diabetes.

Antiphospholipid antibodies in patients with autoimmune blistering disease

Echigo T, Hasegawa M, Inaoki M, Yamazaki M, Sato S, Takehara K. J Am Acad Dermatol 2007; 57: 397–400.

A higher prevalence of antiphospholipid antibodies was detected in patients with autoimmune blistering diseases (pemphigus vulgaris, pemphigus foliaceus, bullous pemphigoid, cicatricial pemphigoid, and linear IgA disease) compared with normal controls. Of the 10 patients with an autoimmune blistering disease and positive antiphospholipid antibodies, 7 were found to have occult thromboembolism.

First-Line Therapies

• Clobetasol propionate 0.05%	B
• Systemic corticosteroids	B
• Tetracycline and nicotinamide	B
• Minocycline	C
• Tetracycline	E

A comparison of oral and topical corticosteroids in patients with bullous pemphigoid

Joly P, Roujeau JC, Benichou J, Picard C, Dreno B, Delaporte E, et al. N Engl J Med 2002; 346: 321–7.

A total of 341 patients were enrolled in a nonblinded, randomized, multicenter trial and were stratified by disease severity (moderate or extensive). Patients received either topical clobetasol (40 g/day) or oral prednisolone (0.5 mg/kg for moderate disease and 1 mg/kg for

extensive disease). Topical corticosteroid therapy was found to be equal to oral corticosteroids in both survival and efficacy for moderate BP. Survival was higher in extensive disease with the use of topical steroids compared with oral corticosteroids.

A comparison of two regimens of topical corticosteroids in the treatment of patients with bullous pemphigoid: a multicenter randomized study

Joly P, Roujeau JC, Benichou J, Delaporte E, D'Incan M, Dreno B, et al. *J Invest Dermatol* 2009; 129: 1681–7.

This nonblinded, randomized study stratified 312 patients to moderate or extensive disease and compared treatment with clobetasol propionate cream in a mild regimen (10–30g/day for 4 months) to a standard regimen (40g/day with tapering over 12 months). The mild regimen was as effective as the standard regimen in both moderate and extensive disease. There was a 70% reduction in the cumulative dose of topical steroids with the mild regimen, and there were fewer adverse effects. The mild regimen reduced the risk of death or life-threatening side effects in patients with moderate BP.

Treatment of bullous pemphigoid with prednisolone only: 0.75 mg/kg/day versus 1.25 mg/kg/day. A multicenter randomized study

Morel P, Guillaume JC. *Ann Dermatol Venereol* 1984; 11: 925–8.

A randomized, prospective study of 50 patients found no difference in effectiveness with a higher dose of prednisolone compared with the lower dose.

Bullous pemphigoid in infants: characteristics, diagnosis and treatment

Schwieger-Briel A, Moellmann C, Mattulat B, Schauer F, Kiritsi D, Schmidt E, et al. *Orphanet J Rare Dis* 2014; 9:185.

A group of researchers studying a cohort of infantile BP patients developed the first treatment algorithm for BP in infants. They determined that all patients should be treated with mid- to high-potency topical steroids and those with moderate-to-severe disease should also be started on systemic steroids.

Nicotinamide and tetracycline therapy of bullous pemphigoid

Fivenson DP, Breneman DL, Rosen GB, Hersh CS, Cardone S,

Mutasim D. Arch Dermatol 1994; 130: 753–8.

A randomized, open-label trial of 20 patients showed that the combination of nicotinamide (500 mg three times daily) and tetracycline (500 mg four times daily) was equally efficacious as systemic corticosteroids and resulted in less toxicity.

Minocycline as a therapeutic option in bullous pemphigoid

Loo WJ, Kirtschig G, Wojnarowska F. Clin Exp Dermatol 2001; 26: 376–9.

A retrospective analysis of 22 patients treated with adjuvant minocycline (50–100 mg daily) showed a major response in 6 six patients, a minor response in 11, and no response in 5.

Generalized bullous pemphigoid controlled by tetracycline therapy alone

Pereyo NG, Loretta SD. J Am Acad Dermatol 1995; 32: 138–9.

An 82-year-old woman with generalized BP responded completely to oral tetracycline (500 mg twice daily) within 2 weeks. The tetracycline was successfully tapered over 6 weeks.

Second-Line Therapies

• Azathioprine	B
• Mycophenolate mofetil	B
• Dapsone	C
• Methotrexate	C

Azathioprine in the treatment of bullous pemphigoid

Greaves MW, Burton JL, Marks J. Br Med J 1971; 1: 144–5.

Of 11 patients on long-term maintenance therapy with systemic

corticosteroids, 9 remained symptom free on azathioprine alone and 2 were able to have a reduced dosage of prednisone.

Azathioprine plus prednisone in treatment of pemphigoid

Burton J, Harman R, Peachey R, Warin R. *Br Med J* 1978; 2: 1190–1.

A controlled trial of 25 patients comparing azathioprine (2.5 mg/kg daily) plus prednisone with prednisone alone showed that azathioprine greatly reduced the need for prednisone and improved outcome.

A comparison of oral methylprednisolone plus azathioprine or mycophenolate mofetil for the treatment of bullous pemphigoid

Beissert S, Werfel T, Frieling U, Böhm M, Sticherling M, Stadler R, et al. *Arch Dermatol* 2007; 143: 1536–42.

In this nonblinded, randomized controlled trial of 73 patients on methylprednisolone, 38 received azathioprine 2 mg/kg/day and 35 received mycophenolate mofetil 2 g/day. Both regimens were found to be equally effective, although faster remission and a lower cumulative dose of methylprednisolone was seen with azathioprine. Azathioprine was associated with more liver toxicity. Both treatment groups had 100% remission of lesions.

Dapsone as first line therapy for bullous pemphigoid

Venning VA, Millard PR, Wojnarowska F. *Br J Dermatol* 1989; 120: 83–92.

In an open trial of 13 patients placed on dapsone as initial treatment, 6 were completely controlled with dapsone (50–100 mg daily). Dapsone may be used as initial treatment for BP, particularly when there are contraindications to the use of corticosteroids or immunosuppressants.

Combined treatment with low-dose methotrexate and initial short-term superpotent topical steroids in bullous pemphigoid: an open, multicentre, retrospective study

Du-Thanh A, Merlet S, Maillard H, Bernard P, Joly P, Esteve E, et al. *Br J Dermatol* 2011; 165: 1337–43.

A retrospective review of 70 patients treated concurrently with superpotent topical steroids and low-dose methotrexate (5–15 mg/week) showed complete clinical remission in all patients. Seventy-six percent of patients showed sustained clinical remission on low-

dose methotrexate with a mean treatment duration of 8 months. Twenty-four percent of patients experienced one or more side effects, primarily hematologic and gastrointestinal.

Low-dose methotrexate treatment in elderly patients with bullous pemphigoid

Paul MA, Jorizzo JL, Fleischer AB, White WL. J Am Acad Dermatol 1994; 31: 620–5.

In a retrospective chart review of 34 patients, 8 therapy-resistant patients received low-dose weekly methotrexate (average 5–10 mg) combined with oral prednisone. Patients receiving combination therapy required significantly lower doses of prednisone to control their disease at 1 month compared with baseline.

Low-dose oral pulse methotrexate as monotherapy in elderly patients with bullous pemphigoid

Heilborn JD, Ståhle-Bäckdahl M, Albertioni F, Vassilaki I, Peterson C, Stephansson E. J Am Acad Dermatol 1999; 40: 741–9.

In a prospective study of low-dose oral methotrexate (5–12.5 mg/week) in 11 elderly patients with generalized BP, every patient demonstrated a rapid decrease in disease activity within 4 to 30 days.

Third-Line Therapies

• Intravenous immunoglobulin (IVIG)	C
• Chlorambucil + prednisolone	C
• Pulse intravenous corticosteroids	D
• Cyclophosphamide + pulse intravenous corticosteroids	E
• Cyclophosphamide	E
• Ciclosporin	E
• Etanercept	E
• Rituximab	E
• Daclizumab	E
• Omalizumab	E

Consensus statement on the use of intravenous immunoglobulin therapy in the treatment of autoimmune mucocutaneous blistering diseases

Ahmed AR, Dahl MV. Arch Dermatol 2003; 139: 1051–9.

In 27 of 32 cases of BP reported in the literature as unresponsive to conventional therapy, IVIG was of significant benefit and produced lasting clinical results with minimal adverse effects. General recommendations included dosing at 2 mg/kg per cycle with a cycle consisting of the total dose divided into three equal doses, given on 3 consecutive days. Before starting therapy, an IgA level should be obtained. A cycle should be given every 3 to 4 weeks, and a slow tapering is advised to prevent recurrences and sustain the obtained clinical benefit.

Chlorambucil as a steroid-sparing agent in bullous pemphigoid

Chave TA, Mortimer NJ, Shah DS, Hutchinson PE. Br J Dermatol 2004; 151: 1107–8.

In a retrospective study of 45 patients, 26 patients received prednisolone only and 19 received prednisolone and chlorambucil (0.1 mg/kg/day reduced after 2 weeks to 0.05 mg/kg/day, and after 1 month to 2 mg daily). Patients treated with chlorambucil had a shorter treatment course and reduced total steroid requirement.

High-dose methylprednisolone in the treatment of bullous pemphigoid

Siegel J, Eaglstein WH. Arch Dermatol 1984; 120: 1157–65.

Seven of eight hospitalized patients with active BP responded within 24 hours after receiving methylprednisolone pulse therapy (15 mg/kg intravenously over 1 hour daily for 3 days). Moderate doses of oral prednisone (0.4 mg/kg) were required for maintenance.

Severe bullous pemphigoid responsive to pulsed intravenous dexamethasone and oral cyclophosphamide

Dawe RS, Naidoo DK, Ferguson J. Br J Dermatol 1997; 137: 826–7.

Refractory BP in a 59-year-old woman with diabetes mellitus cleared with pulsed intravenous dexamethasone therapy (100 mg dexamethasone in 500 mL 5% dextrose infused over 4 hours on three consecutive days, monthly) and low-dose oral cyclophosphamide (50

mg/day between pulses).

Successful treatment of bullous pemphigoid with pulsed intravenous cyclophosphamide

Itoh T, Hosokawa H, Shirai Y, Horio T. *Br J Dermatol* 1996; 134: 931–3.

A 67-year-old man with refractory BP was reported to respond to monthly pulsed intravenous doses of cyclophosphamide (500–1000 mg) along with low-dose oral cyclophosphamide (50 mg/day).

Treatment of bullous pemphigoid with low-dose oral cyclophosphamide: a case series of 20 patients

Gual A, Iranzo P, Mascaro JM Jr. *J Eur Acad Dermatol Venereol* 2014; 28: 814–8.

A retrospective study assessing the efficacy and safety of low-dose oral cyclophosphamide in patients with moderate-to-severe BP found a marked therapeutic effect in 79% of patients. Additionally, of the patients to achieve complete resolution of BP, 73% did so on a low dose of cyclophosphamide.

Effects of cyclosporin on bullous pemphigoid and pemphigus

Thivolet J, Harthelemy H, Rigot-Muller G, Bendelac A. *Lancet* 1985; 1: 334–5.

Ciclosporin (6 mg/kg daily), adapted to obtain a plasma level of 80 to 180 µg/L, was successful in treating two patients with BP.

Treatment of coexisting bullous pemphigoid and psoriasis with the tumor necrosis factor antagonist etanercept

Yamauchi PS, Lowe NJ, Gindi V. *J Am Acad Dermatol* 2006; 54: S121–2.

A 64-year-old man with both psoriasis and bullous pemphigoid failed mycophenolate mofetil treatment and was started on prednisone 60 mg/day. To reduce rebound effect with steroid tapering, etanercept 50 mg/week was started. Bullae returned as the prednisone was tapered, so the dose of etanercept was increased to 50 mg twice weekly. At this dose, prednisone could be tapered and the psoriasis and BP remained in remission.

Rituximab for treatment-refractory pemphigus and pemphigoid: a case series of 17 patients

Kasperkiewicz M, Shimanovich I, Ludwig R, Rose C, Zillikens D,

Schmidt E. J Am Acad Dermatol 2011; 65: 552–8.

Two patients with BP and five with mucous membrane pemphigoid (MMP) were treated with rituximab at a dose of 375 mg/m² weekly for four doses or twice with 1000 mg at a 2-week interval. One patient with MMP showed a complete remission off therapy, four patients (two patients with MMP, two patients with BP) showed a complete remission while on therapy, and two patients with MMP had a partial remission. Six of the seven patients were on concomitant immunosuppressive therapy.

Bullous and mucous membrane pemphigoid show a mixed response to rituximab: experience in seven patients

Lourari A, Herve C, Doffoel-Hantz V, Meyer N, Bulai-Livideanu C, Viraben R, et al. JEADV 2011; 25: 1230–42.

In a retrospective study of five patients with BP and two with MMP, all patients received four infusions of rituximab at a dose of 375 mg/m² weekly. One patient received an additional four doses at 11 months' follow-up due to relapse of disease. Four patients showed complete remission on therapy, and two patients showed partial remission. The median time to improvement was 4 months.

Daclizumab: a novel therapeutic option in severe bullous pemphigoid

Mockenhaupt M, Grosber M, Norganer J. Acta Dermatol Venereol 2005; 85: 65–6.

A 52-year-old with diffuse BP failed combination treatment with prednisolone 100 mg/day plus azathioprine 100 mg/day, ciclosporin 200 mg/day, and mycophenolate mofetil 2 g/day. The steroids were reduced to 5 mg/day secondary to glucose intolerance, so daclizumab was added at 1 mg/kg/day. The patient had six infusions and remained on prednisolone 5 mg/day and azathioprine 50 mg/day, with complete resolution of lesions at 2 weeks.

Daclizumab inhibits the IL-2 receptor and downstream T cell activation

Pathogenicity of IgE in autoimmunity: successful treatment of bullous pemphigoid with omalizumab. Fairley J, Baum C, Brandt D, Messingham K. J Allergy Clin Immunol 2009; 123: 704–5.

A 70-year-old woman with a 1-year history of BP showed poor control on prednisone 40 mg/day, azathioprine 150 mg/day, and

minocycline 200 mg/day. Prednisone was discontinued and omalizumab 300 mg subcutaneously every 2 weeks for 16 weeks was initiated. By 16 weeks, affected body surface area decreased from 50% to 5%. The patient relapsed 4 months after discontinuing omalizumab therapy but lesions resolved once treatment was reinstituted. No side effects were reported.

Omalizumab therapy for bullous pemphigoid

Yu KK, Crew AB, Messingham KA, Fairley JA, Woodley DT. *J Am Acad Dermatol* 2014; 71: 468–74.

Researchers were able to demonstrate a therapeutic benefit in six patients treated with systemic omalizumab, an IgE monoclonal antibody. None of the patients had untoward side effects from omalizumab.

Successful management of severe infant bullous pemphigoid with omalizumab

Dufour C, Souillet AL, Chaneliere C, Jouen F, Bodemer C, Jullien D, et al. *BJD* 2012; 166: 1140–1.

A 5-month-old male infant with BP failed prednisolone 2.5 mg/kg daily and was subsequently treated with prednisolone 3 mg/kg daily, dapsone 2 mg/kg daily, azithromycin 10 mg/kg daily, three pulse doses of intravenous methylprednisolone 120 mg, and topical betamethasone 0.05% without control. He was then given omalizumab 100 mg subcutaneously and achieved disease control within 8 days. He received omalizumab injections every 2 weeks for 3 months, then monthly for 4 months. He remained in clinical remission after a 7-month follow-up period.

Burning mouth syndrome (glossodynia)

John J. Kohorst, Cooper C. Wriston, and Rochelle R. Torgerson

Primary burning mouth syndrome (BMS) is a rare, chronic, debilitating disease characterized by intraoral burning in the absence of systemic disease or identifiable abnormalities on physical examination and laboratory testing. Current evidence suggests that altered neurophysiology of the central or peripheral nervous system may play an etiopathogenic role. The diagnosis of primary BMS is a clinical diagnosis of exclusion. Various medical conditions and medications can induce oral burning, a condition referred to as *secondary BMS*.

Management Strategy

A detailed history and physical examination should be completed to identify all alternative or correctable causes of oral burning. Several associated factors may be simultaneously present requiring treatment. Correctable, associated factors may be local, systemic, or psychological.

Local factors

Local factors include xerostomia (age, medication, radiotherapy); direct irritation (oral care products, tobacco); mechanical trauma (rough dental restorations, poorly fitting dental prostheses); parafunctional habits (bruxism, tongue thrusting); microbial infection or colonization (candidiasis, herpetic, fusospirochetal); geographic or fissured tongue; mucocutaneous diseases (lichen planus, pemphigus, pemphigoid); and allergic contact stomatitis (flavorings, food additives, dental materials).

Systemic factors

Systemic factors include deficiency states (iron, zinc, folate, cobalamin, thiamin, riboflavin, pyridoxine, ascorbic acid, magnesium); autoimmune disease (Sjögren syndrome); gastrointestinal disease (gastroesophageal reflux); neurologic disease (trigeminal neuralgia, acoustic neuroma, Parkinson disease, glossopharyngeal neuralgia); medication related (angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], antidepressants, antihistamines, antiretrovirals,

benzodiazepines, proton pump inhibitors [PPIs], anticonvulsants, radiochemotherapy); and endocrinopathies (hypothyroidism, diabetes).

Psychological factors

Psychological factors include anxiety (including cancerophobia), depression, adjustment disorder, and psychosocial stressors.

Specific Investigations

Laboratory evaluation and empiric treatment should be directed by the history and physical examination findings. If burning persists after eliminating or treating potential local, systemic, and psychological factors, a working diagnosis of primary BMS is adopted. Although consensus on treatment for primary BMS is lacking, many have found some degree of success with multimodal approaches resembling those used for the treatment of chronic, neuropathic pain.

Pathophysiology of primary burning mouth syndrome

Jaaskelainen SK. Clin Neurophysiol 2012; 123: 71–7.

A review of the evidence for neurophysiologic alterations in the peripheral or central nervous systems in the etiopathogenesis of BMS. A neurophysiologic evaluation is suggested to characterize the neuropathology in individual patients and target treatments.

Psychiatric comorbidity in patients with burning mouth syndrome

Bogetto F, Maina G, Ferro G, Carbone M, Gandolfo S. Psychosom Med 1998; 60: 378–85.

In a case-control study of 102 patients with BMS, 59.8% had concomitant psychiatric disorders.

Interventions for the treatment of burning mouth syndrome

Zakrzewska JM, Forssell H, Glenny AM. Cochrane Database Syst Rev 2005; CD002779.

In nine comparative trials identified for BMS, only α -lipoic acid, clonazepam, and cognitive behavior therapy were effective. Therapeutic efficacy for painkillers, hormones, and antidepressants

was not found.

Clinical assessment and outcome in 70 patients with complaints of burning or sore mouth symptoms

Drage LA, Rogers RS, 3rd. Mayo Clin Proc 1999; 74: 223–8.

A burning or sore mouth was retrospectively associated with psychiatric disease (30%), xerostomia (24%), geographic tongue (24%), nutritional deficiency (21%), and allergic stomatitis (13%) in 70 patients.

Table 34.1
Specific investigations

History	
Oral symptoms	Timing, quality, duration, location, alleviating/exacerbating factors
Medications	Efavirenz, clonazepam, fluoxetine, sertraline, venlafaxine, enalapril, captopril, lisinopril, candesartan, eprosartan, omeprazole, topiramate, hormone replacement therapy
Dental	Prostheses, recent procedures, dentifrices, topical medicaments
Parafunctional habits	Bruxism, tongue thrusting
Review of symptoms	Weakness, headache, fatigue, concentration, sleep disturbance, arthralgia
Physical examination	
Oral	Complete oral examination, including head and neck (remove any dental prostheses)
Nodal	Adenopathy
Musculoskeletal	Temporomandibular joint

Table 34.2
Laboratory evaluation

Hematologic	Complete blood count, ferritin, serum folate, cobalamin (+ methylmalonic acid, homocysteine)
Metabolic	Serum thiamine, riboflavin, pyridoxine, zinc (+ alkaline phosphatase), magnesium
Endocrinologic	Glycosylated hemoglobin, thyrotropin (+ free thyroxine)
Immunologic	Antinuclear factor (+ Ro/SSA, La/SSB)
Dermatologic	Biopsy (+ direct immunofluorescence) if visible abnormality on oral examination
Microbiology testing	Herpes simplex (polymerase chain reaction [PCR]); varicella zoster (PCR); candidosis (swab from site of pain for direct examination and culture); human immunodeficiency virus screening

Table 34.3
Consultations

Otolaryngology	Nasopharyngoscopy
Gastroenterology	Esophagogastroduodenoscopy
Oral/maxillofacial	Periapical radiographs, magnetic resonance imaging
Mental health	Psychiatry consultation
Neurology	Neurologic examination, magnetic resonance imaging
Hypersensitivity testing	Epicutaneous patch testing (preservatives, oral flavors, metals, adhesives)

Burning mouth syndrome: an update

Lopez-Jornet P, Camacho-Alonso F, Andujar-Mateos P, Sánchez-Siles M, Gómez-García F. Med Oral Patol Oral Cir Bucal 2010; 15: e562–8.

BMS is reviewed as a chronic orofacial pain disorder. Serotonin reuptake inhibitors, clonazepam, and capsaicin may be effective treatments.

Burning mouth syndrome

Torgerson RR. Dermatol Ther 2010; 23: 291–8.

Multiple possible etiologies of BMS, including neuropathic, exocrine dysfunction, taste disturbance, mucosal atrophy, and psychological illness, are reviewed. Recommendations for evaluation and management are given.

First-Line Therapies

• Acknowledge and validate patient symptoms and experience; reassure	E
• Avoid contact irritants (alcohol-based oral rinses, caustic mouthwashes, flavored dentifrices, acidic foods, carbonated beverages)	E
• Treat xerostomia (sialagogues, artificial oral lubricants)	D
• Discontinue or change causative medications (ACE inhibitor, ARB, selective serotonin reuptake inhibitor [SSRI], serotonin-norepinephrine reuptake inhibitor, benzodiazepine, nonnucleoside reverse-transcriptase inhibitor, PPI, anticonvulsant, anticholinergics)	E
• Replace thiamine, riboflavin, pyridoxine, folate, cobalamin, iron, zinc, ascorbic acid, magnesium	C
• Manage concomitant psychiatric illness	C
• Assess and address parafunctional habits (bruxism, tongue thrusting)	E
• Assess oral prostheses and dental work	C
• Imidazole/azole therapy (presence of functional pain)	C

Patients complaining of a burning mouth. Further experience in clinical assessment and management

Main DM, Basker RM. Br Dent J 1983; 154: 206–11.

A high rate of intraoral burning attributable to shortcomings in denture design.

Glossodynia from Candida-associated lesions, burning mouth syndrome, or mixed causes

Terai H, Shimahara M. Pain Med 2010; 11: 856–60.

Ninety-five glossodynia patients with no objective tongue findings were assessed for functional pain (significant increase in tongue pain while eating or no tongue pain at rest). Seventy-two (75.7%) of the patients with functional glossodynia improved with imidazole therapy (25 mg gel four times a day for 2–4 weeks).

Drug-induced burning mouth syndrome: a new etiologic diagnosis

Salort-Llorca C, Minguez-Serra MP, Silvestre FJ. *Med Oral Patol Oral Cir Bucal* 2008; 13: E167–70.

Antihypertensive medications that interact with the renin–angiotensin system are the most frequent cause of drug-associated BMS. Efavirenz, clonazepam, venlafaxine, fluoxetine, and sertraline were also associated.

Proton pump inhibitors

Scully C. *Br Dent J* 2010; 208: 147.

A case report of BMS-like symptoms that resolved after discontinuing omeprazole.

Topiramate-induced burning mouth syndrome

Friedman DI. *Headache* 2010; 50: 1383–5.

A case report of BMS that resolved after discontinuing topiramate. Symptoms recurred upon rechallenge.

Zinc deficiency may be a cause of burning mouth syndrome as zinc replacement therapy has therapeutic effects

Cho GS, Han MW, Lee B, Roh JL, Choi SH, Cho KJ, et al. *J Oral Pathol Med* 2010; 39: 722–7.

In a series of 276 patients with BMS, 55 zinc-deficient patients who received zinc supplementation reported a greater reduction of oral pain compared with patients without supplementation ($p = 0.004$).

Second-Line Therapies

• Topical capsaicin	A
• Topical clonazepam	B
• Low-dose clonazepam	A
• Low-dose tricyclic antidepressant (doxepin)	C
• Paroxetine	D
• Milnacipran	D
• Low-dose pregabalin	E
• Duloxetine	E
• Low-dose olanzapine	E
• Cognitive behavioral therapy	B

Application of a capsaicin rinse in the treatment of burning mouth syndrome

Silvestre FJ, Silvestre-Rangil J, Tamarit-Santafé C, Bautista D. Med Oral Patol Oral Cir Bucal 2012; 17: e1–4.

A randomized, double-blind, crossover study of topical capsaicin rinse (0.02%) or placebo three times daily found reduced pain scores among capsaicin-treated, but not placebo-treated, patients with BMS.

Spice R, Hagen NA. Capsaicin in burning mouth syndrome: titration strategies. J Otolaryngol 2004; 33: 53–4.

Guidelines and recommendations for the use of capsaicin in BMS.

Topical clonazepam in stomatodynia: a randomised placebo-controlled study

Gremeau-Richard C, Woda A, Navez ML, Attal N, Bouhassira D, Gagnieu MC. Pain 2004; 108: 51–7.

Forty-eight patients with BMS received either “suck and spit” clonazepam (1 mg) or placebo three times daily for 14 days. Patients receiving topical clonazepam had a greater reduction in pain scores.

A double-blind study on clonazepam in patients with burning

mouth syndrome

Heckmann SM, Kirchner E, Grushka M, Wichmann MG, Hummel T. *Laryngoscope* 2012; 122: 813–6.

Twenty patients with BMS received either clonazepam (0.5 mg) or placebo daily for 9 weeks. Clonazepam-treated patients had reduced pain scores.

Outcome predictors affecting the efficacy of clonazepam therapy for the management of burning mouth syndrome (BMS)

Ko JY, Kim MJ, Lee SG, Kho HS. *Arch Gerontol Geriatr* 2012; 55: 755–61.

One hundred patients with BMS took clonazepam (0.5 mg) once or twice daily for 4 weeks. Patients with fewer psychological symptoms, higher initial pain scores, and the presence of xerostomia or taste disturbance experienced greater therapeutic efficacy.

A population-based study of the incidence of burning mouth syndrome

Kohorst JJ, Bruce AJ, Torgerson RR, Schenck LA, Davis MD. *Mayo Clin Proc* 2014: 1545–52.

Annual age- and sex-adjusted incidence of BMS of 11.4 per 100,000 person-years.

An open-label, noncomparative, dose escalation pilot study of the effect of paroxetine in treatment of burning mouth syndrome

Yamazaki Y, Hata H, Kitamori S, Onodera M, Kitagawa Y. *Oral Surg Oral Med Oral Pathol Oral Radiol Endod* 2009; 107: e6–11.

Out of 52 BMS patients, 42 (80.8%) responded to paroxetine (10–30 mg daily) over 12 weeks. Nineteen (70.4%) had a complete response by the end of the treatment period. The effects were dose dependent.

Milnacipran dose–effect study in patients with burning mouth syndrome

Kato Y, Sato T, Katagiri A, Umezaki Y, Takenoshita M, Yoshikawa T. *Clin Neuropharmacol* 2011; 34: 166–9.

An open-label, dose-escalation pilot study of milnacipran in 56 patients with BMS. The cumulative response rate was 67.9% and 50.8% for daily dosages of 90 mg and 60 mg, respectively.

Marked response of burning mouth syndrome to pregabalin

treatment

Lopez V, Alonso V, Martí N, Calduch L, Jordá E. Clin Exp Dermatol 2009; 34: e449–50.

Report of one case of BMS responsive to pregabalin treatment (50 mg daily).

Gabapentin has little or no effect in the treatment of burning mouth syndrome: results of an open-label pilot study

Heckmann SM, Heckmann JG, Ungethüm A, Hujoel P, Hummel T. Eur J Neurol 2006; 13: e6–7.

A dose-escalation pilot study of gabapentin in BMS showed none to minimal benefit. Maximum titrated dose was 2400 mg daily.

Burning mouth syndrome responsive to duloxetine: a case report

Mignogna MD, Adamo D, Schiavone V, Ravel MG, Fortuna G. Pain Med 2011; 12: 466–9.

Report of one case of BMS responsive to duloxetine (60 mg daily).

Two cases of burning mouth syndrome treated with olanzapine

Ueda N, Kodama Y, Hori H, Umene W, Sugita A, Nakano H. Psychiatry Clin Neurosci 2008; 62: 359–61.

Two cases of BMS responsive to olanzapine treatment (2.5–5.0 mg daily).

Alpha lipoic acid in burning mouth syndrome: a randomized double-blind placebo-controlled trial

Cavalcanti DR, da Silveira FR. J Oral Pathol Med 2009; 38: 254–61.

Alpha-lipoic acid failed to provide a therapeutic benefit.

Cognitive therapy in the treatment of patients with resistant burning mouth syndrome: a controlled study

Bergdahl J, Anneroth G, Perris H. J Oral Pathol Med 1995; 24: 213–5.

A randomized trial in resistant BMS found cognitive therapy superior to an attention program.

Third-Line Therapies

• Avoid contact allergens	E
• Group psychotherapy	B
• Low-level laser therapy (diode)	D

Burning mouth syndrome

Zakrzewska J, Buchanan JA. BMJ Clin Evid 2016. Pii; 1301.

A systematic review of benzodiazepines, benzydamine hydrochloride, cognitive behavior therapy, SSRIs, and tricyclic antidepressants for BMS treatment.

Type 3 burning mouth syndrome: psychological and allergic aspects

Lamey PJ, Lamb AB, Hughes A, Milligan KA, Forsyth A. J Oral Pathol Med 1994; 23: 216–9.

In 33 patients with BMS and intermittent symptoms at atypical sites, 65% were found to have positive patch tests to food flavorings or additives. Symptoms improved in 80% with allergen avoidance.

Group psychotherapy: an additional approach to burning mouth syndrome

Miziara ID, Filho BC, Oliveira D, Rodrigues dos Santos RM. J Psychosom Res 2009; 67: 443–8.

Forty-four patients with BMS were randomized to oral capsules (placebo) for 30 days or a psychological interview and weekly group psychotherapy for 3 months. Seventeen patients (70.8%) receiving group psychotherapy and eight patients (40%) receiving placebo capsules experienced some improvement in pain intensity.

The low level laser therapy in the management of neurological burning mouth syndrome. A pilot study

Romeo U, Del Vecchio A, Capocci M, Maggiore C, Ripari M. Ann Stomatol (Roma) 2010; 1: 14–8.

Twenty-five patients with BMS received twice-weekly treatment with low-level double diode laser therapy ($\lambda = 650$ and 910 nm,

contemporarily; fluence = 0.53 J/cm²; time = 15 minutes) to the sides of the tongue for 4 weeks. Seventeen patients (68%) experienced a reduction in pain scores.

Treatment of burning mouth syndrome with a low-level energy diode laser

Yang HW, Huang YF. Photomed Laser Surg 2011; 29: 123–5.

Seventeen patients with BMS received low-level energy diode laser therapy (λ = 800 nm; power = 3 W; 50-msec intermittent pulsing; frequency = 10 Hz) to the affected tongue surface between one and seven times. The average reduction in pain was 47.6%, and it persisted for up to 12 months.

Calcinosis cutis

Ian H. Coulson, and Rajani Nalluri

Calcinosis cutis is a rare disease of aberrant calcium deposition in the skin and subcutaneous tissue. There are four major types:

- Idiopathic: occurs without tissue injury or metabolic defect (e.g., idiopathic scrotal calcinosis)
- Dystrophic: (most common form) secondary to local tissue damage or alterations in collagen, elastin, or subcutaneous fat but normal calcium and phosphate levels (e.g., in autoimmune connective

tissue diseases, posttrauma or infection)

- Metastatic: abnormal calcium and/or phosphate metabolism leading to precipitation of calcium salts in normal tissue (hyperparathyroidism, sarcoidosis, chronic kidney failure, malignant neoplasms)
- Iatrogenic: secondary to a treatment or procedure (such as extravasation of calcium or phosphate infusions)

Other rare variants of calcinosis cutis that have been described include calcinosis cutis circumscripta, calcinosis universalis, tumoral calcinosis, transplant-associated calcinosis cutis, and milia-like idiopathic calcinosis cutis (usually associated with Down syndrome). Firm white or yellow dermal lesions may ulcerate and extrude a gritty material. It most commonly involves the extensor aspect of joints, particularly the fingers, but can also involve large areas of the body. Stiffening of the skin can limit joint mobility and function, and fingertip lesions may be painful.

Management Strategy

The first step in management is to identify any underlying cause. Dystrophic calcification occurs in approximately 25% of patients with systemic sclerosis (SSc) and 10% to 40% of patients with juvenile dermatomyositis, but is rare in systemic lupus erythematosus. Examination and investigations for connective tissue disease are therefore strongly recommended. Skin biopsy can help to distinguish cutaneous calcification from ossification.

Elevated interleukin-1 levels, along with interleukin-6, interleukin-1 β , and tumor necrosis factor (TNF)- α , are found in patients with juvenile dermatomyositis. Mannose-binding lectin levels were significantly increased in SSc patients with calcinosis. It is positively associated with positive anticentromere, anti-PM/Scl, and anticardiolipin antibodies in SSc patients with calcinosis.

A number of malignancies have been implicated in causing metastatic calcification (e.g., leukemia and multiple myeloma). However, successful treatment of the underlying cause does not always have an impact on calcinosis cutis, which frequently requires other treatment modalities. There are no large studies for the treatment of calcinosis cutis, and most therapies are based on case reports or small case series.

Spontaneous extrusion of calcium salts may occur; this may need

surgical encouragement. General measures to improve blood flow to extremities such as avoiding smoking, stress, and cold exposure are crucial. *Intralesional corticosteroids, aluminum hydroxide supplements, bisphosphonates, diltiazem, colchicine, and probenecid* have shown success, mostly in calcinosis associated with dermatomyositis. Low-dose *minocycline* has been reported to reduce the frequency of ulceration and inflammation associated with cutaneous calcinosis in patients with limited SSc. The mechanism of action may be mainly through inhibition of matrix metalloproteinases and antiinflammatory effects.

Warfarin has been advocated in both dermatomyositis and SSc-associated calcinosis for small calcified deposits. *Carbon dioxide laser vaporization, extracorporeal shock wave lithotripsy, and intravenous immunoglobulin* are recent approaches that have been tried in cutaneous calcinosis secondary to CREST syndrome. Surgical removal can be of benefit for larger lesions.

Specific Investigations

- Full blood count
- Urea and creatinine
- Serum calcium and phosphate
- Parathyroid hormone levels
- Vitamin D levels
- Serum electrophoresis
- Muscle enzymes: creatine kinase, lactate dehydrogenase (LDH), aldolase
- Connective tissue disease screen: antinuclear antibodies (ANAs) and other autoantibodies
- Skin biopsy
- Plain radiographs
- Bone scintigraphy
- Computed tomography (CT) and magnetic resonance imaging (MRI)

First-Line Therapies

• No treatment/self-healing	E
• Diltiazem	C
• Aluminum hydroxide	D
• Intralesional corticosteroid/oral prednisolone	E

Self-healing dystrophic calcinosis following trauma with transepidermal elimination

Pitt AE, Ethington JE, Troy JL. *Cutis* 1990; 45: 28–32.

A case of dystrophic calcinosis after trauma that resolved over 8 weeks with spontaneous transepidermal elimination.

Calcinosis cutis: part II. Treatment options

Reiter N, El-Shabrawi L, Leinweber B, Berghold A, Aberer E. *J Am Acad Dermatol* 2011; 65: 15–22.

Calcinosis cutis in dermatomyositis has been successfully treated with diltiazem (2–4 mg/kg/day), with lower doses being ineffective. Surgical excision or curettage is the treatment of choice in idiopathic calcinosis cutis, especially scrotal calcinosis. It is also effective for small, digital calcified skin lesions. A 16-year-old boy with morphea profunda developed small calcified deposits on both arms, his chest, and left thigh. He was treated with ceftriaxone 2 g/day intravenously for 20 days, and the calcification diminished within weeks.

A case of juvenile dermatomyositis with severe calcinosis and successful treatment with prednisone and diltiazem

Jiang X, Yi Q, Liu D, Wang S, Li L. *Int J Dermatol* 2011; 50: 74–7.

A 12-year-old boy with calcinosis secondary to juvenile dermatomyositis received diltiazem at a dose of 30 mg/day resulting in obvious softening and radiologic regression and functional improvement at 4 months.

Calcinosis cutis occurring in association with autoimmune connective tissue disease: the Mayo Clinic experience with 78 patients, 1996 to 2009

Balin SJ, Wetter DA, Andersen LK, Davis MD. *Arch Dermatol* 2012;

148: 455–62.

Nine of 17 patients with autoimmune connective tissue disorders showed partial response to treatment with diltiazem at the dose of <480 mg/day. This is recommended as first-line treatment. Eight patients were treated with colchicine (<1.2 g/day), resulting in one patient showing complete response and two patients showing partial response. Six patients received minocycline (200 mg/day). Only one patient showed partial response, two patients did not respond, and the response was unknown in three patients. Four patients were treated with warfarin with only one patient partially responding. Out of the 11 patients who received surgical excision alone, all 11 responded, with 8 having a complete response. Another 17 patients had surgical and medical treatment with complete response in 14 patients, partial response in 2 patients, and no response in 1 patient.

Large subcutaneous calcification in systemic lupus erythematosus: treatment with oral aluminium hydroxide administration followed by surgical excision

Park YM, Lee SJ, Kang H, Cho SH. J Korean Med Sci 1999; 14: 589–92.

A 22-year-old woman with systemic lupus erythematosus developed soft tissue calcification with ulceration, infection, and abscess formation. She was treated with aluminum hydroxide 600 mg three times a day with reduction in size and softening of the deposits after 9 months.

Calcinosis cutis in juvenile dermatomyositis responsive to aluminum hydroxide treatment

Nakagawa T, Takaiwa T. J Dermatol 1993; 20: 558–60.

A case of calcinosis cutis in juvenile dermatomyositis was successfully treated with oral aluminum hydroxide; near-complete clearance was observed after 8 months of therapy.

The use of these agents in patients with renal insufficiency may result in aluminum toxicity.

Localized calcinosis in juvenile dermatomyositis: successful treatment with intralesional corticosteroids injection

Al-Mayouf SM, Alsonbul A, Alismail K. Int J Rheum Dis 2010; 13: e26–8.

A 10-year-old boy with juvenile dermatomyositis had calcinosis of his left elbow. It was treated with Depo-Medrol 80 mg and Xylocaine

1% under ultrasound guidance with significant improvement.

Severe calcinosis cutis with cutaneous ulceration in juvenile dermatomyositis

Meher BK, Mishra P, Sivaraj P, Padhan P. Indian Pediatr 2014; 51: 925–7.

A 7-year-old girl with severe calcinosis cutis with ulceration improved, with healing of the ulcer and resolution of nodules, after 1 month of oral prednisolone (1mg/kg/day) and methotrexate (10 mg/week).

Second-Line Therapies

• Bisphosphonates	D
• Probenecid	E
• Colchicine	E
• Minocycline	E

Dramatic improvement of subcutaneous calcinosis by intermittent, high-dose etidronate plus cimetidine in a patient with juvenile dermatomyositis

Wakabayashi T, Sasaki N, Chinen N, Suzuki Y. Case Rep Rheumatol 2015; 2015: Article ID 817592.

A 17-year-old boy with juvenile dermatomyositis and bilateral extensive lower limb calcinosis extending into the subcutaneous tissue and muscle showed marked improvement with intermittent 6 monthly high-dose etidronate (800 mg/day for 3 months) and cimetidine for over 5 years.

Effectiveness of the treatment with intravenous pamidronate in calcinosis in juvenile dermatomyositis

Marco Puche A, Calvo Penades I, Lopez Montesinos B. Clin Exp Rheumatol 2010; 28: 135–40.

Three children with juvenile dermatomyositis received treatment with intravenous pamidronate at 1 mg/kg/day on 3 consecutive days every 3 months. In all three cases calcinosis significantly decreased and even totally cleared in one of them.

Improvement of calcinosis using pamidronate in a patient with juvenile dermatomyositis

Martillotti J, Moote D, Zemel L. Pediatr Radiol 2014; 44: 115–8.

A 7-year-old girl with juvenile dermatomyositis developed severe calcinosis, despite an extensive medication regimen. Three administrations of intravenous pamidronate (1 mg/kg/dose every month for 3 months) produced significant improvement in calcinosis, pain, and function, leading to remission less than 1 year after induction of therapy.

Efficacy of probenecid for a patient with juvenile dermatomyositis complicated with calcinosis

Nakamura H, Kawakami A, Ida H, Ejima E, Origuchi T, Eguchi K. J Rheumatol 2006; 33:1691–3.

An 11-year-old boy with juvenile dermatomyositis developed calcinosis of both legs. Probenecid was used to reduce calcinosis, resulting in remarkable improvement of calcinosis accompanied by normalization of serum phosphorus level.

Treatment of cutaneous calcinosis in limited systemic sclerosis with minocycline

Robertson LP, Marshall RW, Hickling P. Ann Rheum Dis 2003; 62: 267–9.

In an open-label study, eight out of nine patients with limited cutaneous SSc prescribed minocycline 50 or 100 mg daily showed definite improvement. The frequency of ulceration and inflammation associated with the calcinosis deposits decreased with treatment. A reduction in calcinosis size was evident but less dramatic, with improvement occurring by 5 months. The mean duration of treatment was 3.5 years.

See also Balin et al. earlier regarding colchicine and minocycline.

Third-Line Therapies

• Warfarin	D
• Ceftriaxone	E
• Rituximab	E
• Intravenous immunoglobulin	D
• Intravenous sodium thiosulfate	E
• Topical sodium thiosulfate	E
• Topical sodium metabisulfite	E
• Surgery	C
• Carbon dioxide laser	E
• Extracorporeal shock wave lithotripsy	D

Low dose warfarin treatment for calcinosis in patients with systemic sclerosis

Cukierman T, Elinav E, Korem M, Chajek-Shaul T. Ann Rheum Dis 2004; 63: 1341–3.

Three patients with disseminated subcutaneous calcinosis were treated with low doses of warfarin (1 mg/day) for 1 year. Two patients (relatively small lesions up to 2 cm in diameter) had complete resolution within 2 months. The other patient (larger and longer-standing lesions reaching up to 5 cm) did not respond to treatment. None of the patients showed a prolongation of prothrombin time, partial thromboplastin time, or an increased tendency for bleeding.

See also Reiter et al. earlier regarding ceftriaxone.

Rituximab-induced regression of CREST-related calcinosis

de Paula DR, Klem FB, Lorencetti PG, Muller C, Azevedo VF. Clin

Rheumatol 2013; 32: 281–3.

A 54-year-old lady with limited cutaneous scleroderma and calcinosis in her hands had complete resolution 7 months after the first infusion of rituximab (four weekly infusions 375 mg/m²).

Treatment of systemic sclerosis-associated calcinosis: a case report of rituximab-induced regression of CREST-related calcinosis and review of the literature

Daoussis D, Antonopoulos I, Liossis SN, Yiannopoulos G, Andonopoulos AP. Semin Arthritis Rheum 2012; 41: 822–9.

This patient with frequently ulcerating and painful extensive CREST-related calcinosis received two rituximab courses (consisting of four weekly infusions, 375 mg/m² each); calcinosis significantly improved and pain disappeared.

Intravenous immunoglobulin for treatment of dermatomyositis-associated dystrophic calcinosis

Galimberti F, Li Y, Fernandez AP. J Am Acad Dermatol 2015; 73: 174–6.

In a retrospective analysis of dermatomyositis-associated calcinosis in an institution, five out of eight patients showed clinical improvement of calcinosis after IV immunoglobulin (1–3 g/kg over 2 days monthly).

Calcinosis cutis associated with amyopathic dermatomyositis: response to intravenous immunoglobulin

Peñate Y, Guillermo N, Melwani P, Martel R, Hernández-Machín B, Borrego L. J Am Acad Dermatol 2009; 60: 1076–7.

A 55-year-old female with amyopathic dermatomyositis and progressive dystrophic calcinosis on the limbs with ulceration and pain failed to respond to various immunosuppressants and diltiazem. She had treatment with intravenous immunoglobulin (IVIG) (2 g/kg/month) at a dose of 0.4 g/day for 5 consecutive days, in combination with a reduced dose of prednisolone. After five courses of IVIG the dermal calcifications reduced, both clinically and radiologically, and became asymptomatic.

Successful treatment of severe iatrogenic calcinosis cutis with intravenous sodium thiosulfate in a child affected by T-acute lymphoblastic leukemia

Raffaella C, Annapaola C, Tullio I, Angelo R, Giuseppe L, Simone C. *Pediatr Dermatol* 2009; 26: 311–15.

A 5-year-old boy with T-cell acute lymphoblastic leukemia developed soft tissue calcification with motility impairment at sites of intravenous 10% calcium gluconate infusion. Treatment with intravenous sodium thiosulfate 435 mg/kg three times a week for 3 months resulted in massive reduction of soft tissue calcification and functional recovery of affected limbs.

Sodium thiosulfate for the treatment of calcinosis secondary to juvenile dermatomyositis

Pagnini I, Simonini G, Giani T, Marrani E, Moretti D, Vannucci G, et al. *Clin Exp Rheumatol* 2014; 32: 408–9.

There was successful use of sodium thiosulfate in a patient with juvenile dermatomyositis complicated by ulcerative skin disease and progressive calcinosis.

Dramatic diminution of a large calcification treated with topical sodium thiosulfate

Ratsimbazafy V, Bahans C, Guigonis V. *Arthritis Rheum* 2012; 64: 3826.

A 12-year-old boy with a large subcutaneous calcification on the left elbow showed significant reduction in the mass, both clinically and radiologically, after 6 months of once-daily application of sodium thiosulfate topically.

Topical sodium metabisulfite for the treatment of calcinosis cutis: a promising new therapy

Del Barrio-Díaz P, Moll-Manzur C, Álvarez-Veliz S, Vera-Kellet C. *Br J Dermatol* 2016; 175: 608–11.

Four female patients with calcinosis cutis showed decrease in size, erythema, and pain after 6 weeks of topical 25% sodium metabisulfite twice daily.

See also Reiter et al earlier regarding surgical excision.

Surgical debridement of painful fingertip calcinosis cutis in CREST syndrome

Saddic N, Miller JJ, Miller OF 3rd, Clarke JT. *Arch Dermatol* 2009; 145: 212–3.

A 58-year-old woman with CREST syndrome underwent 2-mm

curettage. There was immediate pain relief, and 7 months after the procedure, calcinosis had not recurred.

See also Balin et al earlier. Surgical excision of large, discrete, and symptomatic lesions can be beneficial to patients.

A dystrophic calcinosis cutis case treated with CO₂ laser

Kutlubay Z, Yardimci G, Gokler G, Engin B. J Cosmet Laser Ther 2014; 16: 144–6.

A 12-year-old boy with 2- to 4-mm calcinosis on his right knee was treated with 8 to 10 passes with a CO₂ laser (Candela CO2RE) at a wavelength of 10.600 nm, in classical mode, 3- to 5-mm spot size, fluence of 5 mJ, and pulse duration of 0.104 ms. There was resolution and no recurrence after 3 months.

Therapy of calcinosis cutis using erbium-doped yttrium aluminum garnet laser treatment

Meissner M, Ochsendorf F, Kaufmann R. Dermatol Surg 2010; 36: 727–8.

Patients with subcutaneous nodules smaller than 2 cm in diameter were given local anesthesia, then the skin over the mass was opened using a focused erbium-doped yttrium aluminum garnet (Er:YAG) beam (5 J/cm², 5 mm diameter, 5 Hz). The chalky material was then removed with a swab or curette. Reepithelialization and cosmetic recovery were seen at 2 to 3 weeks and 14 weeks, respectively.

Treatment of calcinosis cutis by extracorporeal shock-wave lithotripsy

Sultan-Bichat N, Menard J, Perceau G, Staerman F, Bernard P, Reguiat Z. J Am Acad Dermatol 2012; 66: 424–9.

A single center study, including eight consecutive patients (with 10 calcinosis cutis lesions) who underwent three extracorporeal shock wave lithotripsy sessions at 3-week intervals for 6 months. At the end of this treatment period the median area had decreased by more than 50% in three calcinosis cutis lesions, with pain scores decreasing significantly in five patients and analgesia consumption decreasing in three patients, with no difference in results according to the underlying causal disease.

Calciophylaxis

Alexander Doctoroff

Calciophylaxis (calcific uremic arteriolopathy, uremic small-artery disease with medial calcification and intimal hyperplasia, vascular calcification–cutaneous necrosis syndrome, calcifying panniculitis) is a serious and often lethal condition affecting mostly patients with renal disease, although normorenal calciophylaxis is becoming

increasingly recognized. Calciphylaxis may be considered the cutaneous equivalent of myocardial infarction. Medial calcification and subintimal fibrosis of arterioles result in arteriolar stenosis. This is followed by thrombotic occlusion and cutaneous necrosis. Calciphylaxis can present either with tender subcutaneous plaques or skin ulcers reflecting various stages of the progression of the disease process.

Management Strategy

Because calciphylaxis is a deadly disease with a mortality rate of up to 80%, early diagnosis via skin biopsy and aggressive treatment are essential.

Monitoring the patient's metabolic environment is of utmost importance. Hyperphosphatemia must be controlled with non-calcium-containing *phosphate binders*. Phosphorus-restricted diet should be introduced, and *vitamin D supplementation stopped*. *Discontinuation of warfarin* due to its proposed procoagulant effect is paramount. Aggressive *wound debridement* needs to be initiated without delay. Monitoring for infection and appropriate use of *antibiotics* are a mainstay of treatment, because most patient deaths occur from sepsis.

Intravenous sodium thiosulfate recently emerged as a promising new treatment for calciphylaxis. This medication is currently used as an antidote for the treatment of cyanide poisoning and prevention of toxicity in cancer therapies. The mechanism of action is believed to be chelation of calcium resulting in dissolution of calcium deposits. Additionally, sodium thiosulfate appears to act as an antioxidant, reducing damage from intravascular reactive oxygen species. The evidence in favor of sodium thiosulfate is limited to multiple case reports. Yet it appears to be safe and nontoxic and therefore deserves a trial as a first-line therapy for calciphylaxis.

Bisphosphonates are another group of medications that alone or in combination with sodium thiosulfate are emerging as an important part of calciphylaxis treatment. They are thought to inhibit local proinflammatory cytokines and decrease arterial calcification.

Cinacalcet may also be used for patients with elevated parathyroid hormone. This medication is believed to act by reducing serum parathyroid hormone and stabilizing calcium and phosphate levels. It is useful in patients with elevated parathyroid hormone levels.

Parathyroid hormone should be monitored throughout treatment to minimize the risk of adynamic bone disease associated with cinacalcet therapy.

If the patient's calciphylaxis is uncovered at an early stage (indurated plaques without ulcerations), oral *prednisone* appears to be helpful.

The use of zero or *low-calcium dialysate* with induction of hypocalcemia and calcium shift into intravascular space appears to be a reasonable therapy. If *hyperbaric oxygen therapy* is available, it can be very helpful to some patients.

Parathyroidectomy, which improves calcium, phosphate, and parathyroid hormone levels, is a useful therapy for those patients with high parathyroid hormone levels. Despite being a subject of controversy, for many patients this surgery results in rapid healing of ulcerations. In many cases the use of cinacalcet avoids parathyroidectomy.

The treatment of calciphylaxis should be a multidisciplinary effort with internists, critical care specialists, nephrologists, dermatologists, infectionists, surgeons, and pain specialists being involved.

Specific Investigations

- Skin biopsy
- Serum parathyroid hormone, calcium, phosphate
- Bone scan
- Measurements of transcutaneous oxygen saturation
- X-ray or xeroradiography

Pathogenesis of calciphylaxis: Hans Selye to nuclear factor kappa-B

Weenig RH. J Am Acad Dermatol 2008; 58: 458–71.

Calciphylaxis from nonuremic causes: a systematic review

Nigwekar SU, Wolf M, Sterns RH, Hix JK. Clin J Am Soc Nephrol 2008; 3: 1139–43.

A review of 38 cases of cutaneous calciphylaxis in patients with normal renal function.

Associated conditions were malignancy, connective tissue disease, hyperparathyroidism, alcoholic cirrhosis, and thrombophilia (protein

S and C deficiency). Recent use of steroids, anticoagulants, and weight loss has also been implicated.

First-Line Therapies

• Debridement of necrotic tissue and aggressive wound care	C
• Discontinuation of calcium and vitamin D supplementation	C
• Decrease of serum phosphorus	C
• Treatment of low serum albumin	C
• Monitoring for infection	C
Table Continued	
• Intravenous sodium thiosulfate	D
• Prednisone (for patients without ulcerations only)	C
• Pamidronate	E
• Cinacalcet	D

Calcium use increases risk of calciphylaxis: a case-control study

Zacharias JM, Fontaine B, Fine A. Perit Dial Int 1999; 19: 248–52.

Retrospective case-control study of eight patients suggests increased risk of calciphylaxis with calcium ingestion.

Risk factors and mortality associated with calciphylaxis in end-stage renal disease

Mazhar AR, Johnson RJ, Gillen D, Stivelman JC, Ryan MJ, Davis CL, et al. Kidney Int 2001; 60: 324–32.

Retrospective case-control study of 19 cases demonstrated female gender, hyperphosphatemia, high alkaline phosphatase, and low serum albumin to be risk factors for calciphylaxis.

Calciphylaxis: natural history, risk factor analysis, and outcome

Weenig RH, Sewell LD, Davis MD, McCarthy JT, Pittelkow MR. J Am Acad Dermatol 2007; 56: 569–79.

Retrospective case-control study of 64 cases showed that obesity, liver disease, systemic corticosteroid use, and elevated calcium-phosphate product and serum aluminum were risk factors for calciphylaxis.

The evolving pattern of calciphylaxis: therapeutic considerations

Llach F. *Nephrol Dial Transplant* 2001; 16: 448–51.

This and other reviews suggest aggressive lowering of serum phosphorus with non-calcium-containing phosphate binders (such as Renagel) and dietary control of calcium and phosphorus intake, as well as aggressive wound debridement and monitoring for infection. Six out of eight patients had significant improvement with zero calcium dialysate.

Sodium thiosulfate as first-line treatment for calciphylaxis

Ackermann F, Levy A, Daugas E, Schartz N, Riaux A, Derancourt C, et al. *Arch Dermatol* 2007; 143: 1336–7.

This is one of several case reports of successful calciphylaxis therapy with IV infusions of sodium thiosulfate (25 g IV infusions three times per week).

Calciphylaxis is usually nonulcerating: risk factors, outcome and therapy

Fine A, Zacharias J. *Kidney Int* 2002; 61: 2210–7.

Review of 36 patients who presented without ulcerations but with subcutaneous indurated plaques in the legs who demonstrated improvement from steroid therapy (prednisone 30–50 mg orally daily for 3–8 weeks) in 80% of cases. Contraindications to steroid therapy include ulceration anywhere (related to peripheral vascular disease [PVD] or calciphylaxis) or high risk of infection.

Proximal calciphylaxis treated with calcimimetic “cinacalcet.”

Mohammed IA, Sekar V, Bibtana AJ, Mitra S, Hutchison AJ. *Nephrol Dial Transpl* 2008; 23: 387–9.

A case report of successful calciphylaxis treatment with 30 mg/day of cinacalcet. *Doses from 30 mg to 120 mg/day have been used in other cases.*

Rapid improvement of calciphylaxis after intravenous pamidronate therapy in a patient with chronic renal failure

Monney P, Nguyen QV, Perroud H, Descombes E. Nephrol Dial Transplant 2004; 19: 2130–2.

Five intravenous doses of 30 mg pamidronate resulted in healing of ulcerations in a patient whose clinical condition was worsening despite other medical therapy. When 6 weeks after discharge calciphylaxis returned, an additional 30 mg pamidronate dose aborted the recurrence.

Multiintervention management of calciphylaxis: a report of 7 cases

Baldwin C, Farah M, Leung M, Taylor P, Werb R, Kiaii M, et al. Am J of Kidney Dis 2011; 58: 988–91.

Various combinations of intravenous sodium thiosulfate (12.5–25 g IV three times a week), oxygen therapy (given through a face mask or hyperbaric chamber), and cinacalcet resolved calciphylaxis in six out of seven patients.

Second-Line Therapies

• Parathyroidectomy (for patients with elevated parathyroid hormone)	C
• Hyperbaric oxygen therapy	D
• Low-calcium dialysate	D
• Vitamin K supplementation in patients who are deficient	E
• Tissue plasminogen activator	E

Calciphylaxis: a syndrome of skin necrosis and acral gangrene in chronic renal failure

Hafner J, Keusch G, Wahl C, Berg G. Vasa 1998; 27: 137–43.

Meta-analysis of all case reports of calciphylaxis from 1936 to 1996 revealed that 70% of patients who were parathyroidectomized survived compared with 43% of those who did not receive the operation. *This study did not stratify patients into those with and without hyperparathyroidism.*

Hyperbaric oxygen in the treatment of calciphylaxis: a case series

Podymow T, Wherrett C, Burns KD. Nephrol Dial Transplant 2001; 16: 2176.

In this retrospective study, two out of five patients with calciphylaxis had complete resolution of their ulcers with hyperbaric oxygen therapy.

Successful treatment of severe calciphylaxis in a hemodialysis patient using low-calcium dialysate and medical parathyroidectomy: case report and literature review

Wang HY, Yu CC, Huang CC. Ren Fail 2004; 26: 77–82.

This is one of several case reports of successful calciphylaxis treatment with low-calcium dialysis.

Skin necrosis and protein C deficiency associated with vitamin K depletion in a patient with renal failure

Soundararajan R, Leehey DJ, Yu AW, Miller JB. Am J Med 1992; 93: 467–70.

Vitamin K replacement resulted in reversal of calciphylaxis in a vitamin K–deficient patient.

Low-dose tissue plasminogen activator for calciphylaxis

Sewell LD, Weenig RH, Davis MD, McEvoy MT, Pittelkow MR. Arch Dermatol 2004; 140: 1045–8.

Tissue plasminogen activator (tPA; alteplase) in a 10-mg intravenous daily dose for 14 days, followed by warfarin anticoagulation resulted in eventual healing of ulcerations.

Third-Line Therapies

• Maggot therapy and pentoxifylline	E
• Ozone therapy	E
• Cryofiltration apheresis	E

Painful ulcers in calciphylaxis – combined treatment with maggot

therapy and oral pentoxifylline

Tittelbach J, Graefe T, Wollina UJ. *Dermatolog Treat* 2001; 12: 211–4.

Maggot therapy and 800 mg/day of oral pentoxifylline were successful in healing ulcers over a 6-month period.

Ozone therapy in a dialyzed patient with calcific uremic arteriolopathy

Biedunkiewicz B, Tylicki L, Lichodziejewska-Niemierko M, Liberek T, Rutkowski B. *Kidney Int* 2003; 64: 367–8.

Fifteen sessions of treatment with ozonated autohemotherapy with ozone concentration of 50 to 70 µg/mL over 3 weeks, accompanied by local wound lavage with ozonated water, led to healing of necrotic areas.

Intensive tandem cryofiltration apheresis and hemodialysis to treat a patient with severe calciphylaxis, cryoglobulinemia, and end-stage renal disease

Siami GA, Siami FS. *ASAIO J* 1999; 45: 229–33.

This is a report on tandem cryofiltration apheresis (CFA) and hemodialysis (HD) in a critically ill patient with type II mixed cryoglobulinemia, hepatitis C virus infection, calciphylaxis, and end-stage renal disease. The patient received 18 tandem CFA/HD treatments and 4 extra HD treatments in 1 month. His plasma cryoglobulin level dropped, and his calciphylaxis also improved.

Capillaritis (pigmented purpuric dermatoses)

Cord Sunderkötter, and Thomas A. Luger

Capillaritis (a generic term for the various pigmented purpuric dermatoses) presents with the common feature of petechial macules or plaques and is characterized histologically by erythrocyte extravasation and perivascular infiltration with T lymphocytes.

Lesions develop a characteristic brown-to-orange color due to hemosiderin deposits in macrophages. These conditions may also present with additional, distinctive, and sometimes overlapping, morphologic patterns, which have given rise to several descriptive or eponymous names: papules in pigmented purpuric lichenoid dermatosis (of Gougerot and Blum) or in the rarely described granulomatous pigmented purpura (nonnecrotizing granulomata with concomitant lymphocytic infiltrate); eczematous spongiosis with pruritus in eczematoid-like purpura; annular forms with telangiectases and central clearing in purpura annularis telangiectodes (Majocchi disease); and often solitary, ochre-golden plaques or patches with bandlike infiltrates, including a grenz zone in lichen aureus. Sites of predilection are mostly both lower extremities. A form of unilateral linear capillaritis or involvement of other areas of the skin is rare. Pigmented purpuric dermatoses also occur in children, albeit less frequently than in adults.

The etiology of capillaritis, including these variants, is not known. The reason for extravasation of erythrocytes is not an inflammatory fibrinoid necrosis of vessels (no vasculitis). Possible pathophysiologic factors that can be addressed therapeutically are a cell-mediated immune response, increased venous pressure, increased vascular permeability, or vascular fragility due to subtle defects in the extracellular matrix.

Management Strategy

Diagnostic hallmarks are the yellow-brown or orange patches with superimposed pinpoint cayenne pepper spots, which represent petechiae and persist with diascopy. The main differential diagnosis is leukocytoclastic or small vessel vasculitis. The discerning criterion is the lack of a palpable infiltrate in capillaritis, but there are courses or variants of small vessel vasculitis with petechial maculae only. Thus biopsies are warranted when in doubt.

In the differential diagnosis, allergic contact dermatitis may be purpuric or hemorrhagic (e.g., in response to textile or azo dyes), mimicking capillaritis. Thrombocytopenia, hypergammaglobulinemic purpura of Waldenström, and the pigmented purpuric dermatitis-like variant of mycosis fungoides also need to be excluded. Capillaritis has a benign course and therefore must be differentiated from these more serious diseases.

Usually there is no need for treatment unless the patient has pruritus or suffers from cosmetic disfigurement. Detection and avoidance of possible eliciting agents should always be attempted. Reported causes include:

- Drugs (14% in one series), for example, acetaminophen, acetylsalicylic acid, bromine-containing drugs, carbamazepine, furosemide, interferon- α , nonsteroidal antiinflammatory drugs (NSAIDs), raloxifene (selective estrogen receptor modulator), thiamine, or sildenafil.

As a rule, drug-induced capillaritis is more generalized and does not usually present with epidermal involvement or lichenoid infiltrate; its onset is around 10 days after intake of the suspected drug.

- Dietary supplements or ingredients; reported triggers include creatine or Coca-Cola and apple-cherry fruit spritzer, as well as ingredients of an energy drink (vitamin B complex, caffeine, taurine).
- Chronic infections such as viral hepatitis B or C (though relation is questionable) or odontogenic infections.

When the etiology remains obscure, therapy has to be empirical. However, immunohistochemical analyses have suggested a cell-mediated immune response, so treatment with *local corticosteroids*, *calcineurin inhibitors*, or *psoralen plus UVA* (PUVA) may be rational. Increased venous pressure (particularly in the legs) or exercise are not direct causes, but can aggravate capillaritis. In these cases compression stockings may be helpful.

There is some evidence for increased vascular permeability or vascular fragility due to subtle defects in the extracellular matrix. This may explain reported responses to *bioflavonoids* (which may be due to inhibition of elastase and hyaluronase and of leukocyte activation), *ascorbic acid* (antioxidant effects and perhaps reduction of vascular permeability), and *calcium dobesilate* (reduction of microvascular permeability in part by antioxidant properties).

Specific Investigations

- Careful drug history
- Look for signs of chronic infection or rheumatoid arthritis
- Exclude chronic venous insufficiency and purpuric contact

eczema (e.g., by modified patch test performed at the site of skin lesions to look after a petechial reaction to azo dyes, for example)

- Dermoscopy
- Hematology (complete blood count)
- C-reactive protein
- Immunoglobulins, protein electrophoresis
- Histology
- In granulomatous variant: triglycerides and cholesterol

Purpura simplex (inflammatory purpura without vasculitis): a clinicopathologic study of 174 cases

Ratnam KV, Su WP, Peters MS. J Am Acad Dermatol 1991; 25: 642–7.

A retrospective review of 174 cases. A correlation between purpuric reaction and drugs was observed in 14%. Of the 87 patients who were followed up, 67% appeared to eventually have clearing of lesions.

Pigmented purpuric dermatosis: clinicopathologic characterization in a pediatric series

Coulombe J, Jean SE, Hatami A, Powell J, Marcoux D, Kokta V, et al. Pediatr Dermatol 2015; 32: 358–62.

A retrospective chart review of 17 children. Pigmented purpuric dermatosis resolved in 13 cases with a median duration <1 year in 5 of them without treatment; those cases treated with topical corticosteroids improved in 75%, those with narrowband ultraviolet B in 100%. No associated disease or drug exposure was found.

Granulomatous pigmented purpuric dermatosis: report of a case with atypical clinical presentation including dermoscopic findings

MacKenzie AI, Biswas A. Am J Dermatopathol 2015; 37: 311–4.

Granulomatous pigmented purpuric dermatosis is rare and affects the distal extremities of mainly Far East Asian patients. There was an association with hyperlipidemia or other associated systemic derangements.

Progression of pigmented purpura-like eruptions to mycosis fungoides: report of three cases

Barnhill RL, Braverman IM. J Am Acad Dermatol 1988; 19: 25–31.

Initial eruptions, resembling pigmented purpuric dermatitis both

clinically and histologically, developed into histologically definite mycosis fungoides in follow-up period averaging 8.4 years.

Exclusion or diagnosis of mycosis fungoides may require repeated biopsies. In capillaritis small cerebriform lymphocytes exhibiting epidermotropism should be absent.

Drug-induced purpura simplex: clinical and histologic characteristics

Pang BK, Su D, Ratnam KV. Ann Acad Med Singapore 1993; 22: 870–2.

A prospective study of 183 patients with purpura simplex was carried out. Of these, 27 cases were confirmed to be drug induced, as the purpura cleared within 4 months of withdrawal of medications. NSAIDs, diuretics, meprobamate, and ampicillin were the most common offenders.

Acetaminophen-induced progressive pigmentary purpura (Schamberg's disease)

Abeck D, Gross GE, Kuwert C, Steinkraus V, Mensing H, Ring J. J Am Acad Dermatol 1992; 27: 123–4.

Pigmented purpura dermatosis and viral hepatitis: a case-control study

Ehsani AH, Ghodsi SZ, Nourmohammad-Pour P, Aghazadeh N, Damavandi MR. Australas J Dermatol 2013; 54: 225–7.

A prospective case-control study with 60 PPD patients and 230 randomly selected controls. The prevalence of HBS Ag in PPD patients and the controls was 3% and 4.3%, respectively, and the prevalence of HCV was 1.7% vs. 1.3%. Thus direct involvement of HBV or HCV in pathogenesis of PPD is not certain.

Chronic pigmented purpura associated with odontogenic infection

Satoh T, Yokozeki H, Nishioka K. J Am Acad Dermatol 2002; 46: 942–4.

Appearance of purpuric spots in five patients ceased after treatment for periodontitis, pulpitis, or both.

Capillaritis associated with interferon-alfa treatment of chronic hepatitis C infection

Gupta G, Holmes SC, Spence E, Mills PR. J Am Acad Dermatol 2000; 43: 937–8.

Pigmented purpuric dermatosis after taking a dietary supplement

Unal E, Ergül G. Cutan Ocul Toxicol 2015; 10: 1–3.

Dermoscopy of pigmented purpuric dermatoses (lichen aureus): a useful tool for clinical diagnosis

Zaballos P, Puig S, Malvehy J. Arch Dermatol 2004; 140: 1290–1.

Dermoscopy is a useful aid in diagnosis. In lichen aureus, in which the lichenoid tissue reaction is condensed, it shows coppery-red to brownish diffuse coloration of the background (likely caused by the dermal infiltrate and extravascular or intracellular hemosiderin), as well as a partial network of interconnected pigmented lines (hyperpigmentation of the basal layer and pigment released into the dermis); round to oval red dots, globules, or patches (these could reflect dilated vessels and extravasated erythrocytes); and gray dots (probably accumulation of hemosiderin-containing macrophages). It is likely that these criteria also apply for other forms of capillaritis with different accentuations.

Cutaneous symptoms of various vasculitides

Sunderkötter C, Pappelbaum KI, Ehrchen J. Hautarzt 2015; 66: 589–98.

Careful clinical examination allows the differentiation of capillaritis from small vessel vasculitis or similar conditions.

First-Line Therapies

• Oral bioflavonoids and ascorbic acid	C
• Local corticosteroids initially in cases of pruritus/eczematoid or itching purpura	D
• Narrowband UVB or PUVA	D
• Calcium dobesilate	D
• Compression stocking when aggravated by increased venous pressure	E

Early treatment with rutoside and ascorbic acid is highly effective for progressive pigmented purpuric dermatosis

Schober SM, Peitsch WK, Bonsmann G, Metze D, Thomas K, Goerge

T, et al. J Dtsch Dermatol Ges 2014; 12: 1112–9.

A retrospective review of 35 patients treated with 1000 mg ascorbic acid and 2 × 50 mg rutoside (a form of bioflavonoid, often available without a prescription). The mean treatment duration was 8.2 months. 71.4% of the participants experienced complete clearance and 20.0% an improvement of more than 50%; 9 (25.1%) relapsed after discontinuation, and in 7 treatment was successfully reinitiated. Only 3 participants reported mild adverse effects. Participants with shorter disease duration showed better and faster therapeutic success and lower risk of recurrence.

Treatment of progressive pigmented purpura with oral bioflavonoids and ascorbic acid: an open pilot study in 3 patients

Reinhold U, Seiter S, Ugurel S, Tilgen W. J Am Acad Dermatol 1999; 41: 207–8.

First report on this treatment; complete clearance of skin lesions after 4 weeks of treatment.

We recommend rutoside (50 mg twice a day) and ascorbic acid (500 mg twice daily) as our therapy of choice because it is efficacious, especially in early disease and because it has fewer potential side effects than UV light or topical corticosteroids.

Capillaritis: a manifestation of rheumatoid disease

Wilkinson SM, Smith AG, Davis M, Dawes PT. Clin Rheumatol 1993; 12: 53–6.

Seven cases of capillaritis were described in patients with rheumatoid arthritis. In the majority, the rash and itch resolved spontaneously with the use of a topical corticosteroid.

PUVA therapy in lichen aureus

Ling TC, Goulden V, Goodfield MJ. J Am Acad Dermatol 2001; 45: 145–6.

One case of lichen aureus that responded dramatically to photochemotherapy (PUVA).

Treatment of pigmented purpuric dermatoses with narrow-band UVB: a report of six cases

Fathy H, Abdelgaber S. J Eur Acad Dermatol Venereol 2011; 25: 603–6.

Successful treatment was achieved in all six patients after 24 to 28

treatments and maintenance of 9 treatments. Two patients who showed flare of their lesions were efficiently controlled with a further 14 treatments.

Calcium dobesilate (Cd) in pigmented purpuric dermatosis (PPD): a pilot evaluation

Agrawal SK, Gandhi V, Bhattacharya SN. J Dermatol 2004; 31: 98–103.

Nine male patients (seven with Schamberg disease and one each with lichenoid dermatosis of Gougerot and Blum and lichen aureus) were given calcium dobesilate 500 mg twice daily for 2 weeks initially, and then 500 mg once daily for 3 months. No new lesions occurred within 2 weeks, and itching ceased in all patients. The improvement of existing lesions 1 year after cessation of therapy was moderate in 11.11% and mild in 66.67% of cases; 22.22% did not show any improvement.

Second-Line Therapies

• Pentoxifylline	E
• Topical calcineurin inhibitors	E
• Advanced fluorescence technology (AFT) of broadband pulsed light	D

Successful treatment of Schamberg's disease with pentoxifylline

Kano Y, Hirayama K, Orihara M, Shiohara T. J Am Acad Dermatol 1997; 36: 827–30.

Three patients with Schamberg disease were treated with pentoxifylline 300 mg daily for 8 weeks. A significant response was observed within 2 to 3 weeks. One patient had recurrence after discontinuation, but promptly responded to resumption of therapy.

Resolution of lichen aureus in a 10-year-old child after topical pimecrolimus

Böhm M, Bonsmann G, Luger TA. Br J Dermatol 2004; 150: 519–20.

A 10-year-old boy with lichen aureus resistant to topical corticosteroids for 4 months. A significant improvement was observed within 3 weeks with pimecrolimus cream twice daily.

Unlike topical corticosteroids, topical immunomodulators do not cause

fragility of blood vessels, which is an advantage when treating this group of diseases thought to be caused by vascular fragility and permeability.

Treatment of Schamberg's disease with advanced fluorescence technology

Manolakos DA, Weiss J, Glick B, Weiss KD, Weiss E. J Drugs Dermatol 2012; 11: 528–9.

Favorable treatment of five patients with Schamberg disease using advanced fluorescence technology (AFT) pulsed light, a broadband pulsed light platform device used for nonablative treatment of photodamaged skin.

Third-Line Therapies

• Colchicine	E
• Cyclosporine	E
• Methotrexate	E

The authors would recommend neither cyclosporine A nor methotrexate because of the severity of possible adverse events or side effects and because of the benign nature of capillaritis.

Benefit of colchicine in the treatment of Schamberg's disease

Geller M. Ann Allergy Asthma Immunol 2000; 85: 246.

Purpura pigmentosa chronica successfully treated with oral cyclosporin A

Okada K, Ishikawa O, Miyachi Y. Br J Dermatol 1996; 134: 180–1.

Purpura annularis telangiectodes of Majocchi: case report and review of the literature

Hoesly FJ, Huerter CJ, Shehan JM. Int J Dermatol 2009; 48: 1129–33.
A solitary case report on the efficacy of methotrexate.

Cat scratch disease

Adam H. Wiener, Bryan A. Selkin, and George J. Murakawa

Cat scratch disease (CSD) is a benign, usually self-limited disease caused by *Bartonella henselae* (formerly *Rochalimaea henselae*), a gram-negative pleomorphic rod. The primary lesion consists of a 0.5- to 1-cm papule or pustule, which may undergo ulceration, and adjacent unilateral lymphadenopathy is the hallmark of the disease. Systemic symptoms and complications include low-grade fever, malaise, nonspecific exanthem, hepatosplenomegaly, lytic bone lesions, oculoglandular syndrome of Parinaud (granulomatous conjunctivitis and preauricular adenopathy), and encephalopathy.

Management Strategy

No clear guidelines for the treatment of CSD exist. As there is a paucity of data showing a clear benefit of antimicrobial therapy in the treatment of patients with mild to moderate CSD, these patients should be managed with *conservative, symptomatic treatment*. The lymphadenopathy associated with CSD is self-limited and resolves in 2 to 4 months; therefore most patients can be managed with *observation* until involution of the node.

For patients with systemic symptoms and/or complications, antibiotic therapy should be instituted. *Azithromycin* (500 mg on day 1, followed by 250 mg on days 2–5) is the only antibiotic that has been shown in a double-blind, placebo-controlled evaluation to be beneficial to immunocompetent patients with CSD. In a retrospective analysis of 202 patients with CSD who had been on at least 3 days of antimicrobial therapy, only four antibiotics (*rifampin*, *ciprofloxacin*, *gentamicin*, and *trimethoprim–sulfamethoxazole*) provided clinical benefit. Presumably, it is the paucity of organisms and the host inflammatory response that result in the poor efficacy of antibiotics.

In immunosuppressed patients, infection with the CSD bacillus can produce a spectrum of disease, from classic CSD to bacillary angiomatosis (BA), peliosis, or septicemia (see chapter on bacillary angiomatosis). Antimicrobial treatment for such patients is beneficial and clearly indicated. Lesions and symptoms respond rapidly to *erythromycin* 500 mg four times daily or *doxycycline* 100 mg twice daily. Other antimicrobials used to successfully treat BA in immunocompromised patients include *tetracycline*, *minocycline*, *azithromycin*, and *trimethoprim–sulfamethoxazole*. A Jarisch–Herxheimer reaction frequently occurs after the first dose. Patients with AIDS should be maintained on lifelong antimicrobial therapy.

Of note, *B. henselae* has rarely been isolated from patients with CSD; however, patients who are immunosuppressed may be culture positive. A single dose of oral antibiotics will rapidly sterilize blood and lesional cultures.

Specific Investigations

- Histopathology
- Culture
- Serology

- Polymerase chain reaction (PCR)–based techniques

The agent of bacillary angiomatosis

Relman DA, Loutit JS, Schmidt TM, Falkow S, Tompkins LS. N Engl J Med 1990; 323: 153–80.

PCR was used to amplify, clone, and sequence a portion of eubacterial *16S rRNA* gene directly from tissue infected with the presumed agent of BA. Subsequent analysis of this sequence and study of infected tissues from other patients suggested that BA is caused by a rickettsia-like organism closely related to *Rochalimaea quintana*.

***Bartonella*-associated infections**

Spach DH, Koehler JE. Infect Dis Clin North Am 1998; 12: 137–55.

Findings on lymph node biopsy specimens from immunocompetent patients with CSD depend on the stage of the infection. Early in the course, lymphoid hyperplasia and arteriolar proliferation are prominent. Subsequently, granulomas appear. Late in the disease, multiple stellate microabscesses are prominent. Warthin–Starry stains may show clumps of pleomorphic bacilli.

Evaluation of sensitivity, specificity and cross-reactivity in *Bartonella henselae* serology

Vermeulen MJ, Verbakel H, Notermans DW, Reimerink JH, Peeters MF. J Med Microbiol 2010; 59: 743–5.

The combined use of (Houston strain) IFA, IgM, and IgG improves sensitivity with significant reduction of specificity. As falsely diagnosing CSD can have a major impact for the patient, we believe that IgG results must be interpreted with caution.

Cat-scratch disease

Midani S, Ayoub EM, Anderson B. Adv Pediatr 1996; 43: 397–422.

PCR is a powerful tool for the detection of *B. henselae* but is not widely available. Using PCR, *B. henselae* can be detected in aspirates from lymph nodes or cutaneous lesions within 1 to 2 days. Currently, serologic and PCR-based analyses are considered definitive.

Detection by immunofluorescence assay of *Bartonella henselae* in lymph nodes from patients with cat scratch disease

Rolain JM, Gouriet F, Enea M, Aboud M, Raoult D. Clin Diagn Lab Immunol 2003; 10: 686–91.

Immunofluorescence detection in lymph node smears using a specific monoclonal antibody directed against *B. henselae* and a commercial serology assay (IFA) compared with PCR detection showed high specificity in diagnosis of *B. henselae*, especially when associated with histologic analysis and conventional bacterial culture.

The use of *Bartonella henselae*-specific age dependent IgG and IgM in diagnostic models to discriminate diseased from non-diseased in cat scratch disease serology

Herremans M, Vermeulen MJ, Van de Kasstele J, Bakker J, Schellekens JF, Koopmans MP. J Microbiol Methods 2007; 71: 107–13.

The use of diagnostic models using the combination of both the enzyme-linked immunosorbent assay (ELISA) IgM and the IgG results combined with a correcting age factor can be useful in serodiagnosis of CSD.

First-Line Therapy

• Observation only	C
--------------------	---

Bartonellosis

Murakawa GJ, Berger T. In: Freedberg IM, Eisen AZ, Wolff K, Austen KF, Goldsmith LA, Katz SI, et al, eds. Dermatology in General Medicine. 5th edn. New York: McGraw-Hill, 1999; 2249–56.

In the majority of patients with CSD, conservative management with careful observation over several months is sufficient. Spontaneous involution of lymphadenopathy should occur over 6 months.

Second-Line Therapy

• Azithromycin

A

Prospective randomized double blind placebo-controlled evaluation of azithromycin for treatment of cat-scratch disease

Bass JW, Freitas BC, Freitas AD, Sisler CL, Chan DS, Vincent JM, et al. *Pediatr Infect Dis J* 1998; 17: 447–52.

Seven of 14 azithromycin-treated patients (500 mg on day 1, followed by 250 mg on days 2–5) showed an 80% reduction in initial lymph node volume compared with 1 of 15 placebo-treated controls during the first 30 days of observation.

This is the only controlled clinical trial of an antibiotic for the therapy of CSD; the use of all other antibiotics is based on anecdotal reports.

Third-Line Therapies

• Erythromycin	C
• Doxycycline	C
• Rifampin	C
• Ciprofloxacin	C
• Gentamicin	C
• Trimethoprim–sulfamethoxazole	C
• Surgical intervention	C

Immunocompetent individuals

Antibiotic therapy for cat-scratch disease: clinical study of therapeutic outcome in 268 patients and a review of the literature

Margileth AM. *Pediatr Infect Dis J* 1992; 11: 474–8.

In 60 patients with CSD with systemic symptoms, one of four antibiotics was effective at least 72% of the time. Patients who received rifampin (10–20 mg/kg daily for 7–14 days), ciprofloxacin (20–30 mg/kg daily for 7–14 days), gentamicin (5 mg/kg daily intravenously in divided doses every 8 hours for at least 3 days), or trimethoprim–sulfamethoxazole (6–8 mg/kg of trimethoprim component two to three times daily for 7 days) had a shorter mean duration of posttreatment illness than those who received either no antibiotics or antibiotics thought to be ineffective.

Antimicrobial susceptibility of *Rochalimaea quintana*, *Rochalimaea vinsonii*, and the newly recognized *Rochalimaea henselae*

Maurin M, Raoult D. *J Antimicrob Chemother* 1993; 32: 587–94.

In vitro testing revealed β -lactam drugs to be ineffective, tetracyclines to be intermediate, and erythromycin and rifampin to be most effective against *Rochalimaea* spp.

Hepatosplenic cat-scratch disease in children: selected clinical features and treatment

Arisoy ES, Correa AG, Wagner ML, Kaplan SL. *Clin Infect Dis* 1999; 28: 78–84.

Sixteen children with hepatosplenic CSD treated with rifampin (15–20 mg/kg daily), either alone or in combination with gentamicin (7.5 mg/kg daily) or trimethoprim–sulfamethoxazole (10–12 mg/kg daily), showed clinical improvement within 1 to 5 days.

Successful treatment of cat-scratch disease with ciprofloxacin

Holley HP. *JAMA* 1991; 265: 1563–5.

Five patients treated with oral ciprofloxacin, 500 mg twice daily, had a dramatic improvement in symptoms within a few days, with no relapse during follow-up.

It should be noted that quinolones are not recommended for children or adolescents because of concerns about arthropathy. Moreover, in vitro studies show only intermediate efficacy for ciprofloxacin.

Cat-scratch disease of the head and neck in a pediatric

population: surgical indications and outcomes

Munson PD, Boyce TG, Salomao DR, Orvidas LJ. Otolaryngol Head Neck Surg 2008; 139: 358–63.

In children, failure of medical therapy in cases that presented as persistent lymphadenopathy often were accompanied by violaceous skin changes, extreme tenderness to palpation, and even chronic drainage. In this subgroup of patients the benefit of surgical intervention and concurrent tissue examination outweighed the risk.

Molecular epidemiology of *Bartonella* infections in patients with bacillary angiomatosis-peliosis

Koehler JE, Sanchez MA, Garrido CS, Whitfeld MJ, Chen FM, Berger TG, et al. N Engl J Med 1997; 337: 1876–83.

Treatment with macrolide antibiotics (e.g., erythromycin or clarithromycin) is protective for patients with *Bartonella* spp. infection.

Cat scratch disease, bacillary angiomatosis, and other infections due to *Rochalimaea*

Adal KA, Cockerell CJ, Petri WA. N Engl J Med 1994; 330: 1509–15.

For the treatment of BA, bacillary peliosis hepatitis, and *Rochalimaea* spp. bacteremic syndrome, erythromycin 500 mg four times daily is the drug of choice on the basis of an excellent clinical response in virtually all patients treated to date.

Cutaneous vascular lesions and disseminated cat-scratch disease in patients with the acquired immunodeficiency syndrome (AIDS) and AIDS-related complex

Koehler JE, LeBoit PE, Egbert BM, Berger GT. Ann Intern Med 1988; 109: 449–55.

Erythromycin (500 mg four times daily), rifampin, and doxycycline (100 mg twice daily) were effective in the treatment of angiomatous skin nodules in three patients with HIV infection.

Cellulite

Bruce E. Katz, Doris M. Hexsel, and Camile L. Hexsel

Cellulite consists of surface relief alterations resulting in depressions and raised areas and thus an irregular appearance, such as an orange peel, cottage cheese, or mattresslike appearance of the skin, located mainly on the thighs and buttocks but also on the arms, abdomen, legs, and other areas. Depressed lesions are due to the presence of fibrous septa that pull the skin surface down; raised areas result from the projection of underlying fat to the skin surface as shown on anatomic and imaging studies. Women are most frequently affected by this condition; this is due to the structure and anatomy of the subcutaneous septa compared with their structure in men. In addition, cellulite is aggravated by progressive skin laxity or

flaccidity, localized fat deposition, and obesity. Furthermore, other factors have been implicated in the pathogenesis of cellulite, such as hormonal, biochemical, inflammatory, and circulatory factors.

Subcision: a treatment for cellulite

Hexsel DM, Mazzuco R. Int J Dermatol 2000; 39: 539–44.

Based on clinical assessment of pre and post-treatment standardized photographs on 232 patients, subcision was shown to be efficacious in the treatment of high-grade cellulite. Targeted specifically for the treatment of major cellulite depressions on the skin surface of patients with cellulite through three action mechanisms: sectioning the connective tissue septa responsible for the depressions; provoking the formation of new connective tissue.

Management Strategy

Specific treatments:

- Subcision, which treats the subcutaneous septae that pulls the skin down and addresses specifically cellulite depressions
- Devices that target the dermis and thus improve flaccidity and projection of fat and devices that target localized fat
- Weight control to a normal body mass index (BMI)
- Oral treatment
- Topical treatment

The diagnosis is clinical. No imaging studies are required in clinical practice.

Specific Investigations

- Physical examination: patient in standing position with relaxed gluteus muscles. Determine morphologic characteristics of cellulite on each patient, which will help guide treatment option selection:
 - Presence and depth of cellulite depressions
 - Presence of localized fat and obesity
 - Presence of flaccidity and fat herniation
- Pretreatment and posttreatment photographs (relaxed gluteus muscles)
- Validated photonumeric scale: cellulite severity scale (CSS), for

objective assessment of cellulite before and after different treatments

- Preoperative investigations for subcision: prothrombin time (PT), partial thromboplastin time (PTT), and international normalization ratio (INR); history of coagulation disorders; use of medications that alter blood coagulation

A validated photonumeric cellulite severity scale

Hexsel DM, Dal'forno T, Hexsel CL. J Eur Acad Dermatol Venereol 2009; 23: 523–8.

A new photonumeric severity quantitative and qualitative scale was developed and validated; five key morphologic aspects of cellulite were identified for comparison. Each item was graded from 0 to 3, allowing final classification of cellulite as mild, moderate, and severe, according to the sum of the scores of the CSS.

Side-by-side comparison of areas with and without cellulite depressions using magnetic resonance imaging

Hexsel DM, Abreu M, Rodrigues TC, Soirefmann M, do Prado DZ, Gamboa MM. Dermatol Surg 2009; 35: 1471–7.

Thirty female patients with cellulite depressions on the buttocks had underlying fibrous septa, which were thicker, ramified, and perpendicular to the skin surface.

First-Line Therapies

• Subcision	B
• Laser, light sources, devices	B
• Radiofrequency devices	B

Magnetic resonance imaging of cellulite depressed lesions successfully treated by subcision

Hexsel D, Dal Forno T, Hexsel C, Schilling-Souza J, Napolini Bastos

F, Siega C. *Dermatol Surg* 2016; 42: 693–6.

The authors present a 7-month follow-up of cellulite-depressed lesions treated with subcision, showing a considerable reduction in the number and depth of the treated lesions, and thus an evident reduction in CSS grading in the two assessed patients (from severe to moderate). Using magnetic resonance imaging, the authors demonstrated that the subdermal portion of the septum underlying the treated lesion was absent after subcision. This finding suggests that subcision produces long-lasting anatomic alterations in the subcutaneous tissue and positive outcomes in depressed lesions of cellulite.

Treatment of cellulite using a 1440-nm pulsed laser with one-year follow-up

DiBernardo BE. *Aesthet Surg J* 2011; 31: 328–41.

Ten women with cellulite on their thighs received a single treatment with a 1440 nm pulsed laser delivered through a cannula. Mean skin thickness (as shown by ultrasound) and skin elasticity increased. Subjective physician evaluations indicated improvement in the appearance of cellulite.

Quantitative and qualitative evaluation of efficacy of a 1440 nm Nd:YAG laser with novel bi-directional optical fiber in the treatment of cellulite as measured by 3-dimensional surface imaging

Katz BE. *J Drugs Dermatol* 2013; 12: 1224–30.

Fifteen women with cellulite were treated with 1440 nm pulsed laser with side-firing fiber. There was improvement in cellulite in 68% of subjects on photographic evaluation by two independent observers, revealing good-to-excellent results by physician evaluation, and significant improvement in 65% of subjects assessed by three-dimensional surface imaging.

Multicenter pivotal study of vacuum-assisted precise tissue release for the treatment of cellulite

Kaminer MS, Coleman III WP, Weiss RA, Robinson DM, Coleman IV WP, Hornfeldt C. *Derm Surg* 2015; 41: 336–47.

Fifty-five women with moderate-to-severe cellulite underwent one treatment with a vacuum-assisted precise tissue release device. Assessments by subject photographs, cellulite severity scales, GAIS

(Global Aesthetic Improvement Scale), and subject satisfaction showed significant improvements lasting up to 1 year.

Reduction in thigh circumference and improvement in the appearance of cellulite with dual-wavelength, low-level laser energy and massage

Gold MH, Khatri KA, Hails K, Weiss RA, Fournier N. *J Cosmet Laser Ther* 2011; 13: 13–20.

In this controlled, open-label, multicenter study, 83 subjects with mild-to-moderate cellulite received eight treatments with a device comprising a low-level, dual-wavelength diode laser (650 nm and 915 nm, to target fat), combined with heat induction and mechanical massage by suction (Smoothshapes), in one leg, with the untreated contralateral thigh serving as a control. The maximum reduction in thigh circumference of the treated areas (–0.82 cm) occurred in the upper thigh at 1 month. There was subjective clinical improvement of the appearance of cellulite when comparing pretreatment and posttreatment photographs.

A single center, randomized, comparative, prospective clinical study to determine the efficacy of the VelaSmooth system versus the Triactive system for the treatment of cellulite

Nootheti PK, Magpantay A, Yosowitz G, Calderon S, Goldman MP. *Lasers Surg Med* 2006; 38: 908–12.

Twenty female patients were treated twice weekly for 6 weeks with randomization to VelaSmooth on one side and TriActive on the other side. VelaSmooth combines infrared light (680–1550 nm) with bipolar radiofrequency and mechanical massage by vacuum suction. TriActive has six diode lasers (808/810 nm) combined with mechanical massage, suction, and localized cooling. In both treatment groups, 25% of the patients had improvement in the appearance of cellulite, with average percentage improvement in roughness for the VelaSmooth versus TriActive of 7% and 25%, respectively. There was a perceived change grade of cellulite; 75% of subjects showed improvement in the VelaSmooth leg, whereas 55% of subjects showed improvement in the TriActive leg. There was no statistically significant difference ($p > 0.05$) in all variables between the two treatment arms.

Cellulite treatment using a novel combination radiofrequency, infrared light, and mechanical tissue manipulation device

Alster TS, Tanzi EL. *J Cosmet Laser Ther* 2005; 7: 81–5.

Twenty adult women with moderate bilateral thigh and buttock cellulite received eight biweekly treatments to a randomly selected side with a combined bipolar radiofrequency (RF), infrared (IR) light, and mechanical suction–based massage device (Velasmooth), applied at 20 W RF, 20 W IR (700–1500 nm) light, and 200 millibar vacuum (750 mm Hg negative pressure). Clinical improvement scores of photographs were made independently by two blinded physicians and averaged approximately 50% after the series of treatments. Circumferential thigh measurements were reduced by 0.84 cm on the treated side.

A prospective clinical study to evaluate the efficacy and safety of cellulite treatment using the combination of optical and RF energies for subcutaneous tissue heating

Sadick NS, Mulholland RS. *J Cosmet Laser Ther* 2004; 6: 187–90.

Thirty-five females with cellulite on the thighs and/or buttocks were treated with the VelaSmooth device with 8 to 16 treatments twice weekly. Based on physician assessment using pretreatment and posttreatment photographs, all patients showed some level of improvement in skin texture and cellulite. The mean decrease in thigh circumference was 0.8 inches.

The effectiveness of anticellulite treatment using tripolar radiofrequency monitored by classic and high-frequency ultrasound

Mlosek RK, Woźniak W, Malinowska S, Lewandowski M, Nowicki A. *J Eur Acad Dermatol Venereol* 2012; 26: 696–703.

In this randomized controlled study, 28 women with cellulite grade I to III underwent eight treatments with RF; 17 women were in the placebo group, in which the treatments were performed without emitting RF. The treatment began with 110 J/cm², increased by 10 to 20 J/cm² in subsequent procedures. Cellulite was reduced in 89.3% of the women who underwent RF treatment, based on the Nürnberger–Müller scale. In the placebo group, no statistically significant changes were observed.

A multicenter study of cellulite treatment with a variable emission radio frequency system

Van der Lugt C, Romero C, Ancona D, Al-Zarouni M, Perera J, Trelles

MA. Dermatol Ther 2009; 22: 74–84.

The buttocks of 50 patients were treated with bipolar RF technology (ThermaLipo) at 6 J/cm². Twelve weekly sessions were given for 12 minutes on each buttock, with the treatment end point of 42°C external skin temperature. Based on the photography at baseline and at the 2-month assessment, the blinded independent clinicians' objective assessment of the cellulite appearance demonstrated that results were apparent in 66% of patients.

Unipolar radiofrequency treatment to improve the appearance of cellulite

Alexiades-Armenakas M, Dover JS, Arndt KA. J Cosmet Laser Ther 2008; 10: 148–53.

In this randomized, blinded, split-design study, 10 individuals with clinically observable excess of subcutaneous fat and cellulite (grades II–IV) on the thighs received up to six unilateral treatments (number of treatments at the investigator's discretion and resulted in a mean of 4.22 and range of 3 to 6 treatments) at 2-week intervals with unipolar RF (Accent). The untreated side of the thigh served as control. The results were assessed by two blinded investigators by using photographs and the authors' cellulite grading scale. A novel quantitative four-point cellulite grading system was applied. All participants responded to treatment. The blinded evaluations of photographs using the cellulite grading scale demonstrated the following improvements in mean grading scores for the treated leg versus the control leg: 11.2% in dimple density, 10.7% in dimple distribution, 2.5% in dimple depth, and 8±2.8% mean score improvement.

Second-Line Therapies

• Topical retinol, caffeine, and ruscogenin	B
• Occluded topical caffeine with extracts of green tea, black pepper seed, citrus, ginger, and cinnamon	B
• Topical retinol	C
• Topical caffeine	B
• Topical phosphatidylcholine gel and light-emitting diode (LED)	C

A double-blind evaluation of the activity of an anticellulite

product containing retinol, caffeine, and ruscogenin by a combination of several noninvasive methods

Bertin C, Zunino H, Pittet JC, Beau P, Pineau P, Massonneau M, et al. J Cosmet Sci 2001; 52: 199–210.

A placebo-controlled, double-blind study ($n = 46$) evaluated a topical anticellulite product that combined *retinol* microcapsules, *caffeine*, *asiatic centella*, *L-carnitine*, *esculoside*, and *ruscogenin*. The product was more effective than placebo in reducing cellulite appearance: decrease of the “orange peel” effect and increase in cutaneous microcirculation.

A two-center, double blinded, randomized trial testing the tolerability and efficacy of a novel therapeutic agent for cellulite reduction

Rao J, Gold MH, Goldman MP. J Cosmet Dermatol 2005; 4: 93–102.

This placebo-controlled study ($n = 34$ women with moderate degree of cellulite) assessed a cream containing a combination of caffeine, green tea extract, black pepper seed extract, citrus extract, ginger root extract, cinnamon bark extract, and capsicum annum resin under occlusion with bioceramic-coated neoprene shorts. The average measured decrease in thigh circumference was 1.9 cm with active product versus 1.3 cm with placebo. Upon review of the prestudy and poststudy photographs, dermatologists noted greater improvement in the treated group in 68% of subjects.

Topical retinol improves cellulite

Kligman AM, Pagnoni A, Stoudmayer T. J Dermatol Treat 1999; 10: 119–25.

This placebo-controlled study ($n = 19$) demonstrated improvement in cellulite on the side treated with topical *retinol* 0.3% on the thighs for 6 months in 63.1% of the patients compared with the untreated side by clinical dermatologic evaluation.

Parallel placebo-controlled clinical study of a mixture of herbs sold as a remedy for cellulite

Lis-Balchin M. Phytother Res 1999; 13: 627–9.

This placebo-controlled clinical trial study showed lack of effect of the topical combination product Cellasene.

Evaluation of the effects of caffeine in the microcirculation and

edema on thighs and buttocks using the orthogonal polarization spectral imaging and clinical parameters

Lupi O, Semenovitch IJ, Treu C, Bottino D, Bouskela E. *J Cosmet Dermatol* 2007; 6: 102–7.

This controlled clinical study investigated 7% caffeine solution ($n = 134$). There was a reduction of 2.1 cm in the thigh circumference in >80% of women. No specific measurement of effect on the appearance of cellulite was assessed.

The effectiveness and safety of topical PhotoActiv phosphatidylcholine-based anticellulite gel and LED (red and near-infrared) light on grade II–III thigh cellulite: a randomized, double-blinded study

Sasaki GH, Oberg K, Tucker B, Gaston M. *J Cosmet Laser Ther* 2007; 9: 87–96.

In this placebo-controlled, double-blinded study, nine subjects with grade II–III thigh cellulite were randomly treated twice daily with a phosphatidylcholine-based anticellulite gel on one thigh. Twice weekly, each thigh was exposed for a 15-minute treatment with LED array (660 nm and 950 nm) for 24 treatments. At the end of 3 months, eight out of nine thighs treated with the combination were downgraded to a lower cellulite grade by clinical examination, digital photography, and pinch test assessment. At the 18-month evaluation period for the eight responsive thighs, five thighs had reverted back to their original cellulite grading.

Third-Line Treatments

Cellulite treatment: a myth or reality: a prospective randomized, controlled trial of two therapies, Endermologie and aminophylline cream

Collis N, Elliot LA, Sharpe C, Sharpe DT. *Plast Reconstr Surg* 1999; 104: 1110–4. Discussion 1115–7.

This randomized, controlled trial assessed the efficacy of aminophylline cream and Endermologie ($n = 52$). Neither of these two treatments was effective.

Cellulitis and erysipelas

Adrian H.M. Heagerty, and Natasha Harper

Cellulitis is strictly an acute, subacute, or chronic infection of the subcutaneous tissues, whereas erysipelas is an infection of the dermis and superficial subcutis. Infection of the more superficial layers gives rise to superficial edema and inflammation, with the consequent development of a palpable, often advancing, edge. In the literature, these infections, along with abscesses and wound infections with significant skin involvement, are now sometimes grouped together and referred to as *acute bacterial skin and skin-structure infection* (ABSSSI). The causative organism is usually regarded as *Streptococcus*,

though many organisms have been isolated, including *Staphylococcus*, *Haemophilus influenzae*, and more rarely, *Aeromonas hydrophilia* and *Pseudomonas aeruginosa*, as well as fungi and gram-negative rods. Fulminating and necrotic cellulitis and fasciitis may occur rarely, usually in relation to immunosuppression or atypical organisms. These are rare, but necrotizing fasciitis may have a mortality of up to 50%.

Management Strategy

The management of cellulitis and erysipelas should initially be directed to assessment of systemic features of sepsis, which may suggest that admission to hospital and/or intravenous antibiotics is required, trying to identify the organism responsible for the infection when indicated, and then directing appropriate antimicrobial therapy. Any underlying and predisposing condition should be identified and treated to prevent subsequent recurrence.

The distinction between purulent and nonpurulent cases is an important one as the therapeutic strategy is different. The cause of purulent cellulitis (where there is purulent discharge or pustules present) is much more likely to be *Staphylococcus*, and possibly methicillin-resistant *Staphylococcus aureus* (MRSA), whereas most cases of nonpurulent cellulitis will be caused by *Streptococcus*.

Clinical knowledge summaries provided by the National Institute for Health and Care Excellence suggest that the Eron Classification System should be used for the assessment of the patient with cellulitis, although this is more likely to be used in the primary care setting.

Eron Classification System

Class I — There are no signs of systemic toxicity and the person has no uncontrolled comorbidities.

Class II — The person is either systemically unwell or systemically well but with a comorbidity (e.g., peripheral arterial disease, chronic venous insufficiency, or morbid obesity), which may complicate or delay resolution of infection.

Class III — The person has significant systemic upset such as acute confusion, tachycardia, tachypnea, hypotension, or unstable

comorbidities that may interfere with a response to treatment, or a limb-threatening infection due to vascular compromise.

Class IV — The person has sepsis syndrome or a severe life-threatening infection such as necrotizing fasciitis.

Uncomplicated cellulitis and erysipelas may be managed without admission if the patient does not exhibit signs of systemic toxicity (i.e., Eron Classification I). In such cases *oral broad-spectrum antibiotics*, chosen to cover group A streptococci and staphylococci, may be sufficient. The drug of choice is *oral penicillin V* (*phenoxymethylpenicillin*) and/or *flucloxacillin* (especially when there is a suspicion of possible staphylococcal involvement). Many local antibiotics guidelines in the UK recommend *flucloxacillin* alone as the first-line treatment, as when given in high doses it is effective against *Streptococcus* as well as *Staphylococcus*. *Clarithromycin* is used if the patient has a known penicillin allergy. Some authorities have recommended the use of *clindamycin* rather than a macrolide because of apparent increased tissue penetration, but this may be associated with an increased incidence of *Clostridium difficile* superinfection. Further, although most group A β -hemolytic streptococci are sensitive to this, increasing numbers of MRSA are displaying resistance to clindamycin, and widespread use may exacerbate this resistance. The incidence of MRSA as the causative organism in ABSSSI is increasing, especially in the United States. It is therefore important to take a swab when the condition is purulent and to consider MRSA as a possible cause of treatment failure. Immunocompromised patients, those with signs of systemic toxicity, and otherwise debilitated patients (Eron Classification II–IV) should be treated with *intravenous antimicrobials*. First line is usually *penicillin G* (benzylpenicillin) and/or *flucloxacillin*, depending on local guidelines. A wide range of antibiotics may be used second line such as *ciprofloxacin*, *vancomycin*, *teicoplanin*, *imipenem/cilastatin*, *daptomycin*, *linezolid*, or even new agents such as *oritavancin*. Some patients may be safely treated on an outpatient basis (outpatient parenteral antimicrobial therapy). If there is evidence of head and neck disease or sinus infection, *amoxicillin combined with clavulanic acid* should be considered to cover *H. influenzae* infection.

Sites of entry for infection should be sought, such as excoriations in eczema or after trauma, and these should be treated. Perhaps the commonest condition that is not identified and treated is toe web tinea pedis, which provides a portal of entry for infection.

Lymphedema can be associated with recurrence of cellulitis and so should be treated effectively.

The use of long-term antibiotics for the prevention of recurrent cellulitis has produced some conflicting evidence, but the PATCH I and II trials concluded that antibiotic prophylaxis reduces cellulitis recurrence by nearly a third.

Specific Investigations

- Blood cultures—not routinely done in uncomplicated patients due to low yield
- Swabs of any purulent exudate, pustules, or wounds
- ASO titer/anti-DNase B
- Cultures of aspirates
- Skin scrapings for mycology

Blood cultures may be positive and significant in only about 10% to 25% of cases but should be taken if there is any evidence of systemic toxicity or if staphylococcal involvement is suspected. Swabs of wounds, pus, and broken skin may be helpful, but surface swabs of unbroken skin provide little or no useful information. If available, aspirate of bullae may yield positive cultures. Slightly better rates for isolation than those of needle aspirates have been achieved with punch skin biopsies.

If there is doubt regarding the presence of an abscess, ultrasound should be performed as this has therapeutic implications.

Rising titers of streptococcal antibodies (ASO titer and anti-DNase B) may be helpful but are more commonly of value retrospectively.

In the case of cellulitis or erysipelas of the lower leg, skin scrapings from toe webs should be taken for mycologic examination. Facial erysipelas should warrant sinus radiographs to exclude underlying sinusitis. Crepitus should prompt the clinician to the presence of either clostridia or non-spore-forming anaerobes, either alone or mixed with other bacteria such as *Pseudomonas*, *Escherichia coli*, or *Klebsiella* spp.

Cellulitis: a review

Raff AB, Kroshinsky D JAMA 2016; 316: 325–37.

A review article from 2016 advises that nonpurulent cellulitis without systemic toxicity should be treated with antistreptococcal

agents

Current and future trends in antibiotic therapy of acute bacterial skin and skin-structure infections

Russo A, Concia E, Cristini F, De Rosa FG, Esposito S, Menichetti F, et al. Clin Microbiol Infect 2016; 22 (Suppl 2): S27–36.

New terminology — ABSSSI. The new classification includes cellulitis, erysipelas, major skin abscesses, and wound infection with a considerable extension of skin involvement, clearly referring to a severe subset of skin infections.

Blood cultures in the evaluation of uncomplicated cellulitis

Bauer S, Aubert CE, Richli M, Chuard C. Eur J Intern Med 2016; 36: 50–6.

Blood cultures are no longer recommended in uncomplicated cellulitis due to poor yield.

Methicillin-resistant *S. aureus* infections among patients in the emergency department

Moran GJ, Krishnadasan A, Gorwitz RJ, Fosheim GE, McDougal LK, Carey RB, et al. N Engl J Med 2006; 355: 666–74.

A study of 422 patients in the United States who presented with purulent skin and soft tissue infections found that swabs showed 59% had MRSA, 17% had methicillin-sensitive *S. aureus*, and 2.9% had β -hemolytic *Streptococcus*. This demonstrates the importance of swabs in such cases.

Costs and consequences associated with misdiagnosed lower extremity cellulitis

Weng QY, Raff AB, Cohen JM, Gunasekera N, Okhovat JP, Vedak P, et al. JAMA Dermatol 2016. 2017; 153: 141–6.

Misdiagnosis of lower extremity cellulitis is common and may lead to unnecessary patient morbidity and considerable health care spending.

First-Line Therapies

• Penicillin G	B
• Penicillin G with flucloxacillin	B
• Penicillin V	B
• High-dose flucloxacillin	A
• Amoxicillin with clavulanic acid	B
• Ceftriaxone	A
• Roxithromycin	B

Interventions for cellulitis and erysipelas

Kilburn SA, Featherstone P, Higgins B, Brindle R. Cochrane Database Syst Rev. 2010; 16: CD004299.

A Cochrane review in 2010 could not recommend any particular antibiotic regimen for cellulitis and erysipelas due to the large variation in treatment regimens studied.

The course, costs and complications of oral versus intravenous penicillin therapy of erysipelas

Jorup-Ronstrum C, Britton S, Gavlevik A, Gunnarsson K, Redman AC. Infection 1984; 12: 390–4.

In this study of 60 patients there appeared to be no appreciable benefit from intravenous rather than oral therapy with penicillin for erysipelas, and so oral therapy is recommended if there are no associated complications with the infection.

Management and morbidity of cellulitis of the leg

Cox NH, Colver GB, Paterson WD. J R Soc Med 1998; 91: 634–7.

A case note review of 92 patients admitted for inpatient care for ascending cellulitis of the leg revealed a portal of entry, most commonly minor injury. The mean hospital stay was 10 days. Bacteriology was seldom helpful, but group G streptococci were the

most frequently identified pathogens. Benzylpenicillin was used in 43 cases (46%). The authors emphasize the need for benzylpenicillin, treatment of tinea pedis, and retrospective diagnosis of streptococcal infection by serology.

Skin concentrations of phenoxymethylpenicillin in patients with erysipelas

Sjoblom AC, Bruchfeld J, Eriksson B, Jorup-Rönström C, Karkk1n K, Malmborg AS, et al. *Infection* 1992; 20: 30–3.

Tissue and serum blood levels were measured in 45 patients with erysipelas after oral penicillin (phenoxymethylpenicillin); the minimal inhibitory concentrations were exceeded for streptococci isolated, supporting the role of oral therapy.

A randomized comparative study of once-daily ceftriaxone and 6-hourly flucloxacillin in the treatment of moderate to severe cellulitis. Clinical efficacy, safety and pharmacoeconomic implications

Vinen J, Hudson B, Chan B, Vinen J, Hudson B, Chan B, et al. *Clin Drug Invest* 1996; 12: 221–5.

A randomized comparative study in 58 patients with cellulitis; intravenous ceftriaxone cured 92%, but intravenous flucloxacillin cured only 64% after 4 to 6 days.

Roxithromycin versus penicillin in the treatment of erysipelas in adults: a comparative study

Bernard P, Plantin P, Roger H, Sassolas B, Villaret E, Legrain V, et al. *Br J Dermatol* 1992; 127: 155–9.

This prospective randomized multicenter trial compared oral roxithromycin with intravenous benzylpenicillin. Overall efficacy was similar.

Amoxicillin combined with clavulanic acid for the treatment of soft tissue infections in children

Fleischer GR, Wilmott CM, Capos JM. *Antimicrob Agents Chemother* 1983; 24: 679–81.

Amoxicillin with clavulanic acid was compared with cefaclor in children with impetigo and cellulitis due to staphylococci, streptococci, and *Haemophilus* spp. There was a 100% response to therapy with the combination, compared with 90% with the

cephalosporin; the incidence of relapse and reinfection and side effects was small but greater with the combination therapy.

Nurse-led management of uncomplicated cellulitis in the community: evaluation of a protocol incorporating intravenous ceftriaxone

Seaton RA, Bell E, Gourlay Y, Semple L. *J Antimicrob Chemother* 2005; 55: 764–7.

The safety and efficacy of a nurse-led outpatient parenteral antibiotic therapy service for cellulitis were examined in 114 patients and 230 historical controls. No alteration in outcomes, complications, or readmission rates was seen compared with the earlier physician-supervised outpatient treatment. Treatment duration was reduced from 4 to 3 days.

Prospective evaluation of the management of moderate to severe cellulitis with parenteral antibiotics at a pediatric day treatment centre

Gouin S, Chevalier I, Gautier M, Lamarre V. *Paediatr Child Health* 2008; 44: 214–8.

The clinical outcomes of 92 children receiving outpatient treatment in a day treatment center were examined prospectively; after a mean of 2.5 days of intravenous therapy, 73 patients (79.3%) were switched to oral agents and discharged from the day treatment center. There were no relapses in this group.

Oral flucloxacillin and phenoxymethylpenicillin versus flucloxacillin alone for the emergency department outpatient treatment of cellulitis: study protocol for a randomised controlled trial

Quirke M, Wakai A, Gilligan P, O'Sullivan R. *Trials* 2013; 14: 164.

There are no studies comparing oral flucloxacillin alone or in combination with phenoxymethylpenicillin for cellulitis, but a trial is planned in Ireland.

Second-Line Therapies

• Ciprofloxacin	B
• Teicoplanin	B
• Imipenem/cilastatin	B
• Linezolid	A
• Daptomycin	A
• Vancomycin	A
• Oritavancin	A

Comparative efficacy of antibiotics for the treatment of acute bacterial skin and skin structure infections (ABSSSI): a systematic review and network meta-analysis

Thom H, Thompson JC, Scott DA, Halfpenny N, Sulham K, Corey GR. *Curr Med Res Opin* 2015; 31: 1539–51.

This meta-analysis of 52 trials concluded that there is equivalence of clinical efficacy between vancomycin, daptomycin, linezolid, and the novel antimicrobial agent, oritavancin. However, they noted the heterogeneity of the available evidence and the need for further research.

Ciprofloxacin for soft tissue infections

Wood MJ, Logan MN. *J Antimicrob Chemother* 1986; 18: 159–64.

Twenty-one patients with cellulitis or other soft tissue infection were treated with oral ciprofloxacin; 19 were clinically cured or improved, and 1 was withdrawn from the study because of nausea

and vomiting. Nine of the original 18 bacterial isolates were eradicated, but the majority of failures were due to staphylococci and streptococci.

Teicoplanin in the treatment of skin and soft tissue infections

Turpin PJ, Taylor GP, Logan MN, Wood MJ. *J Antimicrob Chemother* 1988; 21: 117–22.

Twenty-four patients with cellulitis or other soft tissue infection were treated with once-daily teicoplanin, resulting in clinical cure or improvement without severe adverse reactions but with a rise in the plasma platelet count.

Twice daily intramuscular imipenem/cilastatin in the treatment of skin and soft tissue infections

Sexton DJ, Wlodaver CG, Tobey LE, Yangco BG, Graziani AL, MacGregor RR. *Chemotherapy* 1991; 37: 26–30.

Of 102 patients enrolled in this study with mild to moderately severe skin and soft tissue infections, 74 were evaluable, with 20 having cellulitis, 23 wound infections, and 31 abscesses.

Imipenem/cilastatin was given intramuscularly using doses of 500 or 750 mg 12-hourly. In this study there was no assessment by type of infection, but 82% were cured and 16% improved. Eight patients reported minor side effects.

Randomized comparison of linezolid (PNU-100766) versus oxacillin-dicloxacillin for treatment of complicated skin and soft tissue infections

Stevens DL, Smith LG, Bruss JB, McConnell-Martin MA, Duvall SE, Todd WM, et al. *Antimicrob Agents Chemother* 2000; 12: 3408–13.

Eight hundred twenty-six hospitalized adult patients were randomized to receive linezolid (600 mg intravenously) every 12 hours or oxacillin (2 g intravenously) every 6 hours; after sufficient clinical improvement, patients were switched to the respective oral agents (linezolid 600 mg orally every 12 hours or dicloxacillin 500 mg orally every 6 hours). The clinical cure rates were 88.6% and 85.8%, respectively.

Third-Line Therapies

• Prednisolone as an adjunct to antibiotics	A
• Granulocyte colony-stimulating factor	A
• Hyperbaric oxygen	E

Antibiotic and prednisolone therapy of erysipelas: a randomized, double blind, placebo-controlled study

Bergkvist PI, Sjöbeck K. Scand J Infect Dis 1997; 29: 377–82.

Although prednisolone may predispose to infection, its use in combination with intravenous antibiotics reduced the median time to cure by 1 day (5 vs. 6 days); at the 90th centile healing time was 10 days vs. 14.6 days, and median hospital stay was reduced from 6 to 5 days. The relapse rate within 3 weeks was approximately the same in both groups.

Randomized placebo controlled trial of granulocyte-colony stimulating factor in diabetic foot infection

Gough A, Clapperton M, Rolando N, Foster A, Philpott-Howard J, Edmonds ME. Lancet 1997; 350: 855–9.

This randomized controlled trial compared the ability of granulocyte-colony stimulating factor (G-CSF) to improve clinical outcome in the treatment of cellulitis in diabetes mellitus, using resolution as the end point. G-CSF stimulates the neutrophil response, which is impaired in diabetes mellitus but is important for defense against infection. The risk is principally that of high white cell counts, which may predispose to coronary and cerebral vascular events.

Cellulitis owing to *Aeromonas hydrophilia*: treatment with hyperbaric oxygen

Mathur MN, Patrick WG, Unsworth IP, Bennett FM. Aust NZ J Surg 1995; 65: 367–9.

This case report of *Aeromonas hydrophilia* cellulitis, unresponsive to antibiotics and surgical debridement, responded to hyperbaric oxygen therapy. Although there are few objective reports of similar treatment in streptococcal necrotizing fasciitis, it has been suggested that in all types of necrotizing fasciitis hyperbaric oxygen reduces mortality.

Prophylaxis

• Low-dose oral penicillin	A
• Intramuscular weekly penicillin	C
• Treatment of predisposing factors	E

Prophylactic antibiotics in erysipelas

Duvanel T, Merot Y, Saurat JH. Lancet 1985; 1: 1401.

Sixteen patients who received weekly intramuscular penicillin as prophylaxis were followed and assessed at 2 years. On cessation of prophylaxis the risk of recurrence rapidly returned to the nontreatment/no prophylaxis level.

Cellulitis and erysipelas

Morris A. Clin Evid 2004; 12: 2268–74.

Although there is a consensus that successful treatment of predisposing factors such as leg edema, tinea pedis, and traumatic wounds reduces the risk of developing cellulitis, there are no randomized controlled trials or observational studies to support this.

Prophylactic antibiotics for the prevention of cellulitis (erysipelas) of the leg: results of the UK Dermatology Clinical Trials Network's PATCH II trial

UK Dermatology Clinical Trials Network's PATCH Trial Team. Br J Dermatol 2012; 166: 169–78.

A double-blind, randomized controlled trial examining whether prophylactic antibiotics prescribed after an episode of cellulitis of the leg can prevent further episodes. A total of 123 patients were recruited and randomized between low-dose oral phenoxymethyl penicillin and placebo for 6 months. Recurrence rates were 20% on penicillin vs. 33% on placebo ($p = 0.08$).

Prophylactic antibiotics to prevent cellulitis of the leg: economic analysis of the PATCH I & II trials

Mason JM, Thomas KS, Crook AM, Foster KA, Chalmers JR, Nunn AJ, et al. PLoS One 2014; 9: e82694.

Economic analysis of the PATCH trials concluded that after a first episode or recurrent cellulitis of the leg, prophylactic low-dose penicillin is a low-cost intervention that is medically effective and cost effective at preventing subsequent attacks.

Antibiotic prophylaxis for preventing recurrent cellulitis: a systematic review and meta-analysis

Oh CC, Ko HC, Lee HY, Safdar N, Maki DG, Chlebicki MP. J Infect 2014; 69: 26.

This meta-analysis concluded that antibiotic prophylaxis can prevent recurrent cellulitis but that further research is needed to establish indication, choice of drug, and dosage regimens.

Chancroid

Iris A. Hagans, and Glenn C. Newell

Chancroid is a genital ulcer disease caused by the gram-negative facultative anaerobic coccobacillus *Haemophilus ducreyi*. It is common in many parts of the world, including Africa, the Caribbean basin, and Southwest Asia. The incidence is decreasing worldwide; however, outbreaks in developed countries can be seen after travelers return from high-risk areas after having unprotected sex. Chancroid is typically a painful, ragged, deep genital ulcer 3 to 20 mm in diameter

without induration. There may be surrounding erythema, and the base is often covered with a yellow-gray exudate. The lesion may be single, but can be multiple as a result of autoinoculation (kissing lesions), and non-genital lesions have been noted. Painful lymphadenitis occurs in 30% to 60% of patients, and approximately one quarter of patients with lymphadenopathy may develop a suppurative bubo. Of note, uncircumcised men may have a higher risk of infection and may take longer to cure.

Diagnosis and Management Strategy

Diagnosis on clinical criteria alone is difficult. The painful ulcer of chancroid can easily be confused with genital herpes or secondarily infected syphilis. A presumptive diagnosis of chancroid can be made with one or more painful genital ulcers, with or without a bubo, with negative laboratory tests for herpes simplex virus (HSV) and syphilis. Coinfection with either of these diseases occurs in as many as 10% of patients.

A definitive diagnosis may be made by culturing the exudates from the ulcer base or by aspiration of a bubo. Gram stain of the ulcer base in chancroid may show gram-negative coccobacilli in a “school of fish” appearance. Special culture media should be used, and the specimen should be handled by laboratories familiar with *H. ducreyi*. It should be noted that sensitivity of culture as shown by DNA amplification techniques can be as low as 75%. The newer nucleic acid amplification tests (NAATs) show higher positivity rates than culture and do not depend on live bacteria, making the test especially useful. However, only few laboratories have established NAATs for the diagnosis of chancroid. Polymerase chain reaction testing has the advantage of simultaneous testing of *H. ducreyi* along with *T. pallidum* and HSV.

Concurrent HIV infection can alter the manifestations of chancroid. HIV prolongs the incubation period of *H. ducreyi* and can increase the number of genital ulcers. With HIV coinfection, ulcers tend to heal poorly and non-genital ulcers are frequently found. Recent research shows that this may be more strongly correlated with coinfection with HSV rather than HIV. Treatment guidelines for patients coinfecting with HIV are the same as for those without HIV, but closer follow-up and a potentially longer course of therapy may be recommended, as there are increased treatment failures with HIV coinfection.

Additionally, chancroid has been noted to increase the susceptibility to HIV, probably by disrupting mucosal integrity. Patients should be tested for HIV at the time of chancroid diagnosis and should be retested for HIV 3 months after the diagnosis of chancroid if initial testing was negative.

A recent study found that many skin lesions diagnosed as yaws were instead *Haemophilus ducreyi* infections. These lesions are often not sexually transmitted and can be found in children as well as adults (see later under Special Considerations).

Specific Investigations

- Gram stain of ulcer base or bubo aspirate
- Culture of ulcer base or bubo aspirate
- NAATs
- Syphilis serology
- HIV serology

First-Line Therapies

• Azithromycin 1 g orally (one dose)	A
• Ceftriaxone 250 mg intramuscularly (one dose)	A

European guideline for the management of chancroid

Kemp M, Christensen JJ, Lautenschlager S, Vall-Mayans M, Moi H. Int J STD AIDS 2011; 22: 241–4.

A comprehensive review of chancroid diagnosis and management. The authors cite an unblinded prospective study that found that ceftriaxone versus azithromycin in doses noted earlier were equally efficacious.

UK National Guideline for the management of chancroid

O'Farrell N, Lazaro N. Int J STD AIDS 2014; 25: 975–83.

Thorough guidelines confirming prior management choices are presented as well as an epidemiology update. The prevalence of

chancroid, even in endemic countries, is decreasing, and HSV is now the most common cause of ulcerative genital lesions worldwide.

Second-Line Therapies

• Ciprofloxacin 500 mg twice a day for 3 days	B
• Erythromycin 500 mg orally four times a day for 7 days	B
• Granulated thiamphenicol 5.0 g orally (one dose)	B

A randomized, double-blind, placebo-controlled trial of single dose ciprofloxacin versus erythromycin for the treatment of chancroid in Nairobi, Kenya

Malonza IM, Tyndall MW, Ndinya-Achola JO, Maclean I, Omar S, MacDonald KS, et al. J Infect Dis 1999; 180: 1886–93.

This clinical trial compared single-dose therapy with ciprofloxacin to a 7-day course of erythromycin for the treatment of chancroid. Cure rates of 92% and 91% were reported with ciprofloxacin and erythromycin, respectively, for the 111 participants with chancroid. Failure rates were attributed to ulcer etiologies of HSV or syphilis.

A comparative study of a single-dose treatment of chancroid using thiamphenicol versus azithromycin

Junior WB, Di Chiacchio NG, Di Chiacchio N, Romiti R, Criado PR, Velho PE, Braz J. Infect Dis 2009; 13: 218–20.

For 54 patients with chancroid, cure rates with single-dose treatment were 73% with azithromycin and 89% with thiamphenicol. HIV seropositivity was found to be associated with treatment failure ($p=0.001$). The treatment failed in all HIV-positive patients treated with azithromycin ($p=0.002$), and this drug should be avoided in these coinfecting patients. In the view of the authors, thiamphenicol is the most indicated single-dose regimen for chancroid treatment.

Special considerations: Evacuation of buboes and unusual manifestations

Incision and drainage versus aspiration of fluctuant buboes in the emergency department during an epidemic of chancroid

Ernst AA, Marvez-Valls E, Martin DH. Sex Transms Dis 1995; 22: 217–20.

Evacuation of buboes has historically been recommended to prevent fistula formation, and needle aspiration was previously the procedure of choice. This study compared incision and drainage with packing to needle aspiration of suppurative buboes during an epidemic in Louisiana. No difference in cure rate was seen; however, aspirated buboes required reaspiration in 6/15 patients. As such, the authors recommended considering incision and drainage as an alternative to needle aspiration.

***Haemophilus ducreyi*: from sexually transmitted infection to skin ulcer pathogen**

Lewis DA, Mitjà O. Curr Opin Infect Dis 2016; 29: 52–7.

The authors of this review discuss recent investigations discerning yaws from chancroid as the culprit for chronic skin ulceration in endemic countries. They suggest that chancroid be considered in the evaluation of chronic limb ulceration.

Chilblains

Antonios Kanelleas, and John Berth-Jones

Chilblains (also called *perniosis*) are localized, inflammatory, erythematous lesions that are caused by exposure to cold ambient temperatures above freezing point. High humidity and wind, which exacerbate conductive heat loss, also play a significant part. They are thought to be caused by a persistent vasoconstriction of the deep cutaneous arterioles with accompanying dilatation of the small superficial vessels. The onset is usually in the autumn or winter. Chilblains are more common in temperate climates, when winters get rather cold and damp and people are not used to these conditions. Lesions occur acutely as single or multiple erythematous or dusky

swellings that may occasionally ulcerate or blister. They are usually accompanied by pruritus or a burning sensation. Sites of predilection are the fingers, toes, heels, lower legs, thighs, nose, and ears. A specific subset occurs on the thighs of patients wearing tight-fitting, poorly insulating trousers (e.g., as worn by young horsewomen). Perniosis can also be a manifestation of eating disorders (anorexia nervosa, poor nutrition) and systemic diseases (lupus erythematosus and hematologic malignancies).

Management Strategy

Appropriate investigation to exclude myeloproliferative disorders, connective tissue diseases, and eating disorders is sometimes required. Particularly in children, chilblains have been linked with cold-sensitive dysproteinemia. In elderly patients and those with ulcerative lesions, peripheral vascular insufficiency must be excluded. The condition must be distinguished from chilblain lupus erythematosus (LE). The latter is a form of cutaneous LE manifesting with lesions resembling chilblains. Lesions develop in cold weather but tend to persist and ulcerate. Chilblain LE may be accompanied by discoid LE. Up to 20% of patients with chilblain LE will develop systemic LE.

For cold-induced perniosis with no underlying pathology, the most important aspect of management is *prophylaxis*. This will be achieved through the use of *warm clothing and warm, properly insulated housing*. Avoidance of exposure in cold weather is, obviously, equally important. Once chilblains occur, they usually run a self-limiting course over a period of a few weeks. Treatment includes *rest in a warm environment and possibly topical antipruritics*, if needed. *Vasodilator calcium channel blockers* (nifedipine 20–60 mg daily, diltiazem 60–120 mg three times daily) have been shown to be an effective therapy and preventative measure in patients with idiopathic acral perniosis and in those patients with perniosis associated with low body weight. *Pentoxifylline* provides a safe alternative approach. A range of topical vasodilators and other treatments have been deployed with a largely anecdotal evidence base.

Specific Investigations

Investigation is not routinely required in typical cases, but consider:

- Full blood count
- Autoimmune profile
- Cryoglobulins
- Cold agglutinins
- Cryofibrinogen
- Vascular assessment in elderly patients
- Histology and immunofluorescence

Chilblain lupus erythematosus – a review of literature

Hedrich CM, Fiebig B, Hauck FH, Sallmann S, Hahn G, Pfeiffer C, et al. Clin Rheumatol 2008; 27: 949–54.

This article reviews the clinical presentation, pathogenesis, diagnosis, and management of chilblain lupus erythematosus.

Pernio. A possible association with chronic myelomonocytic leukaemia

Kelly JW, Dowling JP. Arch Dermatol 1985; 121: 1048–52.

A series of four elderly men has been described in whom perniosis preceded the onset of chronic myelomonocytic leukemia.

Anorexia nervosa associated with acromegaloid features, onset of acrocyanosis and Raynaud's phenomenon and worsening of chilblains

Rustin MH, Foreman JC, Dowd PM. J Roy Soc Med 1990; 83: 495–6.

Two patients are reported who developed severe perniosis in association with anorexia nervosa.

Perniosis in association with anorexia nervosa

White KP, Rothe MJ, Milanese A, Grant-Kels JM. Paediatr Dermatol 1994; 11: 1–5.

Celiac disease presenting with chilblains in an adolescent girl

St Clair NE, Kim CC, Semrin G, Woodward AL, Liang MG, Glickman JN, et al. Pediatr Dermatol 2006; 23: 451–4.

This is a case report of an adolescent girl in whom chilblains were the main presenting sign of celiac disease. A gluten-free diet resulted in both weight gain and resolution of chilblains.

Childhood pernio and cryoproteins

Weston WL, Morelli JG. *Pediatr Dermatol* 2000; 17: 97–9.

A 10-year retrospective study of a pediatric clinic identified eight patients with perniosis, four of whom had cryoglobulins or cold agglutinins and two had positive rheumatoid factor.

First-Line Therapies

• Conservative management	C
• Avoidance of further cold injury	E
• Calcium channel blockers	C
• Topical corticosteroids	E

Clinical characteristics, etiologic associations, laboratory findings, treatment, and proposal of diagnostic criteria of pernio (chilblains) in a series of 104 patients at Mayo Clinic, 2000 to 2011

Cappel JA, Wetter DA. *Mayo Clin Proc* 2014; 89: 207–15.

Conservative treatments (e.g., warming, drying, and smoking cessation) provided complete response in 23 (82%) of the 28 patients for whom follow-up data were available.

The treatment of chilblains with nifedipine: the results of a pilot study, a double blind placebo-controlled randomized study and a long term open trial

Rustin MH, Newton JA, Smith NP, Dowd PM. *Br J Dermatol* 1989; 120: 267–75.

Ten patients with severe recurrent acral perniosis were treated with 20 mg of nifedipine retard or placebo in a double-blind crossover trial for 12 weeks total. No patients developed new lesions while on treatment, and 70% were clear after a mean of 8 days. In the open study, 34 patients received up to 60 mg of nifedipine retard for 2 months; this was shown to be effective in reducing the healing time

and symptoms of lesions.

Diltiazem vs. nifedipine in chilblains: a clinical trial

Patra AK, Das AL, Ramadasan P. Indian J Dermatol Venereol Leprol 2003; 69: 209–11.

The authors compared two groups of patients with chilblains. Group A (12 patients) was treated with diltiazem 60 mg three times daily and group B (24 patients) with nifedipine 10 mg three times daily until complete relief and then 20 mg twice daily for maintenance. They concluded that nifedipine has greater efficacy than diltiazem (80%–90% of patients from group B showed relief by the fourteenth day of treatment).

Corticosteroid therapy for pernio

Gaynor S. J Am Acad Dermatol 1983; 8: 13.

This author reports successful treatment of patients with perniosis using topical corticosteroids (0.025% fluocinolone cream) under occlusion nightly.

Topical corticosteroids are frequently used for the treatment of chilblains, but their use is not based on controlled trials.

Second-Line Therapies

• Topical nitroglycerine	C
• Pentoxifylline	A
• Topical 2% hexyl nicotinate cream	E
• Minoxidil 5% lotion	E
• Acidified nitrate cream	E
• Tamoxifen	E

Topical nitroglycerine in perniosis/chilblains

Verma P. *Skinmed* 2015; 13: 176–7.

An uncontrolled study on 0.2% nitroglycerine ointment. Eighteen of 22 patients had regression of lesions within a week.

Treatment of primary perniosis with oral pentoxifylline (a double-blind placebo-controlled randomized therapeutic trial)

Al-Sudany NK.

Dermatol Ther 2016; 29: 263–8.

Pentoxifylline 400 mg three times daily for 3 weeks proved superior to placebo in a double-blind trial undertaken in Iraq.

Chilblains

Dowd PM, Blackwell V. In: Lebwohl M, Heymann W, Berth-Jones J, Coulson I, eds. *Treatment of Skin Disease: Comprehensive Therapeutic Strategies*, 2nd edn. Chicago: Mosby, 2006; 39–40.

These authors reported use of 2% hexyl nicotinate in aqueous cream preparation and minoxidil 5% lotion applied three times a day in patients with chilblains and Raynaud phenomenon and acidified nitrite cream (3% salicylic acid and 3% potassium nitrate) three times daily in patients with chilblains intolerant of calcium channel blockers. Low-dose (5 mg daily) tamoxifen proved useful in anorexia-associated perniosis.

Third-Line Therapies

• Salbutamol sulfate ointment	E
• Nonsteroidal antiinflammatory drugs	E
• Prednisolone	E
• Hydroxychloroquine	E
• Intense pulsed light	E

Anon:

<http://www.drdo.gov.in/drdo/labs/INMAS/collaboration/brochure.h>
Accessed 5/4/16

The use of 0.5% salbutamol sulfate ointment has been proposed by the Defence Research and Development Organization (DRDO) of India for the prevention of cold injuries after pilot studies on soldiers and workers residing in high altitudes.

Treatment of perniosis with oral pentoxifylline in comparison with oral prednisolone plus topical clobetasol ointment in Iraqi patients

Noaimi AA, Fadheel BM. Saudi Med J 2008; 29: 1762–4.

Forty patients with chilblains were randomly divided into two equal groups. Group A received oral prednisolone 0.5 mg/kg/day in two doses and topical clobetasol ointment for 2 weeks. Patients in group B received pentoxifylline tablets 400 mg three times daily for 2 weeks. In group B, 5 of 9 patients (55.5%) who completed the study showed a significant improvement, compared with 3 of 11 patients (27.2%) in group A.

Major cluster of chilblain cases in a cold dry Western Australian winter

Larkins N, Murray KJ. J Paediatr Child Health 2013; 49: 144–7.

Thirty-two patients with perniosis are described. Most received some form of treatment including nonsteroidal antiinflammatory drugs, prednisolone, or nifedipine, but most improved spontaneously with warmer weather or responded to cold protection advice.

Successful treatment of perniosis with hydroxychloroquine

Yang X, Perez OA, English JC 3rd. J Drugs Dermatol 2010; 9: 1242–6.

In this retrospective study hydroxychloroquine improved symptoms in four out of five patients with perniosis.

Pernio of the hips in young girls wearing tight-fitting jeans with a low waistband

Weismann K, Grønhøj Larsen F. Acta Dermatol Venereol 2006; 86: 558–9.

Two adolescent girls from Denmark developed chilblains on their right hips. This was attributed to exposure to cold associated with wearing tight-fitting jeans with a low waistband that left uncovered the upper part of the hip region. Both were treated with intense

pulsed light (555–950 nm), 14 J/cm². After three monthly treatments, the redness was reduced.

Chondrodermatitis nodularis helcis chronicus

Clifford Lawrence

Chondrodermatitis is a benign condition; the chief indication for treatment is pain causing sleep disturbance. Painless areas of chondrodermatitis can be ignored or managed conservatively. Lesions on the helix are easier to treat surgically than antihelix lesions

and are easier to cure. A pressure-relieving cushion is a good first-choice alternative to surgery for antihelix lesions.

Management Strategy

Chondrodermatitis usually occurs on the lateral portion of the ear on the preferred sleeping side. It is generally caused by the weight of the head crushing the ear against the pillow during sleep. Ear injury or surgery may leave an irregular cartilage edge that becomes a focus for sleep-related pressure. The most protuberant part of the ear is affected; generally this is the helix in men and the antihelix in women. People who can only adopt one sleeping position due to arthritis, etc., are particularly vulnerable. The incidence increases with age because ear cartilage becomes less flexible with time. Patients should be reassured that it is not skin cancer, advised to use a soft pillow that is still compressible when the head is resting on it, and to change their sleeping position. Conservative or medical treatment, such as *lidocaine (lignocaine)* gel, a potent *topical corticosteroid*, *self-adhesive foam dressing*, or a *pressure-relieving cushion* can be tried in all patients. If sleep is not disturbed, there is really no need for any further intervention unless cosmesis is a concern.

Numerous surgical strategies have been described to treat chondrodermatitis, and most work to some degree; it is tempting to suggest that some techniques make the ear so painful that the subject is forced to adapt his or her sleeping position until the lesion resolves spontaneously. Most authors believe that the principle of surgical treatment is *excision* of the affected area of cartilage without the need for skin or ulcer excision. Other destructive therapies have been advocated but tend to be less effective. Antihelix lesions respond so well to cartilage excision that many recommend surgery as a first-line treatment.

Specific Investigations

- None required.
- Biopsy is only necessary if surgery is indicated or there is doubt about the diagnosis. Lesions managed conservatively do not require biopsy

First-Line Therapies

• Reassurance that chondrodermatitis is not a cancer	B
• Conservative management	B
• Topical corticosteroids	B
• Intralesional corticosteroids	B
• 0.2% topical nitroglycerin	C

Treatment of chondrodermatitis nodularis helicis and conventional wisdom?

Beck MH. Br J Dermatol 1985; 113: 504–5.

Topical corticosteroids (betamethasone valerate cream 0.025%) used twice a day for 6 weeks and intralesional triamcinolone (0.2–0.5 mL or 10 mg/mL) are effective will improve symptoms and aid healing in almost 25% of patients.

Intralesional triamcinolone for chondrodermatitis nodularis: a follow-up study of 60 patients

Cox NH, Denham PF. Br J Dermatol 2002; 146: 712–3.

A retrospective analysis of 60 patients with chondrodermatitis nodularis helicis (CNH) treated with 0.1 mL intralesional triamcinolone acetonide 10 mg/mL or triamcinolone hexacetonide 5 mg/mL showed good response on 43% of helix and 31% of antihelix lesions.

The usefulness of 0.2% topical nitroglycerin for chondrodermatitis nodularis helicis.

Sanz-Motilva V, Martorell-Calatayud A, Gutiérrez García-Rodrigo C, Hueso-Gabriel L, Garcia-Melgares ML, Pelufo-Enguix C, et al. Actas Dermosifiliogr 2015; 106: 555–61.

Ninety-three percent of 29 patients treated showed clinical improvement with a mean follow-up of 5.9 months. There were fewer side effects using the 0.2% preparation compared with the original 2% ointment.

Reassurance that this is not a tumor puts the patient's mind at rest. In many instances the symptoms are mild and can be tolerated without any major intervention. Initially, conservative therapy should be tried. Recommend a 6-week course of a potent topical steroid with a change in sleeping position and a soft pillow that can still be further compressed when the head is resting on it.

Second-Line Therapies

• Helix lesions – excision of cartilage without skin excision	B
• Antihelix lesions – pressure-relieving cushion or device	B

The treatment of chondrodermatitis nodularis with cartilage removal alone

Lawrence CM. Arch Dermatol 1991; 127: 530–5.

Cartilage excision without skin removal resulted in cure rates of 84% for helix and 75% for antihelix lesions. Local anesthesia with lidocaine and epinephrine (adrenaline) reduced bleeding and improved the visibility without ear skin necrosis. On the helix, the skin was reflected back from a helix rim incision to expose the cartilage. On the antihelix, a medially based skin flap was raised to expose cartilage. After exposed cartilage excision, all remaining cartilage edges were left smooth and gently shelving up to the uninvolved cartilage to prevent recurrences that may develop on rough or protuberant cartilage edges. Cartilage excision alone is not disfiguring, and further cartilage edges can be removed if recurrences occur.

Treatment of chondrodermatitis nodularis with removal of the underlying cartilage alone: retrospective analysis of experience in 37 lesions

de Ru JA, Lohuis PJ, Saleh HA, Vuyk HD. J Laryngol Otol 2002; 116: 677–81.

Most otolaryngologists treat patients with chondrodermatitis nodularis by wedge excision. This can leave the patient with an asymmetric deformed ear. The authors described their results after changing to removal of cartilage alone. In a mean follow-up of 30

months, all 34 patients remained symptom free, and only 1 required revisional surgery.

Twelve years' experience of simplified surgical treatment of chondrodermatitis nodularis by cartilage trimming and sutureless skin closure.

Hussain W, Chalmers RJ. Br J Dermatol 2009; 160: 116–8.

After skin incision, mosquito forceps were used to “nibble” away fragments of cartilage to leave a smooth cartilage contour without the need for full exposure of the cartilage edge. Skin nodules or ulcers are not excised but are left to resolve spontaneously. Tape strips were used for skin closure. Thirty-two of 34 (94%) patients with chondrodermatitis, 7 on the antihelix and 27 on the helix, showed no discomfort or clinical recurrence 4 months after this procedure.

Chondrodermatitis nodularis chronica helicis et antihelicis

Munnoch DA, Herbert KJ, Morris AM. Br J Plast Surg 1996; 49: 473–6.

Fifty-four chondrodermatitis lesions (36 helix, 18 antihelix), including 23 recurrent after previous surgery, were treated by minimal skin excision combined with extensive cartilage resection. There were no recurrences and minimal postoperative deformity.

Narrow elliptical skin excision and cartilage shaving for chondrodermatitis nodularis.

Rex J, Ribera M, Bielsa I, Mangas C, Xifra A, Ferrándiz C. Dermatol Surg 2006; 32: 400–4.

A narrow elliptical excision of the papule followed by a slice of the underlying cartilage was taken and trimmed carefully to remove any cartilage spikes. Good cosmetic results were obtained in all 74 patients retrospectively analyzed. The recurrence rate ranged from 10% for helical and 37% for antihelical lesions after a median follow-up of 54 and 50 months, respectively.

Modified surgical excision for the treatment of chondrodermatitis nodularis

Ormond P, Collins P. Dermatol Surg 2004; 30(2 Pt 1): 208–10.

Excision of the cartilage alone is therapeutically and cosmetically effective. To simplify the surgical procedure, a narrow ellipse of skin over the nodule was excised and cold steel dissection of the adjacent skin replaced by hydrodissection to create a plane of cleavage

between the skin and cartilage. These two refinements maintained the clinical and cosmetic efficacy and simplified the surgical technique.

All of these techniques are based on removal of damaged cartilage and avoidance of leaving irregular cartilage margins, as these may act as a focus for recurrence. Treatment outcome is operator dependent. Skin excision can be included if this makes the procedure easier to perform, but this is not required for surgical success.

Auricular pressure relieving cushions for chondrodermatitis nodularis helices

Allen DL, Swinson PA, Arnstein PM. J Maxillofac Prosthet Tech 1998; 2: 5–10.

Thirty-five of 46 patients treated in this way had complete resolution of their symptoms.

Effective treatment of chondrodermatitis nodularis chronica helices using a conservative approach

Moncrieff M, Sassoon EM. Br J Dermatol 2004; 150: 892–4.

A simple-to-construct ear cushion design was used, made up of a bath sponge with the center removed and held in place with a head band. Thirteen out of 15 patients followed for 1 month responded.

The bath sponge pressure-relieving device is commercially available (CNH ear protector, Delasco).

Management of chondrodermatitis nodularis chronica helices using a “doughnut pillow.”

Sanu A, Koppana R, Snow DG. J Laryngol Otol 2007; 121: 1096–8.

Patients used a doughnut-shaped pillow made of a modern orthopedic “memory foam.” This distributes the weight of the recumbent head more evenly and is designed to relieve the pressure on the affected ear. Thirteen of 23 (56%) patients treated remained pain free after a 1-year follow-up.

Management of chondrodermatitis nodularis helices by auricular pressure-relieving device: a retrospective study

Belgi A, Logan RA. Br J Dermatol 2007; 157(Suppl 1): 68.

Seventy-eight patients with CNH used a custom-made ear pressure-relieving device designed and built by the local maxillofacial technicians. Forty-eight patients responded to a questionnaire examining the outcome. Only 7 found it helpful (15%).

Twenty reported no benefit (42%) and 20 some benefit (42%).

Management of chondrodermatitis helix by protective padding: a series of 12 cases and a review of the literature

Timoney N, Davison PM. Br J Plast Surg 2002; 55: 387–9.

Fourteen patients with CNH were prospectively enrolled and used protective padding of the ear at night. Most patients were rapidly relieved of their symptoms, although healing was frequently prolonged.

Chondrodermatitis nodularis chronica helix: a conservative therapeutic approach by decompression

Kuen-Spiegl M, Ratzinger G, Sepp N, Fritsch P. J Dtsch Dermatol Ges 2011; 9: 292–6.

Using a self-made bandage of foam plastic applied during the night, 11 out of 12 patients reported substantial reduction of pain within the first month and were pain free after an average of 1.75 months.

Self-adhering foam: a simple method for pressure relief during sleep in patients with chondrodermatitis nodularis helix

Travelute CR. Dermatol Surg 2013; 39: 317–9.

An inexpensive method using a self-adhering foam sponge (Reston Foam 3M, St Paul, MN) placed on the back of the ear and used nightly for several months described as effective for helix and antihelix lesions.

Various types of ear cushions are described. They all share the same aim, that is, to transfer the weight of the sleeping head from the ear to the surrounding scalp. Authors report a wide range of benefit with between 15% and 80% of patients not requiring surgery. In the hands of this writer the results are generally disappointing. This technique can be helpful for patients in whom surgery has been unsuccessful and in antihelix lesions in frail patients with thin skin who are unable to adapt their sleeping position. In these circumstances postsurgical recurrences are more common.

Third-Line Therapies

• Curettage	B
• Incision and cartilage curettage	E
• CO ₂ laser ablation	C
• Punch and graft	B

Chondrodermatitis nodularis chronica heliciis treated with curettage and electrocauterization: follow-up of a 15-year material

Kromann N, Hoyer H, Reymann F. Acta Derm Venereol 1983; 63: 85–7.

One hundred forty-two cases of chondrodermatitis were principally treated by curettage followed by electrocauterization. Seventy-eight patients were reexamined after an average interval of 7.1 years. This simple surgical technique produced a relapse rate of 31%.

The surgical management of chondrodermatitis nodularis chronica heliciis

Coldiron BM. J Dermatol Surg Oncol 1991; 17: 902–4.

An ellipse of skin is removed around the ulcerated area. The central necrotic or damaged cartilage is removed using a curette and the skin edges sutured. A series is not reported.

Chondrodermatitis nodularis chronica heliciis. Successful treatment with the carbon dioxide laser

Taylor MB. J Dermatol Surg Oncol 1991; 17: 862–4.

The CO₂ laser was used to vaporize the cutaneous nodules and involved cartilage. The wounds were allowed to heal with only minimal care using hydrogen peroxide cleansing and applications of topical antibiotic ointment. Twelve lesions have been treated with no recurrences after 2 to 15 months.

The punch and graft technique: a novel method of surgical treatment for chondrodermatitis nodularis heliciis

Rajan N, Langtry JA. Br J Dermatol 2007; 157: 744–7.

Twenty-three lesions (15 helix, 3 antihelix, 5 not recorded) were treated by punch removal of the nodule and underlying cartilage. The small defect was closed with a full-thickness skin graft taken from behind the ear using the same punch.

This novel “punch and graft” technique eschews all the dogma about the need to just remove cartilage and leave smooth cartilage margins but still produces a cure rate of 83%.

Cryotherapy has been advocated, but there are no published outcomes.

Chromoblastomycosis

Wanda Sonia Robles, and Mahreen Ameen

Chromoblastomycosis is a chronic fungal infection of cutaneous and subcutaneous tissues endemic in Central and South America, Africa, Australia, and Japan. It is caused by the traumatic implantation of pigmented (dematiaceous) fungi, which produce characteristic thick-walled sclerotic bodies (also known as *muriform* or

Medlar bodies) in infected tissues. The most common etiologic agents are *Fonsecaea pedrosoi*, *Phialophora verrucosa*, and *Cladophialophora carrionii*. Clinically, chromoblastomycosis presents as plaques, nodules, or warty, exophytic lesions, which most commonly affect the feet and lower legs. Lesions are slow growing and over years extend centripetally leaving central areas of scarring. Disease is usually localized but can spread through autoinoculation or lymphatic dissemination, producing metastatic lesions away from the primary site. Complications include ulceration, secondary bacterial infection, and lymphedema. Rarely, malignant transformation (squamous cell carcinoma) in chronic lesions and systemic involvement have been reported.

Management Strategy

Chromoblastomycosis is a difficult-to-treat deep mycosis that is characterized by low cure rates and high rates of relapse, particularly in chronic and extensive disease. Studies report highly variable rates of clinical and mycologic cure, ranging from 15% to 80%. The choice of treatment and outcome depend on the etiologic agent, the extent of the lesions, clinical topography, and the presence of complications (dermal fibrosis and edema may reduce tissue antifungal drug levels). *F. pedrosoi* is the most common etiologic agent, but has the lowest sensitivity to the major systemic antifungal agents. *C. carrionii* and *P. verrucosa* are much more sensitive and have been found to respond more favorably to treatment.

Surgical excision may be successful for small and localized lesions. It is performed with wide surgical margins and is usually accompanied by chemotherapy in order to reduce the risk of recurrence. Curettage and electrodesiccation is not recommended because it may promote lymphatic spread. Other physical modalities include cryosurgery using liquid nitrogen, as well as thermotherapy (applying local heat to produce controlled temperatures ranging from 42°C to 45°C that inhibit fungal growth) using a variety of methods, including benzene pocket warmers and pocket handkerchief-type warmers. Cryosurgery and thermotherapy have the advantage that they are relatively inexpensive treatment options.

There are no comparative trials of antifungal chemotherapy for chromoblastomycosis. Itraconazole (100–400 mg daily) and terbinafine (250–500 mg daily) are considered first-line treatments,

with both drugs having shown high in vitro activity against the causative agents of chromoblastomycosis. They are typically given for long periods at high doses. Dual therapy with itraconazole and terbinafine is recommended if it is affordable and tolerated. It is not uncommon for more than one treatment modality to be used, such as oral antifungals combined with surgery, cryotherapy, or thermotherapy. For example, itraconazole and/or terbinafine combined with cryosurgery is advocated for extensive disease. The antifungal is given first until there is a maximum reduction in lesion size, which usually requires 6 to 12 months of chemotherapy. The lesions then require several treatments with cryosurgery.

Of the other antifungal agents, ketoconazole is not recommended for treating chromoblastomycosis, as it cannot be given at high doses for long treatment periods because of its toxicity profile. Despite a few cases in the early literature reporting successful treatment with fluconazole, it, too, is not recommended as in vitro studies have shown that it has little activity against black fungi. Flucytosine (converted into 5-fluorouracil in fungal cells) was an early treatment that demonstrated some degree of efficacy. It is associated with a high risk of developing resistance, but this can be overcome if it is used in combination with another antifungal. It is also hepatotoxic and myelotoxic, requiring regular monitoring of serum levels. With the emergence of newer antifungals it is rarely used now except for resistant cases. Amphotericin B monotherapy is ineffective, and even in combination with other antifungals results are generally poor. However, amphotericin B and flucytosine dual therapy has demonstrated efficacy, with in vitro studies having demonstrated synergistic activity between the two drugs. The new second-generation triazoles such as posaconazole and voriconazole are promising drugs in the management of deep cutaneous mycoses, but experience to date is limited by their prohibitively high costs in endemic settings.

Specific Investigations

- Direct microscopy
- Culture
- Histopathology

A positive direct examination of scrapings in 10% potassium

hydroxide will demonstrate the thick-walled, brown sclerotic cells that are pathognomonic of chromoblastomycosis, irrespective of the causative species. Specimens are more likely to yield a positive result if they include the “black dots” visible on the surface of the lesion. Culture enables the identification of the causative agent. It is a slow-growing fungus, and culture may be inconclusive due to poor morphologic differentiation. Polymerase chain reaction (PCR) has been developed for the identification of *Fonsecaea* and *C. carrionii*. Serologic tests such as enzyme-linked immunosorbent assay (ELISA) can be useful in evaluating therapy response, but like PCR, they are not widely available in most endemic settings. A biopsy demonstrates the typical sclerotic bodies in a granulomatous lesion with transepithelial elimination.

First-Line Therapies

• Itraconazole	B
• Terbinafine	B
• Posaconazole	D

Treating chromoblastomycosis with systemic antifungals

Bonifaz A, Paredes-Solis V, Saul A. Expert Opin Pharmacother 2004; 5: 247–54.

A review article highlighting the difficulties in treating this condition. The authors state that the best results for therapy have been obtained with combination and high-dose itraconazole and terbinafine for a minimum treatment period of 6 to 12 months.

Chromoblastomycosis

López Martínez R, Méndez Tovar LJ. Clin Dermatol 2007; 25: 188–94.

A comprehensive review article. Itraconazole is considered the treatment of choice in combination with surgery in some cases.

Chromoblastomycosis: an overview of clinical manifestations, diagnosis and treatment

Queiroz-Telles F, Esterre P, Perez-Blanco M, Vitale RG, Salgado CG, Bonifaz A. Med Mycol 2009; 47: 3–15.

The authors state that there is no treatment of choice but rather several treatment options: they suggest that physical therapies should augment chemotherapy and that systemic combination therapies may increase cure rate but may be associated with a higher risk of adverse effects.

Chromoblastomycosis: clinical and mycologic experience of 51 cases

Bonifaz A, Carrasco-Gerard E, Saúl A. Mycoses 2001; 44: 1–7.

This is a study of 51 cases diagnosed over a 17-year period in a tertiary referral center in Mexico. Ninety percent of the cases were caused by *F. pedrosoi*. The overall cure rate for all treatment modalities was 31%, and a further 57% showed clinical improvement. For large lesions, itraconazole proved to be the most effective treatment, and cryosurgery for small lesions. Itraconazole combined with cryosurgery was also effective.

Subcutaneous mycoses

Queiroz-Telles F, McGinnis MR, Salkin I, Graybill JR. Infect Dis Clin North Am 2003; 17: 59–85.

In this study from Brazil, 30 patients with chromoblastomycosis due mainly to *F. pedrosoi* were treated with itraconazole 200 to 400 mg daily depending on the clinical severity. Nineteen patients (63%) achieved clinical and mycologic cure after 12 months of treatment (range 5–31 months). Treatment success depended on lesion size and extent.

This is the largest case series of itraconazole monotherapy for chromoblastomycosis.

Pulse itraconazole 400 mg daily in the treatment of chromoblastomycosis

Ungpakorn R, Reangchainam S. Clin Exp Dermatol 2006; 31: 245–7.

In this small study, six cases of *F. pedrosoi* infection in Thailand were treated with pulse itraconazole, 400 mg daily, for 1 week each month. All achieved clinical and mycologic cure. Four patients were cured after 12 pulses of treatment, and one after 15 pulses of treatment. The remaining patient required 20 pulses of itraconazole as well as cryosurgery. Disease severity and duration did not appear to be predictive of treatment response. This study demonstrated that the monthly pulse regimen is well tolerated and as effective as the conventional continuous 200- to 400-mg daily regimen for the treatment of *F. pedrosoi*. The authors recommend that treatment is continued until absence of organisms is proven by histology and tissue culture. Given that the total drug dosage is reduced, there is a marked reduction in cost of therapy by 50% to 75%. They also claim that pulse therapy is associated with higher compliance, although therapy duration remains long.

The cost of long-term itraconazole therapy is expensive in endemic settings, making this an important and relevant study.

Chromoblastomycosis: a clinical and molecular study of 18 cases in Rio de Janeiro, Brazil

Mouchalouat Mde F, Gutierrez Galhardo MC, Zancopé-Oliveira RM, Monteiro Fialho PC, de Oliveira Coelho JM, Silva Tavares PM, et al. *Int J Dermatol* 2011; 50: 981–6.

The vast majority of these cases were caused by *F. pedrosoi*, and disease duration varied from 4 months to 32 years. Systemic treatment included either itraconazole monotherapy 200 to 400 mg daily ($n=6$) or itraconazole 200 to 400 mg daily combined with fluconazole 200 mg daily ($n=5$), which was given for 12 to 60 months. There was an 80% cure rate and no relapse after 2 years of follow-up.

This study demonstrated good tolerability to combination azole therapy, which was given for more severe disease forms that also responded well to drug therapy, suggesting that there may be a role for fluconazole in combination with itraconazole.

Treatment of chromomycosis with terbinafine: preliminary results of an open pilot study

Esterre P, Inzan CK, Ramarcel ER, Andriantsimahavandy A, Ratsioharana M, Pecarrere JL, et al. *Br J Dermatol* 1996; 134: 33–6.

A multicenter study from Madagascar. Of 43 patients treated, 36 (*F. pedrosoi*, $n=29$; *C. carrionii*, $n=7$) could be completely evaluated.

Approximately one third of the patients had been resistant to previous treatment with thiabendazole. Oral terbinafine 500 mg daily was given for 6 to 12 months. Within 2 to 4 months of commencement of treatment, there was a marked clinical improvement with resolution of secondary bacterial infection, edema, and elephantiasis. There was mycologic cure in 83% (24/29) of patients infected with *F. pedrosoi* at 12 months. Of those infected with *C. carrionii*, there was cure in one and clinical improvement in a further three. Total cure was observed even in imidazole-refractory patients or those with chronic disease present for over 10 years. There was a mild transient rise of hepatic enzymes in some patients, but no serious adverse effects were reported.

Treatment of chromoblastomycosis with terbinafine: experience with four cases

Bonifaz A, Saúl A, Paredes-Solis V, Araiza J, Fierro-Arias L. J Dermatolog Treat 2005; 16: 47–51.

Four cases from Mexico (*F. pedrosoi*, *n*=3; *P. verrucosa*, *n*=1) were treated with oral terbinafine 500 mg daily. Three cases achieved clinical and mycologic cure after a mean treatment period of 7 months. Treatment was well tolerated with no abnormalities of liver enzymes.

Treatment of chromoblastomycosis with terbinafine: a report of four cases

Xibao Z, Changxing L, Quan L, Yuqing H. J Dermatolog Treat 2005; 16: 121–4.

Four cases from China (*C. carrionii*, *n*=2; *F. pedrosoi*, *n*=2) treated with terbinafine 500 mg daily for the first month followed by 250 mg daily were cured after 4 to 8 months of therapy without evidence of relapse at follow-up 6 months later. The total dosage of terbinafine ranged from 37.5g to 60g.

Alternate week and combination itraconazole and terbinafine therapy for chromoblastomycosis caused by *Fonsecaea pedrosoi* in Brazil

Gupta AK, Taborda PR, Sanzovo AD. Med Mycol 2002; 40: 529–34.

Four patients with long-standing disease refractory to standard therapies were treated with alternate week and combination therapy with itraconazole (200–400 mg daily) and terbinafine (250–1000 mg

daily). Combination therapy proved to be more effective and was well tolerated.

The authors suggest that combination therapy with itraconazole and terbinafine may be synergistic, with in vitro studies having already demonstrated this against other fungi. Larger studies are required to evaluate combination therapy with itraconazole and terbinafine. However, it must be noted that both drugs are expensive in endemic settings.

Posaconazole treatment of refractory eumycetoma and chromoblastomycosis

Negroni R, Tobon A, Bustamante B, Shikanai-Yasuda MA, Patino H, Restrepo A. Rev Inst Med Trop Sao Paulo 2005; 47: 339–46.

Cure was achieved in five of six patients with chromoblastomycosis refractory to standard antifungal therapies. They were treated with posaconazole 800 mg in divided doses. The maximum treatment period was for 34 months. Treatment was very well tolerated.

This new triazole demonstrates high efficacy and tolerability, but its use in most endemic settings is currently restricted due to its high cost.

Chromoblastomycosis: a neglected tropical disease

Queiroz-Telles F. Rev Inst Med Trop Sao Paulo 2015; 57 (Supl 19): 46–50.

Itraconazole, either as monotherapy or associated with other drugs or with physical methods, is the mainstay of treatment. More recently photodynamic therapy has been successfully used in combination with antifungals.

Second-Line Therapies

• Cryotherapy	B
• Surgical excision	D
• Thermotherapy	D

Treatment of chromoblastomycosis with itraconazole, cryosurgery, and a combination of both

Bonifaz A, Martinez-Soto E, Carrasco-Gerard E, Peniche J. Int J Dermatol 1997; 36: 542–7.

This study included 12 patients assigned to three different groups. Group 1, with small lesions, was treated with itraconazole 300 mg/day. Group 2, also with small lesions, was treated with one or more sessions of cryosurgery. Group 3, with large lesions, started treatment with itraconazole 300 mg/day until reduction of lesions was achieved, followed by one or more sessions of cryosurgery. The results showed complete clinical and mycologic cure in two out of four patients in both groups 1 and 3. All four patients in group 2 achieved complete cure.

Although the case numbers were small, this study suggests that cryosurgery is a more suitable treatment option than antifungal therapy for small lesions.

Treatment of chromomycosis by cryosurgery with liquid nitrogen: 15 years' experience

Castro LG, Pimentel ER, Lacaz CS. Int J Dermatol 2003; 42: 408–12.

This retrospective study included 22 patients with *F. pedrosoi*. Small lesions were frozen in a single session, whereas larger lesions were frozen in small parts. The average number of cryosurgery treatments that each patient received was 6.7 (range 1–22 sessions). Nine patients (40.9%) were considered cured (clinically disease-free period of at least 3 years), and eight patients (36.4%) were under observation (clinically disease-free but fewer than 3 years of follow-up). The rest failed to clear with treatment.

This study suggests high efficacy for cryosurgery therapy. This study, as well as others, suggests that cryosurgery is a useful and inexpensive option for small lesions.

Successful treatment of chromoblastomycosis with topical heat therapy

Tagami H, Ginoza M, Imaizumi S, Urano-Suehisa S. J Am Acad Dermatol 1984; 10: 615–9.

Four cases (*F. pedrosoi* isolated from three) were treated with topical application of tolerable heat from pocket warmers. Three patients

responded after 2, 3, and 6 months of treatment. The fourth patient who received treatment in an irregular manner cleared only after a 12-month period.

Third-Line Therapies

• Flucytosine	C
• Amphotericin B	D
• Voriconazole	E
• Posaconazole	E

Six years experience in treatment of chromomycosis with 5-fluorocytosine

Lopez CF, Alvarenga RJ, Cisalpino EO, Resende MA, Oliveira LG. Int J Dermatol 1978; 17: 414–8.

Twenty-three patients with chromoblastomycosis were treated with oral flucytosine for 2 to 67 months. Sixteen patients achieved clinical and mycologic cure (59%). However, seven patients developed resistance, and they failed to respond with subsequent treatment with amphotericin B, calciferol, or thiabendazole. Resistance appeared to occur particularly in those with long-standing lesions or widespread involvement.

A case of chromoblastomycosis with an unusual clinical manifestation caused by *Phialophora verrucosa* on an unexposed area: treatment with a combination of amphotericin B and 5-flucytosine

Park SG, Oh SH, Suh SB, Lee KH, Chung KY. Br J Dermatol 2005; 152: 560–4.

This case from Korea was treated with liposomal amphotericin monotherapy for 3 months, which had some effect. The addition of 5-flucytosine 4 g daily resulted in marked clinical improvement after only 1 month. Amphotericin was then discontinued, and dual therapy with 5-flucytosine and itraconazole 200 mg daily was given for 12 months until mycologic cure.

This case illustrates the low efficacy of amphotericin B monotherapy, and the synergistic activity in combination with 5-flucytosine. 5-Flucytosine is renally excreted, and therefore careful monitoring is required when it is used with other nephrotoxic drugs. Despite the toxicity of both drugs, this combination has been advocated by some mycologists as a very useful alternative to azoles.

Extensive chromoblastomycosis caused by *Fonsecaea pedrosoi* successfully treated with a combination of amphotericin B and itraconazole

Paniz-Mondolfi AE, Colella MT, Negrín DC, Aranzazu N, Oliver M, Reyes-Jaimes O, et al. Med Mycol 2008; 46: 179–84.

This report describes a case of extensive disease affecting the whole of the right lower limb of 22 years' duration that had failed 15 years of previous therapy consisting of ketoconazole and fluconazole. The patient then achieved clinical and mycologic cure with amphotericin (cumulative dose of 2150 mg) in combination with itraconazole 100 mg twice daily for approximately 3 months followed by a further 1 year of itraconazole 100 mg daily.

Extensive long-standing chromomycosis due to *Fonsecaea pedrosoi*: three cases with relevant improvement under voriconazole therapy

Criado PR, Careta MF, Valente NY, Martins JE, Rivitti EA, Spina R, et al. J Dermatolog Treat 2011; 22: 167–74.

Three patients with long-standing (10, 20, and 21 years) and extensive disease refractory to previous therapy with itraconazole and terbinafine were treated with voriconazole 200 mg twice daily for 12 months. Clinical response was evident after 30 to 50 days, but at the end of treatment despite significant clinical improvement, none of the patients achieved cure. All patients showed elevations of serum gamma-glutamyl transpeptidase during the treatment without clinical

relevance, and a single patient developed visual abnormalities and tremors requiring dose reduction.

This is the first report of the use of voriconazole for chromoblastomycosis. The partial response may be attributed to the severity of the disease. The report suggests that voriconazole represents an option for extensive disease refractory to conventional treatment.

Photodynamic therapy combined with terbinafine against chromoblastomycosis and the effect of PDT on *Fonsecaea monophora* in vitro

Hu Y, Huang X, Lu S, Hamblin MR, Mylonakis E, Zhang J, et al. Mycopathologia 2015; 179: 103–9.

Report of one case of refractory chromoblastomycosis treated with nine sessions of photodynamic therapy in combination with terbinafine. The lesions were improved after two sessions of ALA-PDT treatment, each including nine times, at an interval of 1 week, combined with terbinafine 250 mg/day oral, and clinical improvement could be observed.

Successful sequential treatment with itraconazole and ALA-PDT for chromoblastomycosis because of *Alternaria alternata*

Liu ZH, Xia XJ. Dermatol Ther 2014; 27: 357–60.

Case report of chromoblastomycosis due to *Alternaria alternata* successfully treated with systemic antifungals and subsequent 5 ALA-PDT.

Photodynamic antifungal therapy against chromoblastomycosis

Lyon JP, Pedroso e Silva Azevedo Cde M, Moreira LM, de Lima CJ, de Resende MA. Mycopathologia 2011; 172: 293–7.

Report of the use of methylene blue as photosensitizer and a light-emitting diode as light source in the treatment of chromoblastomycosis.

Chronic actinic dermatitis

Sally H. Ibbotson, and Robert S. Dawe

Chronic actinic dermatitis (CAD) is a chronic dermatitis mainly involving photoexposed sites, which is associated with objective evidence of abnormal photosensitivity. The photosensitivity is usually broadband although predominantly involving the ultraviolet B (UVB) waveband and often extending into the ultraviolet A (UVA) and even visible wavebands. The condition is considered to have an immunological basis, and no specific genetic susceptibility has been identified. Typically CAD affects elderly males, although in younger

patients it is reported particularly in association with atopic dermatitis. Indeed, most cases arise on the background of a dermatitis, such as atopic, seborrhoeic, or contact allergic dermatitis. In fact, in more than 75% of cases of CAD, patch testing is positive, confirming the association with contact allergic dermatitis. Patient and clinician may not be aware of the link with sunlight because of perennial symptoms and covered site involvement, leading to delays in diagnosis.

Management Strategy

Thus the essential first step of management is accurate diagnosis and exclusion of other conditions, such as photoaggravated eczema, and reversible causes, particularly drug-induced photosensitivity. Phototesting is essential, and the gold standard investigation is monochromator phototesting, allowing accurate definition of wavelengths involved (action spectrum) and the degree of photosensitivity.

Photoprotection is essential, with emphasis on *environmental and behavioral measures* (use of window film to prevent all ultraviolet (UV) transmission and double-envelope compact fluorescent lamps or light-emitting diodes [LEDs] for those with severe photosensitivity; seeking out the shade and avoiding sunlight in the middle of the day), *clothing choices* (tightly woven and dark colors if visible wavelengths are involved), and high SPF fragrance-free sunscreens. Patient education to reduce exposure to *contact allergens* is also essential, as contact allergy tends to persist indefinitely, whereas photosensitivity can resolve over time.

Active disease should be treated with *emollients* and *topical corticosteroids*. With severe flares or erythroderma, admission to hospital may be required in order to allow the patient to be nursed behind photoprotective screens. *Systemic corticosteroids* may be required for acute flares and then tapered over weeks. *Desensitization with photo(chemo)therapy* may be possible, although patients are usually too UVB sensitive to be able to tolerate UVB phototherapy, and thus, psoralen-UVA (PUVA) may be more effective and better tolerated. If these measures are inadequate for disease control, systemic immunosuppression may be needed.

Specific Investigations

- Phototesting (with UVB, UVA, and visible light from monochromator or broadband sources)
- Provocation testing (with solar simulator or other broadband source)
- Patch and photopatch tests
- Consider concomitant disease

The construction and development of a grating monochromator and its application to the study of the reaction of the skin to light

MacKenzie LA, Frain-Bell W. Br J Dermatol 1973; 89: 251–64.

Phototesting using an irradiation monochromator, if available, should be performed.

False-negative monochromator phototesting in chronic actinic dermatitis

Kerr AC, Dawe RS, Lowe G, Ferguson J. Br J Dermatol 2010; 162: 1406–8.

A case of false-negative monochromator phototesting in a patient with chronic actinic dermatitis taking prednisolone

Ferguson J, Ibbotson SH. Br J Dermatol 2012; 167: 214–5.

If testing shows severe photosensitivity despite topical corticosteroid therapy, this can allow the diagnosis to be made, but topical corticosteroid therapy or even low-dose oral prednisolone (10 mg/day) can lead to misleading false-negative testing.

Chronic actinic dermatitis in the elderly: recognition and treatment

Dawe RS. Drugs Aging 2005; 22: 201–7.

Phototesting is required to diagnose CAD. This review gives guidance on testing where specialized facilities are not available.

A preliminary investigation into the effect of exposure of photosensitive individuals to light from compact fluorescent lamps

Eadie E, Ferguson J, Moseley H. Br J Dermatol 2009; 160: 659–64.

Energy-saving lamps and their impact on photosensitive and normal individuals

Fenton L, Ferguson J, Ibbotson S, Moseley H. Br J Dermatol 2013; 169: 910–5.

Tungsten lamp and chronic actinic dermatitis

Hu SC, Lan CE. Australas J Dermatol 2017; 58: e14–6.

Is photodynamic diagnostic flexible ureterorenoscopy suitable for a patient presenting with chronic actinic dermatitis?

Valentine R, Kata S, Ibbotson S, Nabi G, Moseley H. Photoderm Photoimmunol Photomed 2015; 31: 279–81.

Be aware that patients with CAD may be at risk from exposure to UV radiation from compact fluorescent (“energy saving”) lamps. Indeed, patients with CAD who have severe broadband photosensitivity, including visible light sensitivity (such as visible light through window glass and exposure to a bright “ordinary” tungsten source used for ear cleaning), may be at risk from exposure to a wide range of artificial light sources, and this should be investigated and considered in management approaches.

Contact allergic sensitivity to plants and the photosensitivity dermatitis and actinic reticuloid syndrome

Frain-Bell W, Johnson BE. Br J Dermatol 1979; 101: 503–12.

Contact and photocontact sensitization in chronic actinic dermatitis: sesquiterpene lactone mix is an important allergen

Menagé H du P, Ross JS, Norris PG, Hawk JLM, White IR. Br J Dermatol 1995; 132: 543–7.

A European multicenter photopatch test study

European Multicenter Photopatch Test Study (EMCPPTS) Taskforce. Br J Dermatol 2012; 166: 1002–9.

Photopatch testing: recommendations for a European photopatch test baseline series

Goncalo M, Ferguson J, Bonevalle A, Bruynzeel DP, Gimenez-Amau A, Goossens A, et al. Contact Dermatitis 2013; 68: 239–43.

Contact and/or photocontact allergy is common in CAD. Standard

allergens, including fragrances, plants, and sunscreens, must be considered. Patch and photopatch testing, repeated at intervals as indicated by history, are essential investigations in order not to “miss” new allergens or photoallergens. Because many CAD patients are abnormally sensitive to the UVA sources used for photopatch testing, this technique may be difficult to undertake and interpret. However, photopatch testing with suberythemal UVA doses should be undertaken where possible.

Contact and photocontact sensitization in chronic actinic dermatitis: a changing picture

Chew AL, Bashir SJ, Hawk JLM, Palmer R, White I, McFadden JP. Contact Dermatitis 2010; 62: 42–6.

Be aware of changing allergen patterns with alteration in exposure over time. Para-phenylenediamine reactions in CAD may have increased.

Chronic actinic dermatitis in Asian skin: a Singaporean experience

Tan AW, Lim KS, Chong WS. Photoderm Photoimmunol Photomed 2011; 27: 172–5.

Three of 26 Singaporean patients with CAD were positive for HIV.

Other case series have found even greater proportions of CAD patients to have HIV. This does not prove a cause-and-effect relationship, but the possible association should be considered.

Sunlight exposure behavior and vitamin D status in photosensitive patients: longitudinal comparative study with healthy individuals at UK latitude

Rhodes LE, Webb AR, Berry JL, Felton SJ, Marjanovic EJ, Wilkinson JD, et al. Br J Dermatol 2014; 171: 1478–86.

Photosensitive patients are at higher risk of vitamin D insufficiency/deficiency, and we therefore need to be vigilant about vitamin D status in patients with CAD.

First-Line Therapies

• Photoprotective measures	C
• Avoidance of relevant contact allergens	C
• Topical corticosteroids	C
• Topical emollients	C

Photodermatoses: environmentally induced conditions with high psychological impact

Rizwan M, Reddick CL, Bundy C, Unsworth R, Richards HL, Rhodes LE. Photochem Photobiol Sci 2013; 12: 182–9.

Depression, anxiety, and dermatology life quality index scores were assessed in 185 of 260 adult patients with photosensitivity diseases who returned questionnaires. Twenty-three percent showed evidence of anxiety and 7.9% depression, and particular risk factors were facial involvement and duration of photosensitivity. This study showed high levels of psychological comorbidity in patients with photosensitivity diseases.

Chronic actinic dermatitis: a retrospective analysis of 44 cases referred to an Australian photobiology clinic

Yap LM, Foley P, Crouch R, Baker C. Australas J Dermatol 2003; 44: 256–62.

Restriction of sunshine and allergen exposure, along with sunscreens and topical corticosteroids, gave relief in 36% of CAD patients. The remainder also required oral immunosuppressants or phototherapy.

Photosensitivity dermatitis/actinic reticuloid syndrome in an Irish population: a review and some unusual features

Healy E, Rogers S. Acta Derm Venereol 1995; 75: 72–4.

Of nine CAD patients treated with sunscreens, emollients, topical corticosteroids, and antigen avoidance, six responded well, two achieved complete remission, and four were controlled on topical corticosteroids alone, although five also required oral corticosteroids initially.

Protection against ultraviolet radiation by commercial summer clothing: need for standardised testing and labeling

Gambichler T, Rotterdam S, Altmeyer P, Hoffmann K. BMC Dermatol 2001; 1: 6.

Summer clothing textiles ($n = 236$) were investigated spectrophotometrically for their ultraviolet protection factors (UPF). Over 70% of wool and polyester, but less than 30% of cotton, linen, and viscose fabrics, had UPFs over 30.

New advances in protection against solar ultraviolet radiation in textiles for summer clothing

Aguilera J, de Galvez MV, Sanchez-Roldan C, Herrera-Ceballos E. Photochem Photobiol 2014; 90: 1199–206.

Some clothing, such as normal shirts, may offer very little protection against ultraviolet radiation (UVR), and information about UVR protection levels should be included in textile labeling.

Dosimetric investigation of the solar erythematous UV radiation protection provided by beards and moustaches

Parisi AV, Turnbull DJ, Downs N, Smith D. Radiat Prot Dosimetry 2012; 150: 278–82.

Some protection from UVR is provided by facial hair, with the ultraviolet protection factor ranging from 2 to 21. However, protection levels may not be high, particularly at the higher solar zenith angle; thus beards and moustaches should not be considered reliable means of photoprotection in CAD.

Second-Line Therapies

• Azathioprine	A
• cyclosporine	E
• Mycophenolate	E
• Hydroxycarbamide	E
• PUVA	D
• UVB	D
• Topical calcineurin inhibitors	B

Chronic actinic dermatitis

Paek SY, Lim HW. *Dermatol Clin* 2014; 32: 355–61.

If conservative management of CAD with photoprotection and topical therapies is insufficient, systemic immunosuppressants, such as glucocorticoids, azathioprine, cyclosporine, or mycophenolate mofetil, may be effective.

Azathioprine treatment in chronic actinic dermatitis: a double-blind controlled trial with monitoring of exposure to ultraviolet radiation

Murphy GM, Maurice PD, Norris PG, Morris RW, Hawk JL. *Br J Dermatol* 1989; 121: 639–46.

Five of eight patients with CAD treated in this randomized trial had complete clinical disease remission within 6 months of azathioprine (150 mg/day) commencement. No useful clinical response was seen in 10 patients treated with placebo. It is not known whether azathioprine causes objective improvement in photosensitivity.

Azathioprine in dermatology: a survey of current practice in the UK

Tan BB, Gawkrödger DJ, English JSC. *Br J Dermatol* 1997; 136: 351–5.

A questionnaire survey of 253 UK dermatologists demonstrated that 68% use azathioprine in CAD, 66% alone, and the others as a steroid-sparing agent. Most used 100 mg daily, with only 13% prescribing it by body weight. CAD had the highest proportion of perceived efficacy (62%) of all disorders treated with azathioprine.

Severe chronic actinic dermatitis treated with cyclosporine: 2 cases

Paquet P, Piérard GE. *Ann Dermatol Venereol* 2001; 128: 42–5.

Two patients with CAD unresponsive to high-dose oral steroids responded well to oral cyclosporine without significant adverse effects. One was in remission for 3 years after stopping cyclosporine.

Chronic actinic dermatitis treated with mycophenolate mofetil

Thomson MA, Stewart DG, Lewis HM. *Br J Dermatol* 2005; 152: 784–6.

Two patients with CAD who had failed to respond to topical steroids, prednisolone, PUVA, azathioprine, and cyclosporine were treated with mycophenolate mofetil, resulting in clearance over weeks, without adverse effects.

Chronic actinic dermatitis (photosensitivity dermatitis/actinic reticuloid syndrome): beneficial effect from hydroxyurea

Gramvussakis S, George SA. *Br J Dermatol* 2000; 143: 1340.

Hydroxycarbamide (previously called hydroxyurea) at 500 to 1000 mg/day induced remission of CAD in one patient.

PUVA therapy of chronic actinic dermatitis

Hindson C, Spiro J, Downey A. *Br J Dermatol* 1985; 113: 157–60.

Four patients with severe CAD were treated twice weekly with PUVA, with starting UVA doses of 0.25 J/cm² and increases of 0.25 to 1 J/cm² up to a maximum 10 J/cm². Topical steroids were applied immediately after each of the first six exposures. All patients responded well and remained controlled on twice-monthly treatments of 10 J/cm².

Chronic actinic dermatitis: two patients with successful management using narrowband ultraviolet B phototherapy with systemic steroids

Khaled A, Kerkeni N, Baccouche D, Zegloui F, Kamoun M,

Mohamed R. EDP Sciences 2011; 66: 453–7.

Two patients were successfully treated with narrowband UVB under cover of systemic corticosteroid therapy.

Actinic reticuloid. A clinical photobiologic, histopathologic, and follow-up study of 16 patients

Toonstra J, Henquet CJ, van Weelden H, van der Putte SC, van Vloten WA. J Am Acad Dermatol 1989; 21: 205–14.

Fifteen CAD patients were treated with broadband UVB phototherapy five times a week, starting at a 10% minimal erythema dose, with gradual increments as tolerated. Thirteen improved well clinically, with increased sunlight tolerance. Discontinuation of therapy was followed by gradual relapse.

Treatment with topical tacrolimus favors chronic actinic dermatitis: a clinical and immunopathological study

Ma Y, Lu Z. J Dermatolog Treat 2010; 21: 171–7.

Forty patients with CAD were treated with topical tacrolimus 0.1%, and skin biopsies were performed pretreatment and posttreatment in 15 patients. Clinical efficacy was seen in 25 (63%), with significant downregulation of Langerhans/dendritic cell function.

Erythrodermic chronic actinic dermatitis responding only to topical tacrolimus

Evans AV, Palmer RA, Hawk JLM. Photodermatol Photoimmunol Photomed 2004; 20: 59–61.

An erythrodermic patient with CAD resistant to oral immunosuppressants and phototherapy responded well to topical tacrolimus.

Successful treatment of chronic actinic dermatitis with topical pimecrolimus

Larangeira de Almeida H. Int J Dermatol 2005; 44: 343–4.

Pimecrolimus can be considered an alternative therapy.

No comparative studies have been reported. Potent topical corticosteroids should generally be favored over topical calcineurin inhibitors, but these newer topical immunomodulators are appropriate to consider for those with inadequate responses to topical corticosteroids.

Third-Line Therapies

• Hydroxychloroquine	D
• Etretinate	E
• Danazol	E
• Thalidomide	E
• Interferon	E
• Infliximab	E

Chronic actinic dermatitis. An analysis of 51 patients evaluated in the United States and Japan

Lim HW, Morison WL, Kamide R, Buchness MR, Harris R, Soter NA. Arch Dermatol 1994; 130: 1284–9.

Photoprotection and topical corticosteroids were useful in 51 patients with CAD. Azathioprine (50–200 mg/day) was also commonly helpful. PUVA and oral corticosteroids were beneficial in 7 patients, cyclosporine in 4, and etretinate in 2. Hydroxychloroquine (200 mg once or twice daily) achieved partial/good responses in 9 patients.

Chronic actinic dermatitis responding to danazol

Humbert P, Drobacheff C, Vigan M, Quencez E, Laurent R, Agache P. Br J Dermatol 1991; 124: 195–7.

A patient with CAD with low α_1 -antitrypsin levels responded dramatically to danazol (600 mg/day for 3 weeks), relapsed on

stopping, improved on restarting, and remained controlled 18 months later while still on the drug. Danazol raises low serum α_1 -antitrypsin and protease inhibitor levels, and a protease–antiprotease imbalance has been said to cause abnormal inflammatory responses in several dermatoses.

Recalcitrant chronic actinic dermatitis treated with low-dose thalidomide

Safa G, Pioto-Le Corvaisier C, Hervagault B. *J Am Acad Dermatol* 2005; 52: E6.

A patient with CAD resistant to PUVA, azathioprine, cyclosporine, and hydroxychloroquine responded dramatically to thalidomide (100 mg/day reduced to 50 mg twice weekly) over 5 months without adverse effect.

Actinic reticuloid: treatment with recombinant interferon alpha-2b

Trevisi P, Farina P, Borda G, Passarini B, Bonelli U. *G Ital Dermatol Venereol* 1993; 128: 327–31.

Natural α -interferon in chronic actinic dermatitis. Report of a case

Parodi A, Gallo R, Guarrera M, Rebora A. *Acta Derm Venereol* 1995; 75: 80.

In one patient with CAD in whom cyclosporine had to be discontinued because of hypertension, natural α -interferon (3 MU three times per week) was effective.

Successful therapy of chronic actinic dermatitis with infliximab

Schopf RE, Poblete-Gutiérrez P. *Exp Dermatol* 2009; 18: 302 (abstract at 36th Annual Meeting of Arbeitsgemeinschaft Dermatologische Forschung, Heidelberg, 2009).

Infliximab infusions were associated with marked improvement in one patient who had not shown useful response to previous therapies, including topical corticosteroids, PUVA, and cyclosporine.

Coccidioidomycosis

Mahreen Ameen, and Wanda Sonia Robles

Coccidioidomycosis is an endemic systemic mycosis caused by inhalation of dimorphic fungi of the genus *Coccidioides* (*C. immitis* and *C. posadasii*). It is endemic in desert regions of the Southwestern

United States and Central and South America. Primary pulmonary disease is usually subacute and self-limiting. The immunocompromised are particularly susceptible to chronic pulmonary disease. One percent progress to disseminated disease, and again those with impaired cell-mediated immunity are at greater risk of this. Coccidioidomycosis is an opportunistic infection with advanced HIV infection and CD4 counts less than 250. Solid organ transplant recipients, patients with hematologic malignancies, and those on long-term immunosuppressants, including corticosteroids and tumor necrosis factor-alpha (TNF- α) antagonists, are also at risk. Extrapulmonary hematogenous dissemination can affect almost any organ but most frequently involves the skin, lymph nodes, skeletal system, and meninges. Dissemination to the skin can give rise to ulcerative and verrucous lesions with a predilection for the nasolabial area. Subcutaneous abscesses, sinus tracts, and fistulae can develop as **a result of coccidioid infection in neighboring lymph nodes, bones, or joints.** Other dermatologic manifestations include erythema nodosum and erythema multiforme associated with primary pulmonary infection. Primary infection of the skin is rare.

Dermatologists should be aware that the combination of atypical skin lesions, pulmonary infiltrates, and a history of travel to endemic areas of the disease may represent disseminated infection with coccidioidomycosis.

Management Strategy

Treatment depends on disease extent and predisposing factors. Those with primary pulmonary infection and no risk factors require only periodic assessments up to 2 years to ensure that the infection is self-limiting. Some clinicians, however, prefer to treat with oral azoles to prevent any risk of progression, although there are no trial data to support this. Antifungal therapy is indicated for severe or chronic pneumonia or progressive or disseminated infection. Fluconazole (400–800 mg daily) and itraconazole (200–600 mg daily) are the initial choice of therapy for most chronic pulmonary and disseminated infections. Ketoconazole (400 mg daily) shows comparable efficacy to the other azoles, but is associated with a higher risk of adverse effects with long-term use. Parenteral amphotericin B (AmB deoxycholate 0.5–1.5 mg/kg/day or lipid formulations of AmB 2.0–5.0 mg/kg/day) is recommended for those with severely acute infection with respiratory

failure, those with rapidly progressive and disseminated infection, women during pregnancy, and those who fail azole therapy. Published reports of its use, however, are still limited to small numbers of patients treated in open-label, nonrandomized studies. There have been no clinical trials assessing the efficacy of lipid formulations of amphotericin B. Newly available antifungals that may be used for refractory infection include the triazoles, posaconazole and voriconazole, with in vitro studies having demonstrated their efficacy. However, there have been no comparative studies as yet evaluating their efficacy against the established azoles used for treating coccidioidomycosis. There are early reports too of the successful use of caspofungin, an echinocandin, although results of in vitro susceptibility studies have varied widely.

In addition to drug therapy, surgery is sometimes indicated for the removal of focal infection such as pulmonary cavities, focal osseous infection, or the debridement of soft tissue. Long-term prophylaxis with azoles is indicated for the immunocompromised, and meningeal infection requires lifelong azole therapy in order to prevent recurrence. Recovery from infection confers lifelong immunity and provides the rationale for the ongoing development of a possible vaccine.

Treatment considerations in pulmonary coccidioidomycosis

Hartmann CA, Aye WT, Blair JE. *Expert Rev Respir Med* 2016; 10: 1079–91.

This review discusses current literature regarding medical treatment options, including the various triazoles and amphotericin B products. In addition, it discusses uncomplicated and complicated pulmonary infections and their sequelae and the approach to managing coccidioidomycosis in certain patient populations, such as pregnant women, transplant recipients, HIV-infected individuals, and recipients of TNF- α inhibitors.

Specific Investigations

- Direct microscopy
- Culture
- Serologic tests
- Imaging studies (chest and bone radiography)

- Serology for HIV/AIDS infection (where relevant)

The characteristic globular spherules may be seen in potassium hydroxide mounts of infected material: sputum, cerebrospinal fluid, or pus. Culture is the definitive method of establishing the diagnosis. *Coccidioides* spp. grow rapidly on most media within 5 days. In the mycelial form, the fungus is highly infectious, so cultures should be handled with care. Serologic tests are useful and can be used to assess response to therapy.

First Line Therapies

• Fluconazole	A
• Itraconazole	A

Fluconazole therapy for coccidioidal meningitis. The NIAID Mycoses Study Group

Galgiani JN, Catanzaro A, Cloud GA, Higgs J, Friedman BA, Larsen RA, et al. Ann Intern Med 1993; 119: 28–35.

Uncontrolled clinical trial that included 50 patients with coccidioidal meningitis. Forty-seven patients were evaluated. Twenty-five had received no previous treatment, and nine were HIV positive. Thirty-seven of 47 patients (79%) responded to treatment. Response rates were similar in patients who had or had not received previous therapy.

Fluconazole demonstrates efficacy in the treatment of coccidioidal meningitis.

Comparison of oral fluconazole and itraconazole for progressive, nonmeningeal coccidioidomycosis. A randomized, double-blind trial

Galgiani JN, Catanzaro A, Cloud GA, Johnson RH, Williams PL, Mirels LF, et al. Ann Intern Med 2000; 133: 676–86.

In this randomized, double-blind, placebo-controlled trial, 198 patients with pulmonary and nonmeningeal infection were treated with either fluconazole 400 mg daily or itraconazole 200 mg twice daily. Overall efficacy rates at 12 months were similar (itraconazole 63%; fluconazole 50%; $p = 0.8$). However, the response rate was higher in patients with bone disease treated with itraconazole (52% vs. 26%; $p = 0.05$). The rates of relapse were comparable (itraconazole, 18%; fluconazole, 28%; $p > 0.2$). Both drugs were well tolerated.

This is the first prospective, randomized trial comparing two different azole drugs for the treatment of an endemic mycosis. The results demonstrate that both itraconazole and fluconazole are effective therapies for nonmeningeal coccidioidomycosis.

Second-Line Therapies

• Amphotericin B	D
• Ketoconazole	B

Amphotericin B and coccidioidomycosis

Johnson RH, Einstein HE. Ann N Y Acad Sci 2007; 1111: 434–41.

This article provides a comprehensive review of the use of amphotericin B in the treatment of coccidioidomycosis. The availability of effective azoles and triazoles mean that amphotericins are only used now for widely disseminated infection, in cases of azole intolerance, or when there are contraindications to azoles, such as pregnancy.

Given that all studies to date of amphotericin use for coccidioidomycosis are limited by small numbers, this review article provides a detailed assessment of current indications for its use.

Ketoconazole therapy of progressive coccidioidomycosis.

Comparison of 400- and 800-mg doses and observations at higher doses

Galgiani JN, Stevens DA, Graybill JR, Dismukes WE, Cloud GA. Am J Med 1988; 84: 603–10.

A randomized clinical trial involving 112 patients with progressive pulmonary, skeletal, or soft tissue infections. Success rate was similar for the two groups (23.2% vs. 32.1% for low- and high-dose therapy). Side effects were significantly higher with high-dose therapy (66% vs. 38%). Relapse rates were higher with high-dose therapy (52% vs. 11%), although it depended also on the organs involved. The study concluded there is little or no benefit with high-dose ketoconazole for nonmeningeal infection.

Third-Line Therapies

• Posaconazole	B
• Voriconazole	C
• Caspofungin	D
• Adjunctive interferon- γ immunotherapy	E

Safety, tolerance, and efficacy of posaconazole therapy in patients with nonmeningeal disseminated or chronic pulmonary coccidioidomycosis

Catanzaro A, Cloud GA, Stevens DA, Levine BE, Williams PL, Johnson RH, et al. Clin Infect Dis 2007; 45: 562–8.

In this multicenter trial, 20 patients with chronic pulmonary or nonmeningeal disseminated coccidioidomycosis were treated with posaconazole 400 mg daily for up to 6 months (median 173 days). Seventeen (85%) patients had a satisfactory response to treatment ($\geq 50\%$ reduction in the Mycoses Study Group score from baseline). No serious adverse effects were reported. Paired baseline and end-of-treatment culture results for *Coccidioides* species were available for four patients, all of whom converted from being positive to being negative for *Coccidioides* species. Relapse was experienced by three of

nine patients who did not receive antifungal therapy during the follow-up period.

Posaconazole therapy for chronic refractory coccidioidomycosis

Stevens DA, Rendon A, Gaona-Flores V, Catanzaro A, Anstead GM, Pedicone L, et al. Chest 2007; 132: 952–8.

This was an open-label multinational study, which included 15 patients with pulmonary ($n = 7$) and disseminated ($n = 8$) disease that was refractory to previous therapy, which included amphotericin B with and without an azole. They were treated with posaconazole 800 mg daily in divided doses for 34 to 365 days (median 306 days). Seventy-three percent of patients (11/15) responded to treatment, with cure in four patients. Treatment was very well tolerated.

Treatment of refractory coccidioidomycosis with voriconazole or posaconazole

Kim MM, Vikram HR, Kusne S, Seville MT, Blair JE. Clin Infect Dis 2011; 53: 1060–6.

This was a retrospective study of all cases treated with either voriconazole ($n = 21$) or posaconazole ($n = 16$) in a single center. There was a 67% and 75% improvement after a median duration of 6 and 17 months of treatment with voriconazole and posaconazole, respectively.

The authors concluded that voriconazole and posaconazole are reasonable, but not infallible, options for salvage treatment of refractory coccidioidomycosis.

Use of the echinocandins (caspofungin) in the treatment of disseminated coccidioidomycosis in a renal transplant recipient

Antony S. Clin Infect Dis 2004; 39: 879–80.

Caspofungin monotherapy was successfully used to treat this case of disseminated infection without meningeal involvement.

Treatment of pediatric refractory coccidioidomycosis with combination voriconazole and caspofungin: a retrospective case series

Levy ER, McCarty JM, Shane AL, Weintrub PS. Clin Infect Dis 2013; 56: 1573–8.

A retrospective review of nine pediatric patients treated with combination voriconazole and caspofungin salvage therapy for

refractory coccidioidomycosis after failing conventional therapy consisting of a triazole, amphotericin B, or a combination of both. Eight of the nine patients achieved remission.

Two cases illustrating successful adjunctive interferon- γ immunotherapy in refractory disseminated coccidioidomycosis

Duplessis CA, Tilley D, Bavaro M, Hale B, Holland SM. J Infect 2011; 63: 223–8.

The authors report two cases of refractory coccidioidomycosis, which demonstrated improved responses with adjunctive interferon (IFN)- γ .

IFN- γ augments the antifungal activity of effector immune cells against a variety of fungi. Adjunctive immunotherapy given with chemotherapy has the potential to improve host immune responses and facilitate complete eradication of pathogens.

Current Guidelines

Coccidioidomycosis

Infectious Diseases Society of America. Galgiani JN, Ampel NM, Blair JE, Catanzaro A, Johnson RH, Stevens DA, et al. Clin Infect Dis 2005; 41: 1217–23.

These guidelines replace the 2005 guidelines and have expanded recommendations for diagnosing and managing early coccidioidal infections, which are the most common clinical presentation, as well as the management of coccidioidal meningitis. Management of coccidioidomycosis in specific at-risk groups such as those with HIV, solid organ transplants, and pregnancy are also specifically addressed. The 2005 guidelines were notable for replacing amphotericin B with fluconazole and itraconazole as first-line therapy for most chronic and disseminated forms of infection. Recommended dosages of these commonly used azoles are fluconazole 400 to 800 mg daily and itraconazole 400 to 600 mg daily.

Confluent and reticulated papillomatosis

Dina Ismail, Noah Scheinfeld, and Ian Coulson

Synonyms: Gougerot-Carteaud syndrome; papillomatose pigmentée innominée; papillomatose pigmentée confluyente et reticule; reticulated and confluent papillomatosis of Gougerot and Carteaud

Confluent and reticulated papillomatosis (CARP) is a rare disorder of epidermal keratinization presenting mainly in young adults, with equal sex incidence. A number of etiologic factors have been proposed, including an abnormal host immune response to *Malassezia furfur* colonization. Bacterial colonization may also play a role, although no species has been consistently isolated. Most cases are sporadic, but several familial cases have been reported. The role of metabolic and endocrine abnormalities has also been proposed.

Typically lesions begin as erythematous, hyperkeratotic, flat-topped papules that coalesce to form confluent plaques with a reticular brown pattern peripherally on the chest, trunk, and back simulating tinea versicolor or acanthosis nigricans.

Management Strategy

In asymptomatic patients, no treatment is an option. Mild topical steroids can be prescribed to manage any associated pruritus, in addition to soap avoidance and emollients. Spontaneous remissions and exacerbations may be encountered.

Randomized controlled trials for therapies are lacking. Treatment advice stems from retrospective analyses, case series, and reports. Diagnostic criteria have also been proposed.

A wide range of antibiotics and topical agents have been effective; however, recurrence rate is high, and repeat treatment is often needed. Topical and oral antifungals are usually not effective. *Minocycline* is regarded as first-line therapy at a dose of 50 to 200 mg daily for a minimum of 6 weeks. Other macrolide antibiotics found to be effective include *clarithromycin* (500 mg daily for 5 weeks), *azithromycin* (500 mg daily for 1 to 4 weeks), *erythromycin* (1000 mg daily for 6 weeks), and *roxithromycin* (300 mg daily for 8 weeks). Alternative antibiotics include *doxycycline* (200 mg daily for 3 months), *amoxicillin* (250 mg 3 times daily for 3 months), *fusidic acid* (1000 mg daily for 4 weeks), *cefdinir* (300 mg daily for 3 days), and topical *mupirocin* 2% ointment for 1 month.

Topical therapies are also an option, either used as a single agent or adjunct to systemic treatment. Both topical *tazarotene* (0.1%) gel and

tretinoin of various strengths (0.1%, 0.01%, and 0.25%) for 6 to 8 weeks have been reported as effective in case reports. *Tacrolimus* 0.1% ointment used twice daily for 3 months achieved clinical improvement. Topical vitamin D analogs have also been used.

Oral retinoids at both high and low doses have been reported as effective in case reports but are usually reserved for patients with recalcitrant CARP in view of the associated side effect profile.

Specific Investigations

- Mycology
- Biopsy
- None required

CARP is a clinical diagnosis that should be suspected in young patients with classical findings and absence of fungal hyphae on potassium hydroxide preparation (KOH) to rule out tinea versicolor. If clinical features remain unclear, a biopsy can be taken to identify the histologic features suggestive of CARP. These include focal parakeratosis, acanthosis, papillomatosis, and superficial perivascular lymphocytic infiltrate.

First-Line Treatments

• Minocycline	C
• Do nothing	E

Confluent and reticulated papillomatosis: response to minocycline

Montemarano AD, Hengge M, Sau P, Welch M. *J Am Acad Dermatol* 1996; 34: 253–6.

An uncontrolled study of nine patients diagnosed with CARP receiving minocycline 50 mg twice a day for 6 weeks. All patients except two had a 90% to 100% response to therapy over an average follow-up period of 11 months. Recurrence was noted in three patients, all of whom responded to retreatment with minocycline.

Confluent and reticulate papillomatosis (Gougerot-Carteaud syndrome): a minocycline-responsive dermatosis without evidence for yeast in pathogenesis. A study of 39 patients and a proposal of diagnostic criteria

Davis MD, Weenig RH, Camilleri MJ. Br J Dermatol 2006; 154: 287–93.

A retrospective review of 39 CARP cases. Minocycline was prescribed for 22 patients. The majority received 100 mg twice daily for 1 to 3 months. Complete clearing of skin eruption was achieved in 14 of 18 (78%), and 4 (22%) showed a partial response. Recurrence occurred in six cases after stopping treatment, mean time 8 months. The authors also propose a useful diagnostic criterion for CARP, which includes excellent response to minocycline.

Clinicopathological and diagnostic characterisation of Confluent and Reticulate Papillomatosis of Gougerot and Carteaud: a retrospective study in a South-East Asian population

Huang W, Ong G, Chong WS. Am J Clin Dermatol 2015; 16: 131–6.

A retrospective review of 29 patients who failed antifungal treatment for CARP. Good or complete clearance was achieved in 100% (11) of patients on minocycline. Three patients had received doxycycline and achieved clearance. Four patients experienced recurrence (mean time 19.4 months), which was cleared with repeat treatment. Patients treated with topical antifungals, retinoids, and salicylic acid failed to respond.

A clinical analysis of 20 patients with confluent and reticulate papillomatosis

Zeng YP, Ma DL, Qu T, Liu YH, Jin HZ, Sun QN, et al. J Clin Dermatol 2011; 40: 206–9.

Minocycline was prescribed for 10 patients, 8 (80%) of whom had complete clearing of the skin eruption (2 cases relapsed after stopping the drug) and 2 (20%) had no response.

Confluent and reticulated papillomatosis: successful treatment

with minocycline

Fung MA, Frieden IJ, LeBoit PE, Berger TG, Epstein E, Kay D, et al. Arch Dermatol 1996; 132: 1400–1.

Eight patients treated with minocycline. Seven achieved complete clearance, and one improved. Three patients developed recurrence.

Several other case series from around the world indicate a high initial response rate to minocycline.

Chronology of confluent and reticulated papillomatosis: spontaneous regression in a case after long-term follow-up may imply transient nature of the condition

Sakiyama T, Amagi M, Ohyama M. J Dermatol 2015; 42: 335–6.

A 50-year-old male patient with IgA nephropathy failed topical ketoconazole and refused oral medications. The cutaneous manifestation repeated a cycle of improvement and exacerbation for about 2 years and 3 months and then finally started to improve.

Second-Line Treatments

• Azithromycin	E
• Doxycycline	E
• Clarithromycin	E
• Erythromycin	E
• Roxithromycin	E
• Oral fusidic acid	E
• Cefdinir	E
• Amoxicillin	E
• Topical retinoids	E
• Topical tacrolimus	E
• Vitamin D analogs	E
• Topical mupirocin	E

For patients in whom minocycline is contraindicated or show no response, other macrolide antibiotics have been used with success. Topical therapies are also an option used as a single agent or adjunct to oral treatments.

Confluent and reticulate papillomatosis: successful treatment with azithromycin

Raja Babu KK, Snehal S, Sudha Vani D. Br J Dermatol 2000; 142: 1252–3.

Seventeen-year-old male patient initially treated with a course of topical antifungal treatment (1% clotrimazole) and keratolytic with no improvement. Azithromycin 500 mg daily for 7 days was initiated. Total regression was noted within 4 weeks. Recurrence after 5 months successfully treated in 3 weeks with a repeat course. No further recurrence noted at 3 months.

Treatment of confluent and reticulated papillomatosis with azithromycin

Gruber F, Zamolo G, Saftic M, Peharda V, Kastelan M. Clin Exp Dermatol 1998; 23: 191.

Eighteen-year-old patient treated with azithromycin 500 mg daily for 7 days. Complete clearance achieved by 4 weeks with no recurrence. A 15-year-old girl initially treated with clotrimazole 1% cream for 2 weeks without improvement. The patient was then given azithromycin 500 mg daily for 1 week, which cleared the eruption.

Several other single-case reports confirm the efficacy of azithromycin 500 mg daily for 7 days as the usual regimen.

Confluent and reticulated papillomatosis accompanied by obesity: three cases

Demirseren DD, Emre S, Akoğlu G, Kılınç F, Yavuz SO, Metin A. 2014. Turk J Dermatol 2014; 3: 166–9.

Three obese female patients in their 20s were treated with doxycycline 100 mg day for 2 months. Two patients developed recurrence.

Confluent and reticulated papillomatosis (Gougerot-Carteaud syndrome) in 2 brothers

Acikgoz G, Huseynov S, Ozmen I, Ozturk Meral A, Gamsizkan M, Caliskan E. Acta Dermato Venerologica Croatica 2014; 22: 57–9.

Two brothers treated with doxycycline 100 mg/day and topical tretinoin cream. After 3 months a marked improvement was noted.

Updated diagnostic criteria for confluent and reticulated papillomatosis: a case report

Jo S, Park HS, Cho S, Yoon HY. Ann Dermatol 2014; 26: 409–10.

A patient was treated with doxycycline 100 mg twice per day for 2 months with complete resolution. Initially treated with oral itraconazole with no response.

Other similar single reports exist; typically 100 mg daily is exhibited for 2 to 3 months.

Confluent and reticulated papillomatosis (Gougerot-Carteaud syndrome) case successfully treated with oral doxycycline and calcipotriol ointment combination

Acikgoz G, Toklu S, Calickan E, Tunca M, Gamsizkan M. Gazi Med J 2015; 26: 112–4.

A female patient failed treatment with topical antifungals. Instead she was treated with doxycycline 100 mg per day for 2 months and topical calcipotriol 0.005% ointment. She required retreatment for 2 months with complete resolution and no recurrence at 6-month follow-up.

Six cases of confluent and reticulated papillomatosis alleviated by various antibiotics

Jang HS, Oh CK, Cha JH, Cho SH, Kwon KS. J Am Acad Dermatol 2001; 44: 652–5.

CARP lesions cleared in 1 patient treated with oral minocycline 100 mg daily for 8 weeks. The eruption recurred after 8 months but cleared with a repeat course. Two patients were treated with oral fusidic acid 1000 mg daily for 4 weeks. Despite clearing the eruption, one patient relapsed after 2 years and required a repeat course. Cutaneous lesions cleared in a 14-year-old girl with clarithromycin 500 mg daily for 5 weeks. In another, clearance was achieved with oral erythromycin 1000 mg daily for 6 weeks. Azithromycin 500 mg daily 3 times per week for 3 weeks treated a CARP eruption of 5 years' duration in a 24-year-old man.

A case of confluent and reticulated papillomatosis that successfully responded to roxithromycin

Ito S, Hatamochi A, Yamazakis S. J Dermatol 2006; 33: 71–2.

A 28-year-old Japanese man was started on oral minocycline 200 mg daily with no improvement after 3 months. The antibiotic was changed to oral roxithromycin 300 mg daily. The eruption almost completely disappeared after 8 weeks of treatment.

Two cases of confluent and reticulate papillomatosis: successful treatments of 1 case with cefdinir and another with minocycline

Yamamoto A, Okubo Y, Oshima H, Oh-i T, Koga M. J Dermatol 2000; 27: 598–603.

Twenty-four-year-old male patient treated with 300 mg per day of cefdinir for 3 days with improvement. Repeat course of cefdinir needed due to recurrence. Eruption cleared after 2 weeks with no reemergence at 16 months.

Confluent and reticulated papillomatosis successfully treated with amoxicillin

Davis RF, Harman KE. Br J Dermatol 2007; 156: 583–4.

A pregnant female patient treated with amoxicillin 250 mg three times per day for a respiratory infection and incidentally noticed improvement of CARP. Eruption recurrence at 3 months was treated with further 1-month course of amoxicillin with complete clearance at 3 weeks.

Response of confluent and reticulate papillomatosis of Gougerot and Carteaud to topical tretinoin

Schwartzberg JB, Schwartzberg HA. Cutis 2000; 66: 291–3.

Three patients treated successfully with topical retinoids. Two brothers were treated with tretinoin 0.025% gel once daily with marked improvement or clearance at 7 to 8 weeks. Topical tretinoin 0.01% gel once daily was used by the third patient. There was a marked improvement after 6 weeks and complete resolution in 10 weeks.

Confluent and reticulated papillomatosis: response to tazarotene

Bowman PH, Davis LS. J Am Acad Dermatol 2003; 48: S80–1.

Treatment with 0.1% tazarotene gel was initiated twice daily. A noticeable decrease in pigmentation and plaques occurred in 1 week, and within 2 months the eruption had completely resolved. There was no recurrence at 9 months.

Confluent and reticulated papillomatosis (Gougerot- Carteaud): report of a case successfully treated with tazarotene

Gallo L, Ayala F, Lembo S, Mansueto G. *G Ital Dermatol Venereol* 2006; 141: 529–32.

Eleven-year-old girl was treated with tazarotene 0.05% gel twice daily, and within 2 months the lesions had completely regressed.

Tacrolimus in confluent and reticulated papillomatosis of Gougerot Carteaud

Tirado-Sanchez A, Ponce-Olivera RM. *Int J Dermatol* 2013; 52: 513–4.

Eighteen-year-old female patient developed CARP recurrence after completion of minocycline treatment. She was retreated with tacrolimus 0.1% ointment for 3 months twice per day with good response and control of recurrence 2 months after withdrawal.

Confluent and reticulated papillomatosis: treatment with topical calcipotriol

Gulec AT, Seckin D. *Br J Dermatol* 1999; 14: 1150–1.

A 34-year-old female patient treated with topical calcipotriol ointment (50 mcg/g) twice daily at a dose of less than 100 g per week. Complete response noted in 4 weeks and no recurrence at 11-month follow-up.

Confluent and reticulated papillomatosis: response to topical calcipotriol

Kürkçüoğlu N, Çelebi CR. *Dermatology* 1995; 191: 341–2.

Twenty-five-year-old patient started on calcipotriol ointment 50 mcg/g twice daily. Clearance of lesions noted after 1 month of treatment.

Confluent and reticulated papillomatosis (Gougerot-Carteaud) successfully treated with topical tacalcitol

Ginarte M, Fabeiro JM, Toribio J. *J Dermatolog Treat* 2002; 13: 27–30.

Fourteen-year-old patient with CARP and *Malassezia furfur* infection eliminated with antifungal, but skin eruption remained. She was treated with topical tacalcitol twice daily for 6 weeks without relapse after 8 months, follow-up.

Calcipotriol treatment of confluent and reticulated papillomatosis (Gougerot-Carteaud syndrome)

Carrozzo AM, Gatti S, Ferranti G, Primavera G, Vidolin AP, Nini G. J Eur Acad Dermatol Venereol 2000; 14: 131–3.

Topical calcipotriol 0.005% ointment was used twice per day for 3 weeks with marked improvement.

Two different therapeutic choices in confluent and reticulated papillomatosis

Patrone P, Trotter D, Stinco G. G Ital Dermatol Venereol 2004; 139: 499–503.

Remission achieved with calcipotriol ointment 0.005% applied twice daily for a period of 3 months. No known recurrence occurred in either.

Successful treatment of confluent and reticulated papillomatosis with topical mupirocin

Gonul M, Cakmak SK, Soylu S, Kilic A, Gul U, Ergul G. J Eur Acad Dermatol Venereol 2008; 22: 1140–2.

Nineteen-year-old patient treated with mupirocin 2% ointment for 1 month with improvement in CARP lesions.

Gougerot-Carteaud syndrome treated with 13-cis-retinoic acid

Carlin N, Marcus LS, Carlin R. J Clin Aesthet Dermatol 2010; 3: 56–7.

Case report of patient treated with daily isotretinoin 1 mg/kg for 20 weeks with excellent response after CARP recurrence after minocycline treatment.

Confluent and reticulated papillomatosis: favourable response to low-dose isotretinoin

Erkek, E, Ayva S, Atasoy P, Emeksiz MC. J Eur Acad Dermatol Venereol 2009; 23: 1342–3.

Forty-eight-year-old female patient treated with isotretinoin 20 mg (0.25 mg/kg) on alternate days. Favorable response was witnessed within 4 weeks, and treatment was terminated at the eighth week when the patient was virtually free of cutaneous lesions. The patient also experienced alleviation of pruritus.

Confluent and reticulated papillomatosis: response to high dose oral isotretinoin therapy and reassessment of epidemiologic data

Lee MP, Stiller MJ, McClain SA, Shupack JL, Cohen DE. J Am Acad Dermatol 1991; 31: 327–31.

Confluent and reticulated papillomatosis: response to isotretinoin

Hodge JA, Ray MC. J Am Acad Dermatol 1991; 24: 654.

Two patients with confluent and reticulated papillomatosis: response to oral isotretinoin and 10% lactic acid lotion

Solomon BA, Laude TA. J Am Acad Dermatol 1996; 35: 645–6.

These are single reports of oral isotretinoin used at 0.5 to 1 mg/kg/day for up to 4 months with remission in most.

Confluent and reticulated papillomatosis. Treatment with etretinate

Baalbaki SA, Malak JA, al-Khars MA. Arch Dermatol 1993; 129: 961–3.

Reported response of CARP to etretinate (0.25–0.4 mg/kg per day for 1 month) in five adult men who had been previously treated with ketoconazole without success.

Cryopyrin-associated periodic syndromes (CAPS)

Alexander Marsland

Cryopyrin-associated periodic syndrome (CAPS) is a rare genetic condition characterized by urticarial rashes, fever, fatigue, articular involvement, and inflammation, which, if left untreated, may result in the long term in irreversible end organ damage. It encompasses a spectrum of conditions previously thought to be separate entities

before inflammasome genetics were better understood at a molecular level. These conditions are familial cold autoinflammatory syndrome (FCAS), Muckle–Wells syndrome (MWS), and chronic infantile neurological cutaneous and articular syndrome (CINCA), and their overlaps (FCAS-MWS and MWS-CINCA).

CAPS is caused by gain-of-function mutations in *NLRP3*, leading to a persistently active inflammatory state. This leads to rashes, conjunctivitis, and articular involvement that are typically triggered by cold exposure. Patients who have more severe involvement may also have sensorineural hearing loss, visual loss, chronic meningitis, and amyloidosis. Treatment of CAPS aims to suppress this inflammatory state, thus reducing symptoms, improving functionality, and preventing end organ damage.

Management Strategy

Early diagnosis and aggressive treatment of CAPS are essential in suppressing inflammatory symptoms and preventing end organ damage. Early CAPS-specific symptoms may be reversible if treatment is commenced expediently. Some manifestations of severe disease such as bone deformities and bony overgrowth may be irreversible.

Symptoms may be present from birth or, in milder forms, may not become apparent until childhood or even early adulthood. Diagnosis is complicated by the fact that, even if molecular genetic analysis of *NLRP3* is available, gain-of-function mutations cannot always be demonstrated; thus expert referral may be indicated to confirm diagnosis on clinical grounds. A model proposed for the diagnosis of CAPS includes one mandatory criterion (raised C-reactive protein [CRP] or serum amyloid A [SAA]) plus at least two of six CAPS-typical symptoms (urticarial rash, cold/stress-triggered episodes, sensorineural hearing loss, musculoskeletal symptoms, chronic aseptic meningitis, and skeletal signs such as frontal bossing or epiphyseal overgrowth).

CAPS is best managed by a multidisciplinary team in a tertiary center with expertise in autoinflammatory disease (AID), where there is access to genetic counseling and psychosocial support. Patients should also have appropriate access to adjunct therapies such as hearing aids, orthotic aids, and physiotherapy. The mainstay of medical management is with drugs that block interleukin 1 (IL-1).

Once a diagnosis has been made, it is important to commence this treatment as soon as possible to prevent complications. During symptomatic flares, short courses of nonsteroidal antiinflammatory drugs (NSAIDs) or oral corticosteroids may be used as adjunct therapy. During flares/inflammatory episodes in patients whose symptoms are normally controlled, infections and other causes of inflammation unrelated directly to CAPS itself must also be considered.

Three IL-1 blockers are currently used to treat CAPS: anakinra, canakinumab, and rilonacept. All are administered as subcutaneous injections. Anakinra is a recombinant IL-1 receptor antagonist that is usually given daily; canakinumab is a human monoclonal antibody targeted at IL-1 beta that has a much longer half-life and is usually given every 8 weeks; and rilonacept, usually administered weekly, is a fusion protein consisting of the binding domains of IL-1 receptor and its accessory protein linked to the Fc portion of human IgG1. All three drugs currently have U.S. Food and Drug Administration (FDA) approval for use in CAPS, whereas European Medicines Agency (EMA) approval only currently exists (January 2017) for anakinra and canakinumab.

Side effects associated with IL-1 blockers include injection-site reactions and an increased propensity to infections such as upper and lower respiratory tract infections, gastroenteritis, sinusitis, and ear infections. Headaches and arthralgia, both symptoms of severe CAPS, may also be side effects associated with IL-1 blockers. Vaccinations with killed vaccines are recommended, as with other biologics, due to the immunosuppressive action of IL-1 blockers.

Anakinra is given at a starting dose of 100 mg daily (adults) or 0.5 to 2 mg/kg/day (children). Some patients require higher doses, however: adults may need treatment during flares of 100 mg twice daily, and doses as high as 8 mg/kg/day have been reported to be required in some children.

Canakinumab is started at 150 mg every 8 weeks (adults) or 2 mg/kg every 8 weeks (children), but some patients require dose escalation to 600 mg every 8 weeks (adults) or up to 8 mg/kg every 8 weeks (children).

Rilonacept has been used at 160 mg weekly or 2.2 mg/kg in adults and children with MWS and FCAS. It is FDA approved for patients with MWS and FCAS 12 years and older. The marketing authorization holder voluntarily withdrew the European marketing

authorization in 2012, citing commercial reasons.

Specific Investigations

- CRP and SAA to demonstrate raised inflammatory state in diagnosis and monitor treatment efficacy
- Genetic testing for *NLRP3* mutations to confirm diagnosis (although mutations may not be apparent in some patients due to mosaicism)

Monitoring

- Full general physical examination, including ophthalmologic examination
- Audiologic testing
- Urinalysis for protein
- Growth monitoring in children
- Laboratory evidence of inflammatory activity with CRP and SAA
- Quality of life using a validated tool such as Dermatology Life Quality Index (DLQI) or Children's Dermatology Life Quality Index (CDLQI)
- Disease activity using a validated tool such as MWS-DAS or AIDAI
- End organ damage using scoring system such as autoinflammatory disease damage index (ADDI)

In patients with severe disease consider

- Cognitive testing
- Radiologic imaging of brain, inner ear, and bones
- Lumbar puncture for investigation of aseptic meningitis

First-Line Therapies

• Anakinra	B
• Canakinumab	A
• Rilonacept	A

Recommendations for the management of autoinflammatory diseases

ter Haar NM, Oswald M, Jeyaratnam J, Anton J, Barron KS, Brogan PA, et al. *Ann Rheum Dis* 2015; 74: 1636–44.

Guidelines for treatment of autoinflammatory diseases, including CAPS, developed by an international consensus committee after a systematic literature review.

Efficacy and safety of anakinra therapy in pediatric and adult patients with the autoinflammatory Muckle-Wells syndrome

Kuemmerle-Deschner JB, Tyrrell PN, Koetter I, Wittkowski H, Bialkowski A, Tzaribachev N, et al. *Arthritis Rheum* 2011; 63: 840–9.

Observational study of 12 patients (5 children and 7 adults) with severe MWS showed excellent responses in all patients within 2 weeks, with sustained improvement over the observational period of 5 to 14 months (median 11 months). Improvement in hearing loss was seen in two patients.

Sustained response and prevention of damage progression in patients with neonatal-onset multisystem inflammatory disease treated with anakinra: a cohort study to determine 3- and 5-year outcomes

Sibley CH, Plass N, Snow J, Wiggs EA, Brewer CC, King KA, et al. *Arthritis Rheum* 2012; 64: 2375–86.

Observational study of 26 patients (adults and children) with CINCA receiving anakinra over 3 to 5 years. Dose escalation was

described in some patients. Damage progression in eye, ear, and CNS was prevented, but bony lesions progressed.

Long-term safety profile of anakinra in patients with severe cryopyrin-associated periodic syndromes

Kullenberg T, Löfqvist M, Leinonen M, Goldbach-Mansky R, Olivecrona H. *Rheumatology* (Oxford, England) 2016; 55: 1499–1506.

Prospective open-label study of 43 patients with severe CAPS treated for up to 5 years, in which 14 patients experienced 24 serious adverse events, such as pneumonia and gastroenteritis, all of which resolved during the study period and did not result in discontinuation of the drug. Continued anakinra treatment during infective episodes did not appear to complicate their course and prevented complications of CAPS.

Anakinra use during pregnancy in patients with cryopyrin-associated periodic syndromes (CAPS)

Chang Z, Spong CY, Jesus AA, Davis MA, Plass N, Stone DL, et al. *Arthritis Rheumatol* 2014; 66: 3227–32.

Observational study of nine women who had 1 to 4 pregnancies (total 24) while on anakinra for all forms of CAPS. There were no serious complications of pregnancy or preterm births reported. A twin pregnancy in which dose escalation occurred resulted in the demise of one twin (who carried the CAPS mutation) due to renal agenesis.

Use of canakinumab in the cryopyrin-associated periodic syndrome

Lachmann HJ, Kone-Paut I, Kuemmerle-Deschner JB, Leslie KS, Hachulla E, Quartier P, et al. *N Engl J Med* 2009; 360: 2416–25.

Randomized, double-blind, placebo-controlled withdrawal study after an open run-in period demonstrated 34 of 35 patients aged 4 to 75 years with CAPS associated with an *NLRP3* mutation had complete response to treatment. Disease flares occurred in 13 of 16 patients receiving placebo, whereas all 15 patients who received canakinumab remained in remission during the withdrawal phase of the study.

Real-life effectiveness of canakinumab in cryopyrin-associated periodic syndrome

Kuemmerle-Deschner JB, Hofer F, Endres T, Kortus-Goetze B, Blank N, Weissbarth-Riedel E, et al. *Rheumatology* (Oxford) 2016; 55: 689–96.

Observational study of 68 patients (27 children, 41 adults) with all types of CAPS who had received canakinumab with a median follow-up of 28 months. Seventy-two percent of patients achieved complete remission, and 53% achieved this with a standard dose alone. Overall, up dosing was more frequent in children and a complete response more frequent in less severely affected patients.

Efficacy and safety of rilonacept (interleukin-1 Trap) in patients with cryopyrin-associated periodic syndromes: results from two sequential placebo-controlled studies

Hoffman HM, Throne ML, Amar NJ, Sebai M, Kivitz AJ, Kavanaugh A, et al. *Arthritis Rheum* 2008; 58: 2443–52.

Forty-seven patients with *NLRP3* mutations and symptoms of CAPS underwent a 6-week trial of weekly 160-mg rilonacept injections versus placebo in a randomized double-blinded trial. A second study followed, which consisted of 9 weeks of single-blind treatment. Eighty-seven percent of patients who received rilonacept achieved at least 50% reduction in key symptom score versus 8% who received placebo.

Long-term efficacy and safety profile of rilonacept in the treatment of cryopyrin-associated periodic syndromes: results of a 72-week open-label extension study

Hoffman HM, Throne ML, Amar NJ, Cartwright RC, Kivitz AJ, Soo Y, et al. *Clin Ther* 2012; 34: 2091–103.

A total of 101 patients were studied, including 44 of the 47 patients who were involved in the phase III studies described earlier. All had *NLRP3* gene mutations. The improvements seen after 6 weeks of treatment with rilonacept were shown to be present in the observation period of up to 96 weeks after treatment, with persistence of normalization of biomarkers seen for up to 48 weeks after treatment.

Second-Line Therapy

Some patients show symptomatic improvement with nonsteroidal

antiinflammatory drugs (NSAIDs) and oral corticosteroids as adjunct therapy (in association with IL-1 blockers described earlier).

Monotherapy with NSAIDs and oral corticosteroids was used before the advent of IL-1 blockers with limited success; due to the potential disease-modifying ability of IL-1 blockers and the lack of evidence for corticosteroids/NSAIDs (and long-term side effect profile of corticosteroids), this is not recommended.

Second-Line Therapies

• NSAIDs	D
• Oral corticosteroids	D

Treatment of autoinflammatory diseases: results from the Eurofever Registry and a literature review

Ter Haar N, Lachmann H, Özen S, Woo P, Uziel Y, Modesto C, et al. Ann Rheum Dis 2013; 72: 678–85.

Analysis of 94 patients with CAPS on the Eurofever Registry found that NSAIDs and corticosteroids were beneficial in 19/24 and 25/36 patients already receiving IL-1 blockers. Four patients receiving NSAIDs alone showed partial response, and one was reported to have complete response. One patient had partial response to corticosteroids alone. Two patients had partial response to NSAIDs and corticosteroids.

Cryptococcosis

Wanda Sonia Robles, and Mahreen Ameen

Cryptococcosis is a systemic mycosis acquired by the respiratory route with the primary focus of infection in the lungs. It is caused by yeasts associated with avian feces of which there are two species: *Cryptococcus neoformans* and *C. gattii*. *C. neoformans* occurs worldwide, and *C. gattii* is restricted mainly to subtropical regions and usually affects immunocompetent hosts. Pulmonary infection is often asymptomatic and self-limiting. Hematogenous dissemination typically involves the central nervous system (CNS), causing meningitis. Dissemination to the skin occurs in 10% to 15% of cases and produces a variety of lesions, including flesh-colored or erythematous papules and nodules. In the immunocompromised individual, molluscum contagiosum-like and acneiform lesions occur, particularly affecting the face. Cryptococcal cellulitis with necrotizing

vasculitis can mimic bacterial cellulitis and occurs more commonly in the immunocompromised patient.

With the global emergence of AIDS, the incidence of cryptococcosis is increasing, and it represents the most common invasive mycosis in advanced HIV infection. With HIV coinfection, the disease is characteristically widespread, affecting the lungs, meninges, skin, bone marrow, and genitourinary tract, including the prostate. In the era of highly active antiretroviral therapy (HAART), the overall survival after cryptococcosis has dramatically improved: immune restoration and low serum cryptococcal antigen titers are associated with lower cryptococcosis relapse rates. However, a subset of HIV-infected individuals commenced on HAART is at risk of immune reconstitution inflammatory syndrome (IRIS)–associated cryptococcosis that can be severe. Other immunosuppressed patients also at risk of cryptococcosis include solid organ transplant recipients, those with hematologic malignancies, and those on long-term immunosuppressive therapy, including corticosteroids and anti-tumor necrosis factor- α therapies. There are also increased reports of infections associated with biologic therapies.

Management Strategy

Cryptococcal infection left untreated is fatal. Treatment depends on disease extent and predisposing factors, particularly AIDS or any other immunosuppressive state. The recommended treatment in the immunocompetent individual with symptomatic nonmeningeal infection is fluconazole 200 to 400 mg daily for 3 to 6 months. An alternative is itraconazole 200 to 400 mg daily for 6 to 12 months. More severe nonmeningeal infection is treated with amphotericin B (AmB) 0.5 to 1.0 mg/kg daily for 6 to 10 weeks. Meningeal infection in the immunocompetent or non-HIV immunocompromised is treated with AmB 0.7 to 1.0 mg/kg daily plus 5-flucytosine 100 mg/kg daily for 2 weeks followed by fluconazole 400 mg daily for a minimum of 10 weeks (up to 6 to 12 months depending on the clinical status of the patient).

Cryptococcal disease with HIV always requires treatment. For nondisseminated infection, fluconazole (200–400 mg daily) is given or itraconazole (200–400 mg daily) as an alternative. More severe infection is treated with a combination of fluconazole (400 mg daily) and flucytosine (100–150 mg daily) for 10 weeks followed by

fluconazole maintenance therapy (200 mg daily). Cryptococcal meningitis with HIV is treated with AmB (0.7–1.0 mg/kg daily) and flucytosine (100 mg/kg daily) for a 2- to 10-week induction period followed by fluconazole maintenance therapy, or alternatively with fluconazole (400–800 mg daily) and flucytosine (100–150 mg/kg daily) for 6 weeks. The lipid formulation of AmB can be used instead in those with impaired renal function. There is now trial data suggesting that it is safe to discontinue maintenance therapy in patients treated for cryptococcal meningitis receiving HAART, provided the CD4 count increases to an excess of 100 cells/ μ L.

The extended-spectrum azoles (posaconazole and voriconazole) may have a role in salvage situations. The echinocandins have no *in vivo* activity against *Cryptococcus* species.

Dexamethasone as adjunctive therapy did not reduce mortality in HIV-associated cryptococcal meningitis.

Specific Investigations

- Direct microscopy
- Culture
- Cryptococcal antigen test (by latex agglutination or enzyme-linked immunosorbent assay [ELISA])
- Histology (Mayer mucicarmine and Masson–Fontana silver stains used to identify *C. neoformans*)
- Pulmonary and brain imaging studies
- Serology for HIV

India ink examination of cerebrospinal fluid (CSF), pus, skin scrapings, and other fluids may demonstrate the yeast. Culture of skin, CSF, blood, sputum, urine, or bone marrow enables confirmation. The cryptococcal antigen test (on CSF, blood, and urine) is sensitive and specific, and it can be used after therapy response. In tissue specimens, *C. neoformans* is difficult to visualize with routine hematoxylin and eosin stains, requiring the use of special stains.

Cryptococcal disease and HIV infection

Waters L, Nelson M. Expert Opin Pharmacother 2005; 6: 2633–44.

This article reviews the epidemiology, clinical features, and management of cryptococcal disease in HIV-infected patients. It focuses particularly on current guidelines and future developments in

antifungal therapy.

Adjunctive dexamethasone in HIV-associated cryptococcal meningitis

Beardsley J, Wolbers M, Kibengo FM, Ggayi AB, Kamali A, Cuc NT, et al. N Engl J Med 2016; 374: 542–54.

A double-blind, randomized, placebo-controlled trial. This trial was stopped for safety reasons and after enrollment of 451 patients. Mortality was reported as 47% in the dexamethasone group and 41% in the placebo group by 10 weeks. The study concluded that dexamethasone did not reduce mortality among patients with HIV-associated cryptococcal meningitis. It was indeed associated with more adverse events and disability was than placebo.

First-Line Therapies

• Amphotericin	B
• Amphotericin B plus flucytosine	B
• Fluconazole	B

Treatment of cryptococcosis in the setting of HIV coinfection

Khawcharoenporn T, Apisarnthanarak A, Mundy LM. Expert Rev Anti Infect Ther 2007; 5: 1019–30.

This review discusses evidence-based treatment algorithms that exist for the use of antifungal drugs, as well as the importance of maintaining normal intracranial pressure in HIV-infected hosts with cryptococcal meningitis. The suggest that further studies are required for the management of refractory infection, cryptococcosis-related immune reconstitution syndrome, and the role of adjuvant therapies. Primary and secondary prevention strategies remain at the crux of global control strategies for cryptococcal disease.

Epidemiology and management of cryptococcal meningitis: developments and challenges

Pukkila-Worley R, Mylonakis E. *Expert Opin Pharmacother* 2008; 9: 551–60.

This article examines developments in the management of cryptococcal meningitis, including new antifungal agents and new strategies for controlling elevated intracranial pressure.

Cryptococcosis in human immunodeficiency virus-negative patients in the era of effective azole therapy

Pappas PG, Perfect JR, Cloud GA, Larsen RA, Pankey GA, Lancaster DJ, et al. *Clin Infect Dis* 2001; 33: 690–9.

A multicenter case study of HIV-negative patients with cryptococcosis from 1990 to 1996. Of 306 patients, there were 109 with pulmonary involvement and 157 with CNS involvement. Patients with pulmonary disease were usually treated with fluconazole (63%), and patients with CNS disease usually received AmB (92%). Two thirds of these patients also received fluconazole for consolidation therapy. Therapy was reported as successful in 74% of patients. The mortality attributable to cryptococcosis was 12%.

Clinical and epidemiological features of 123 cases of cryptococcosis in Mato Grosso do Sul, Brazil

Lindenberg Ade S, Chang MR, Paniago AM, Lazéra Mdos S, Moncada PM, Bonfim GF, et al. *Rev Inst Med Trop Sao Paulo* 2008; 50: 75–8.

In this study, 84.5% (104/123) of patients had HIV infection, 4.9% (6/123) had other predisposing conditions, and 10.6% (13/123) were immunocompetent. There was CNS involvement in 83.7% (103/123); 89.6% were infected with *C. neoformans* and 10.4% with *C. gattii*. For treatment AmB was the drug of choice in 86% (106/123), followed by fluconazole in 60% (57/123).

This cohort of patients typifies features of this infection found in other study cohorts.

Combination antifungal therapies for HIV-associated cryptococcal meningitis: a randomised trial

Brouwer AE, Rajanu Wong A, Chierakul W, Griffin GE, Larsen RA, White NJ, et al. *Lancet* 2004; 363: 1764–7.

This controlled trial assessed the fungicidal activity of combinations of AmB, flucytosine, and fluconazole for the treatment of cryptococcal meningitis. Sixty-four patients with a first episode of HIV-associated cryptococcal meningitis were randomized to initial treatment with

AmB (0.7 mg/kg daily); AmB plus flucytosine (100 mg/kg daily); AmB plus fluconazole (400 mg daily); or triple therapy with AmB, flucytosine, and fluconazole. Results demonstrated that clearance of cryptococci from the CSF was exponential and significantly faster with AmB and flucytosine dual therapy than with any other drug combination.

Primary cutaneous cryptococcosis in Brazil: report of 11 cases in immunocompetent and immunosuppressed patients

Marques SA, Bastazini Jr I, Martins AL, Barreto JA, Barbieri D'Elia MP, Lastória JC, et al. Int J Dermatol 2012; 51: 780–4.

Eleven cases confirmed by culture had atypical clinical features with infiltrative and tumoral lesions. All cases responded to fluconazole 400 mg daily.

Primary cutaneous infection is very rare and is often, but not always, associated with underlying immunosuppression.

Cutaneous cryptococcosis in solid organ transplant recipients

Sun HY, Alexander BD, Lortholary O, Dromer F, Forrest GN, Lyon GM, et al. Med Mycol 2010; 48: 785–91.

Fluconazole and lipid formulations of AmB were used to treat localized and disseminated disease, respectively. The outcomes in both groups were comparable.

This study described cutaneous cryptococcosis representing disseminated infection in transplant recipients with preferential involvement of the extremities.

Successful use of amphotericin B lipid complex in the treatment of cryptococcosis

Baddour LM, Perfect JR, Ostrosky-Zeichner L. Clin Infect Dis 2005; 40: S409–13.

The efficacy and renal safety of AmB lipid complex (ABLC) were assessed in 106 patients, 83 (78%) of whom had CNS infection. Twenty-seven received concomitant azole therapy. Sixty-six percent of evaluable patients (67/101) achieved clinical response (cured or improved). Response rates with and without CNS infection were 65% (51/78) and 70% (16/23), respectively, and for patients with HIV infection it was 58% (30/52). A mean serum creatinine level decrease of 0.02 mg/dL occurred. ABLC was an effective treatment for cryptococcal infection in immunocompromised patients.

High-dose amphotericin B with flucytosine for the treatment of cryptococcal meningitis in HIV-infected patients: a randomized trial

Bicanic T, Wood R, Meintjes G, Rebe K, Brouwer A, Loyse A, et al. Clin Infect Dis 2008; 47: 123–30.

In this study from South Africa, 64 HIV-seropositive, antiretroviral therapy-naïve patients with a first episode of cryptococcal meningitis were randomized to receive either AmB 0.7 mg/kg/day plus flucytosine 25 mg/kg four times daily ($n=30$) or AmB 1 mg/kg daily plus flucytosine 25 mg/kg four times daily ($n=34$). Both regimens were given for 2 weeks followed by oral fluconazole. The primary outcome measure was early fungicidal activity determined by CSF cryptococcal cultures. Early fungicidal activity was significantly greater for the first regimen. The 10-week mortality rate was 24%, with no difference between groups.

Second-Line Therapies

• Itraconazole	B
• Flucytosine plus fluconazole	C
• Voriconazole	B

The efficacy of fluconazole 600 mg/day versus itraconazole 600 mg/day as consolidation therapy of cryptococcal meningitis in AIDS patients

Mootsikapun P, Chetchotisakd P, Anunnatsiri S, Choksawadphinyo K. J Med Assoc Thai 2003; 86: 293–8.

In this trial, HIV-infected patients with primary cryptococcal meningitis who had been treated with AmB for 2 weeks were randomized to receive either fluconazole 600 mg daily or itraconazole 600 mg daily for 10 weeks. The results demonstrated equal efficacy of both of these regimens. In addition, the results suggested that the higher-dose regimens may be superior to treatment regimens using

lower doses of these medications.

Voriconazole treatment for less-common, emerging, or refractory fungal infections

Perfect JR, Marr KA, Walsh TJ, Greenberg RN, DuPont B, de la Torre-Cisneros J, et al. Clin Infect Dis 2003; 36: 1122–31.

A multicenter, controlled clinical trial to assess the efficacy, tolerability, and safety of voriconazole as salvage treatment for patients with refractory and intolerant-to-treatment fungal infections, as well as primary treatment for patients with infections for which there is no approved treatment. The efficacy rate for voriconazole in the treatment of cryptococcosis was 38.9%. Voriconazole was reported to be well tolerated, and discontinuation of treatment was observed in less than 10% of patients.

Third-Line Therapies

Recombinant interferon-gamma 1b as adjunctive therapy for AIDS-related acute cryptococcal meningitis

Pappas PG, Bustamante B, Ticona E, Hamill RJ, Johnson PC, Reboli A, et al. J Infect Dis 2004; 189: 2185–91.

This was a phase II, double-blind, placebo-controlled study to evaluate the safety and antifungal activity of adjuvant recombinant interferon (rIFN)-gamma 1b in patients with AIDS and acute cryptococcal meningitis. Patients received 100 or 200 µg of rIFN-gamma 1b or placebo thrice weekly for 10 weeks, plus standard therapy with AmB, with or without flucytosine, followed by fluconazole. Among 75 patients, 2-week culture conversion occurred in 13% of placebo recipients, 36% of rIFN-gamma 1b (100 µg) recipients, and 32% of rIFN-gamma 1b (200 µg) recipients. There was improved combined mycologic and clinical success in rIFN-gamma 1b recipients (26% vs. 8%; $p=0.078$), and therapy was well tolerated.

This study suggests a role for adjuvant therapies.

Guidelines

Clinical practice guidelines for the management of cryptococcal disease: 2010 update by the Infectious Diseases Society of

America

Perfect JR, Dismukes WE, Dromer F, Goldman DL, Graybill JR, Hamill RJ, et al. Clin Infect Dis 2010; 50: 291–322.

These updated guidelines emphasize that control of host immunity, the site of infection, antifungal drug toxicity, and underlying disease are still the most critical factors for the successful management of cryptococcosis. The management strategy for cryptococcal disease is organized under four major headings with additional subdivisions: treatment of meningoencephalitis (in HIV-infected individuals, transplant recipients, and others); treatment of nonmeningeal cryptococcosis (pulmonary and extrapulmonary sites); complications during treatment (including IRIS and relapse); and cryptococcosis in special clinical situations (pregnancy, children, resource-limited regions, and *C. gattii* infections).

The recommended treatment for immunosuppressed and immunocompetent patients with mild to moderate nonmeningeal cryptococcosis is fluconazole 400 mg daily for 6 to 12 months. The treatment of choice for patients with HIV infection and cryptococcal meningitis is induction therapy with parenteral AmB 0.7 to 1.0 mg/kg daily plus oral flucytosine 100 mg/kg daily for 2 weeks, followed by fluconazole 400 mg daily for a minimum period of 8 weeks. Amphotericin B in lipid formulations can be used for patients with renal impairment. It is recommended that all HIV-infected individuals receive prophylaxis against cryptococcosis and that this be continued for life. Fluconazole 200 mg daily is given or itraconazole 200 mg twice daily in those unable to tolerate fluconazole.

Cutaneous candidiasis and chronic mucocutaneous candidiasis

Caroline Halverstad, and Steven R. Cohen

Cutaneous candidiasis

Cutaneous candidiasis is typically caused by *Candida albicans*, which exists as normal flora of human skin as well as in the gastrointestinal and genitourinary systems. Overgrowth of *Candida* species is

suppressed by normal bacterial flora. Other *Candida* species occasionally cause mucocutaneous infections, the second most common being *Candida tropicalis*. Under certain conditions, these *Candida* species overgrow and become pathogens. Warmth and moisture of the intertriginous skin (axilla, inguinal folds, abdominal creases, inframammary creases), an increased skin pH, and the administration of antibiotics can disrupt the normal bacterial flora, allowing *Candida* to proliferate. Clinically, candidiasis presents as scaly erythematous patches with satellite papules and pustules. The diagnosis is made either microscopically, with a potassium hydroxide (KOH) preparation revealing spores and pseudohyphae, or by culture.

Management Strategy

Topical antifungal agents include, but are not limited to, polyenes, azoles, allylamines, and ciclopirox olamines. Most studies required therapy twice daily for 4 weeks to ensure complete clearance in all patients. Notably, microscopic cure was often present before complete clinical clearance.

Topical corticosteroids are a source of controversy. Although the addition of corticosteroids to local antifungal therapy may reduce local inflammation in acute candidiasis, their use should be limited to 1 or 2 days because of their immunosuppressant properties.

Systemic therapy may be appropriate for cutaneous infections in immunosuppressed patients, in the setting of extensive disease not responding to topical therapy, or in patients noncompliant with topical therapy. Fluconazole 150 mg weekly appears to be as efficacious as fluconazole 50 mg daily. As in topical therapy, microscopic cure often precedes complete clinical clearance. Since 2013, the Food and Drug Administration (FDA) has removed the indication for oral ketoconazole to be used in *Candida* and dermatophyte infections due to the risk of severe hepatotoxicity and adrenal insufficiency.

Specific Investigations

- KOH
- Culture

First-Line Therapies

• Topical antifungal	A
• Topical antifungal combined with topical corticosteroids	A

The efficacy and safety of sertaconazole cream in diaper dermatitis

Bonifaz A, Tiredo-Sanchez A, Graniel MJ, Mena C, Valencia A, Ponce-Olivera RM. Mycopathologia 2013; 175: 249–54.

Twenty-seven patients with a clinical and mycologic diagnosis of candida diaper dermatitis were treated twice daily for 2 weeks with sertaconazole. Eighty-nine percent of patients showed a clinical and mycologic cure by the end of 4 weeks (2 weeks after treatment ended).

A multicenter, open-label study to assess the safety and efficacy of ciclopirox topical suspension 0.77% in the treatment of diaper dermatitis due to *Candida albicans*

Gallup E, Plott T. J Drugs Dermatol 2005; 4: 29–34.

A multicenter, open-label study that included 44 male and female subjects aged 6 to 29 months with diaper dermatitis due to *C. albicans*. The study medication was applied topically to the affected area twice daily for 1 week. The results showed a statistically significant improvement in both the rate of mycologic cure and the reduction of severity score.

Topical treatment of dermatophytosis and cutaneous candidiasis with flutrimazole 1% cream: double-blind randomized comparative trial with ketoconazole 2% cream

Del Palacio A, Cuetara S, Perez A, Garau M, Calvo T, Sánchez-Alor G. Mycoses 1999; 42: 649–55.

A double-blind, randomized study in which the efficacy and tolerance of flutrimazole 1% cream was compared with ketoconazole 2% cream, applied once daily for 4 weeks, in 60 patients with culture-proven dermatophytosis (47 patients) or cutaneous candidiasis (13 patients). The results of this study showed that flutrimazole 1% cream

is as safe and effective as ketoconazole 2% cream for *Candida* and dermatophyte skin infections.

Naftifine cream in the treatment of cutaneous candidiasis

Zaias N, Astorga E, Cordero CN, Day RM, de Espinoza ZD, DeGryse R, et al. *Cutis* 1988; 42: 238–40.

In a double-blind, parallel-group clinical trial, 60 patients with cutaneous candidiasis were randomly assigned to receive naftifine cream 1% or its vehicle twice a day for 3 weeks. Two weeks after the end of therapy, 77% of the naftifine-treated patients were mycologically cured (negative results on KOH preparations and culture) and had no clinically apparent disease, compared with only 3% of patients treated with vehicle alone.

A comparison of nystatin cream with nystatin/triamcinolone acetonide combination cream in the treatment of candidal inflammation of the flexures

Beveridge GW, Fairburn E, Finn OA, Scott OL, Stewart TW, Summerly R. *Curr Med Res Opin* 1977; 4: 584–7.

In a multicenter, double-blind trial, 31 patients with bilateral candidal lesions of the flexures were treated for 14 days with nystatin cream on one side and with a combination of nystatin and triamcinolone acetonide cream on the other side. Both treatments proved equally effective in terms of mycologic cure rate and clinical improvement. There was a weak trend by both patients and physicians to favor the combination preparation because symptoms resolved more rapidly.

Second-Line Therapy

• Systemic azoles	B
-------------------	----------

Prospective aetiological study of diaper dermatitis in the elderly

Foureur N, Vanzo B, Meaume S, Senet P. *Br J Dermatol* 2006; 155: 941–6.

Of 46 patients, all over 85 years of age with dermatitis of the diaper area, 24 were identified as candidiasis. Of these, 8 (33%) were cured after 1 month of topical bifonazole therapy, 3 (12.5%) improved, and 13 (54%) were cured after the addition of oral fluconazole 100 mg once daily for 1 month. Although topical antifungal drugs represent the first line of treatment for diaper dermatitis in the elderly, more than half the patients in this study required an oral antifungal to achieve a complete cure.

A comparison of the efficacy of oral fluconazole, 150 mg/week versus 50 mg/day, in the treatment of tinea corporis, tinea cruris, tinea pedis, and cutaneous candidosis

Nozickova M, Koudelkova V, Kulikova Z, Malina L, Urbanowski S, Silny W. Int J Dermatol 1998; 37: 703–5.

Patients received either fluconazole 150 mg/week or 50 mg/day until clinically cured or for a maximum of 4 weeks. Of the patients in this study with candidiasis, 10 of 11 patients receiving fluconazole 150 mg weekly had a positive response (microscopic cure with marked clinical improvement) and 12 of 13 taking fluconazole 50 mg daily had a positive response. Thus weekly treatment was determined to be equivalent to daily dosing.

Clinical trials and double-blind studies of oral antifungals for cutaneous candidiasis are sparse.

Third-Line Therapies

• Lavender oil	E
• Topical mupirocin	C

Antifungal activity of *Lavandula angustifolia* essential oil against *Candida albicans* yeast and mycelial form

D'Auria FD, Tecca M, Strippoli V, Salvatore G, Battinelli L, Mazzanti G. Med Mycol 2005; 43: 391–6.

The antifungal activity of the essential oil of *Lavandula angustifolia* (lavender oil) and its main components, linalool and linalyl acetate, was studied. Lavender oil showed both fungistatic and fungicidal activity against *C. albicans* strains.

Perianal candidosis: a comparative study with mupirocin and nystatin

De Wet PM, Rode H, Van Dyk A, Millar AJ. Int J Dermatol 1999; 38: 618–22.

This clinical trial compared the efficacy and clinical outcome of 2% mupirocin in a polyethylene glycol base and nystatin cream for the treatment of diaper candidiasis. Eradication of all *Candida* organisms was achieved within 2 to 6 days (mean 2.6 days) in 10 patients receiving topical mupirocin therapy (three to four times daily or with each diaper change). The 10 patients who received topical nystatin cream successfully cleared within 5 days (mean 2.8 days). Although both agents eradicated *Candida*, a major difference was the marked response of the diaper dermatitis to mupirocin, presumably due to its well-documented bacteriocidal effects. The authors conclude that mupirocin is an excellent antifungal agent and a superior therapy for diaper dermatitis because of its polymicrobial toxicity.

Chronic mucocutaneous candidiasis

Chronic mucocutaneous candidiasis (CMC) is a heterogeneous group of disorders with progressive and recurrent infections of the skin, nails, and mucosal surfaces caused by *C. albicans*. The clinical presentation in patients with CMC can range from recurrent or recalcitrant thrush with a mild rash and dystrophic nails to severe, generalized, crusted plaques. Affected individuals have a defect in T-cell-mediated immunity; specifically, Th17 cells have been implicated. CMC typically presents in childhood. Half of those affected are identified as having autoimmune polyendocrinopathy candidiasis and ectodermal dystrophy (APECED). APECED is caused by mutations in the *AIRE* gene, which plays a key role in immunotolerance. It is characterized by hypoparathyroidism, hypothyroidism, and adrenal or gonadal failure. *Candida* susceptibility in APECED is attributed to autoantibodies directed against IL-17 and IL-22. Malabsorption, gastric cell atrophy, or

autoimmune hepatitis occurs in about a third of patients. Alopecia, vitiligo, dental enamel dysplasia, and keratitis are frequent associations.

Other subtypes of CMC include autosomal-dominant CMC with or without thyroid disease and autosomal-recessive, isolated CMC. Recently, mutations in the *STAT1* gene were found to underlie autosomal-dominant CMC and lead to defective Th1 and Th17 responses. Thymoma has been also associated with rare cases of IL-17 and IL-22 autoantibody-positive CMC.

Management Strategy

Once the etiology of the symptoms is confirmed with a positive culture for *C. albicans*, a workup should be done to test for immunodeficiency. Patients should also be tested for endocrine dysfunction characteristic of APECED. If clinical suspicion for APECED is high, genetic analysis for the *AIRE* gene can be performed. An association of CMC with abnormalities in iron metabolism or thymoma has also been reported in adult patients, so iron and radiologic studies may be warranted in HIV-negative patients with adult-onset CMC.

Treatment usually begins with an oral azole, most commonly fluconazole 100 to 200 mg/day. Intermittent use is often advocated to prevent resistance. However, resistance in CMC patients to first-line drugs is frequent, and alternative options include second-generation azoles such as voriconazole and posaconazole, as well as echinocandins such as caspofungin and micafungin. Ketoconazole should be avoided because of the risk of hepatotoxicity and adrenal insufficiency. Amphotericin B can be administered orally with variable response but minimal side effects. Due to toxicity, intravenous amphotericin B should generally be limited to short treatment courses with a transition to alternative therapies. Relapse after withdrawal of these agents is the rule because the inherent immune defect remains. Therapeutic strategies that augment the immune response can be very beneficial, including transfer factor (orally or parenterally) or high-dose cimetidine.

Special Investigations

- Complete blood count with differential
- HIV antibody test
- Thyroid-stimulating hormone
- Fasting blood glucose
- Plasma cortisol level
- Parathyroid hormone
- Serum calcium
- Serum iron and ferritin
- Chest x-ray or computed tomography (CT) scan if thymoma suspected
- Genetic testing for *AIRE* gene if suspicious for APECED

Chronic mucocutaneous candidiasis in APECED or thymoma patients correlates with autoimmunity to Th17-associated cytokines

Kisand K, Boe Wolff AS, Podkrajsek KT, Tserel L, Link M, Kisand KV, et al. *J Exp Med* 2010; 207: 299–308.

Patients with APECED were found to have severely reduced IL-17F and IL-22 responses to *C. albicans* antigens.

STAT1 mutations in autosomal dominant chronic mucocutaneous candidiasis

van der Veerdonk FL, Plantinga TS, Hoischen A, Smeekens SP, Joosten LA, Gilissen C, et al. *N Engl J Med* 2011; 365: 54–61.

DNA sequencing identified missense mutations in *STAT1*.

First-Line Therapy

- | | |
|-------------------------------|----------|
| • Systemic azole antimycotics | C |
|-------------------------------|----------|

Fluconazole in the management of patients with chronic mucocutaneous candidiasis

Hay RJ, Clayton YM. *Br J Dermatol* 1988; 119: 683–4.

Eight patients with CMC (five idiopathic cases, three APECED cases) and oral candidiasis were treated with 50 mg of fluconazole

daily for up to 4 weeks. Clinical and mycologic remissions were achieved in all patients after a mean of 10 days. Three patients relapsed within 4 months (mean 56 days), but all responded to fluconazole 50 mg daily for 3 days. The authors suggest intermittent oral antifungal therapy as the most appropriate method to manage patients with oral candidiasis in CMC after induction of remission.

Itraconazole in the treatment of two young brothers with chronic mucocutaneous candidiasis

Tosti A, Piraccini BM, Vincenzi C. *Pediatr Dermatol* 1997; 14: 146–8.

Two children with CMC involving the mouth and nails were successfully treated with itraconazole 200 mg/day for 2 months. A rapid cure rate of both infections was observed. No relapses of oral or nail candidiasis were identified at a follow-up examination more than a year later. The drug was very well tolerated.

Voriconazole: a broad spectrum triazole for the treatment of serious and invasive fungal infections

Maschmeyer G, Haas A. *Future Microbiol* 2006; 1: 365–85.

This is an excellent review of voriconazole (a second-generation triazole) for treating life-threatening fungal infections. Voriconazole can be given intravenously (6 mg/kg every 12 hours for two doses and then 4 mg/kg every 12 hours for maintenance dosing) or orally (200 mg every 12 hours for individuals over 40 kg and 100 mg every 12 hours for individuals less than 40 kg). It is effective for fluconazole-susceptible and fluconazole-resistant candidiasis.

Although transient visual disturbances, liver enzyme abnormalities, skin cancers, and skin rashes are reported, these rarely lead to discontinuation of treatment.

Successful treatment of chronic mucocutaneous candidiasis caused by azole-resistant *Candida albicans* with posaconazole

Firinu D, Massidda O, Lorrai MM, Serusi L, Peralta M, Barca MP, et al. *Clin Dev Immunol* 2011; 4. Article ID 283239.

A 39-year-old female patient with familial CMC who developed candidiasis that was resistant to multiple antifungal drugs was successfully treated with amphotericin B. She was treated with amphotericin B 50 mg/day intravenously for 2 weeks followed by posaconazole 400 mg twice daily. After 2 months the dose was reduced to 200 mg/day without a relapse in symptoms. When

posaconazole was discontinued, a relapse of oral candidiasis occurred after 2 weeks. She was thereafter maintained successfully on cycles of posaconazole 200 mg, three times per day, for a month with a 15-day discontinuation.

Second-Line Therapies

• Echinocandins	E
• Oral amphotericin B	E
• Intravenous amphotericin B	D

Activity of amphotericin B, anidulafungin, caspofungin, micafungin, posaconazole, and voriconazole against *Candida albicans* with decreased susceptibility to fluconazole from APECED patients on long-term azole treatment of chronic mucocutaneous candidiasis

Rautemaa R, Richardson M, Pfaller MA, Perheentupa J, Saxen H. Diagn Microbiol Infect Dis 2008; 62: 182–5.

Forty-three isolates of *C. albicans* were taken from 23 patients with APECED and tested for resistance to various antifungals. Isolates were divided into two groups: fluconazole-susceptible dose-dependent and fluconazole-susceptible groups. All isolates were highly susceptible to amphotericin B and echinocandins. Posaconazole and voriconazole were active against all isolates, but more active in the fluconazole-susceptible group, suggesting a possibility that patients may develop some cross-resistance to these drugs when they take fluconazole.

Successful treatment of azole-resistant chronic mucocutaneous candidiasis with caspofungin

Jayasinghe M, Schmidt S, Walker B, Rocken M, Schaller M. Acta Derm Venereol 2006; 86: 563–4.

An 18-year-old woman with CMC developed severe symptoms

from an azole-resistant strain of *C. albicans* after 3 years of treatment with fluconazole. After a 70-mg loading dose of intravenous caspofungin on the first day, the regimen was adjusted to 50-mg infusions four to seven times per week for almost 12 months. Clinical improvement of oral and cutaneous candidiasis was sustained during a follow-up period of 12 months. The treatment was well tolerated; the only side effect was a temporary elevation of hepatic enzyme levels that did not necessitate discontinuation of therapy.

Prolonged oral treatment of chronic mucocutaneous candidiasis with amphotericin B

Montes LF, Cooper MD, Bradford LG, Lauderdale RO, Taylor CD. Arch Dermatol 1971; 104: 45–56.

Amphotericin B was given orally to four patients with CMC in doses of 1000 to 1800 mg/day. One patient had complete clearance of extensive candidal granulomas after 6 months of treatment; one patient had a slower but excellent response. Two other patients had minimal or no response; of these, one was hypothyroid and the other had a thymoma. Of note, the serum levels were significantly higher in the first two patients than in the latter two. In all four patients the oral amphotericin B was free of side effects both clinically and in laboratory studies.

Chronic mucocutaneous candidiasis treated with amphotericin B. Case report

Waweru HW, Owili DM. East Afr Med J 1983; 60: 588–91.

A 5-year-old girl with CMC was treated with intravenous amphotericin B at a dose of 1 mg/kg every other day for a cumulative dose of 200 mg. The crusts and plaques completely cleared, but with residual atrophy, hypopigmentation, and scarring alopecia. She remained free of recurrence for 2 years.

Third-Line Therapies

• Transfer factor	C
• Cimetidine and zinc sulfate	E

Case report: successful treatment with cimetidine and zinc sulphate in chronic mucocutaneous candidiasis

Polizzi B, Origgi L, Zuccaro G, Matti P, Scorza R. Am J Med Sci 1996; 311: 189–90.

The clinical efficacy of high-dose cimetidine, 400 mg, three times daily, and zinc sulfate, 200 mg daily (subsequently adjusted to maintain blood zinc levels at the upper normal range), was evaluated in a patient with CMC for 16 months. An impressive reduction in infectious events was correlated with an increased CD4 (helper/inducer) cell count.

Transfer factor in chronic mucocutaneous candidiasis

Masi M, De Vinci C, Baricrdi OR. Biotherapy 1996; 9: 97–103.

Fifteen patients with CMC were treated with an in vitro–produced transfer factor (TF) specific for *C. albicans* antigens and/or with TF extracted from pooled buffy coats of blood donors: 400 million cell equivalent (CEU) per week for the first 2 weeks, followed by 100 million CEU per week for 6 to 12 months. All but one patient experienced significant improvement during treatment with specific TF.

Cutaneous larva migrans

Georgina A. Fremlin, and Anthony Abdullah

Courtesy of Tamara Lazic, MD.

Hookworm-related cutaneous larva migrans (Hr-CLM) is a disease caused by percutaneous penetration and migration of animal hookworm larvae in the human skin, most commonly *Ancylostoma braziliense*, *Ancylostoma caninum*, *Uncinaria stenocephala*, and

Bunostomum phlebotomum. People at risk are the inhabitants and returning travelers from tropical and subtropical countries and children playing in sandpits. Incubation period can vary between a few days and 7 months after exposure to contaminated soil or sand. The clinical picture is that of characteristic “creeping eruption” with serpiginous, papular, vesiculobullous, and erythematous lesions due to the presence of moving parasites. The common sites involved are the feet, buttocks, and thighs. Rare complications include pulmonary eosinophilic infiltrates, hookworm folliculitis, and oral mucosal lesions.

Management Strategy

Hr-CLM is self-limiting: most lesions resolve within 2 to 8 weeks because the human is a “dead-end host.” However, the lesions are extremely pruritic, can be extensive, and can significantly reduce the quality of life, so treatment is often required.

The systemic treatment normally used by the authors for patients over the age of 2 years is oral *albendazole* 400 mg daily for 3 days. An alternative is *ivermectin* given as a single dose of 12 mg orally (or 200 µg/kg) for adults and children older than 5 years or more than 15 kg in weight. Topical treatment usually takes the form of *thiabendazole* in a suitable lipophilic vehicle.

Specific Investigations

Clinical appearance is characteristic. Peripheral eosinophilia and raised serum IgE may be seen.

First-Line Therapies

• Systemic albendazole	B
• Systemic ivermectin	B

One-week therapy with oral albendazole in hookworm-related cutaneous larva migrans: a retrospective study on 78 patients

Veraldi S, Bottini S, Rizzitelli G, Persico MC. *J Dermatolog Treat* 2012; 23: 189–91.

Seventy-eight patients with multiple and/or extensive lesions of Hr-CLM were treated with albendazole 400 mg/day for 1 week. Cure rate was 100% at 3 months' follow-up. The disappearance of pruritus was reported after 2 to 3 days and skin lesions after 5 to 7 days of therapy. The authors concluded that this regimen was very effective and had no severe side effects.

Cutaneous larva migrans: clinical features and management of 44 cases presenting in the returning traveler

Blackwell V, Vega-Lopez F. *Br J Dermatol* 2001; 145: 434–7.

Thirty-one patients received oral albendazole 400 mg daily for 3 to 5 days, and 24 were cured (77%). Five patients received 10% thiabendazole cream topically for 10 days, and 4 were cured (80%). There were no reported side effects. Four patients needed no treatment.

A randomized trial of ivermectin versus albendazole for the treatment of cutaneous larva migrans

Caumes E, Carriere J, Datry A, Gaxotte P, Danis M, Gentilini M. *Am J Trop Med Hyg* 1993; 49: 641–4.

A comparison of efficacy between oral ivermectin (12 mg) and oral albendazole (400 mg). Twenty-one patients were randomly assigned to receive ivermectin ($n = 10$) or albendazole ($n = 11$). All patients who received ivermectin responded and none relapsed (cure rate 100%). All except one patient in the group receiving albendazole responded, but 5 relapsed after a mean of 11 days (cure rate 46%; $p = 0.017$). No major adverse effects were observed. The authors suggest that a single dose of ivermectin is more effective than a single dose of albendazole.

Hookworm-related cutaneous larva migrans in Northern Brazil: resolution of clinical pathology after a single dose of ivermectin

Schuster A, Lesshaft H, Reichert F, Talhari S, de Oliveira SG, Ignatius R, et al. *Clin Infect Dis* 2013; 57: 1155–7.

Ninety-two patients, median age 9.5 years, were treated with a single dose of 200 µg/kg ivermectin. All responded clinically. Two

weeks after treatment there was a significant reduction in complex tracts, and at 4 weeks all complex tracts had disappeared with marked symptomatic improvement.

The efficacy of single dose ivermectin in the treatment of hookworm related cutaneous larva migrans varies depending on the clinical presentation

Vanhaecke C, Perignon A, Monsel G, Regnier S, Bricaire S, Caumes E. J Eur Acad Dermatol Venereol 2014; 28: 655–7.

Sixty-two travelers with Hr-CLM and creeping dermatitis were treated with a single 200- μ g/kg ivermectin dose. Six of these patients had additional hookworm folliculitis. Ivermectin was well tolerated in all patients. Fifty-nine patients (95%) completed responded with one dose. 98% response rate in those with only creeping dermatitis was achieved and 66% (4/6) in the 6 patients presenting with additional hookworm folliculitis ($p = 0.02$). Of the two travelers that failed treatment, 2, 1 responded after a second dose of ivermectin and 1 needed two doses of ivermectin and 5 days of oral albendazole (400 mg BID). The non-hookworm folliculitis cases responded after a second dose of ivermectin.

Treatment of 18 children with scabies or cutaneous larva migrans using ivermectin

Del Mar Saez-De-Ocariz M, McKinster CD, Orozco-Covarrubias L, Tamayo-Sánchez L, Ruiz-Maldonado R. Clin Exp Dermatol 2002; 27: 264–7.

A report of 18 children aged 14 months to 17 years, of whom 7 had Hr-CLM. All 7 were cured with a single dose of 150 to 200 μ g/kg ivermectin, with no significant adverse effects. In the authors' experience ivermectin is a safe and effective alternative treatment for cutaneous parasitosis in children.

Second-Line Therapy

• Topical thiabendazole in a lipophilic vehicle	D
---	----------

Efficacy and tolerability of thiabendazole in a lipophilic vehicle

for cutaneous larva migrans

Chatel G, Scolari C, Gulletta M, Casalini C, Carosi G. Arch Dermatol 2000; 136: 1174–5.

Six patients were treated twice daily for 5 days with topical applications of 15% thiabendazole ointment in a lipophilic vehicle of base fat cream (24 g) and dimethyl sulfoxide gel (35 g). The ointment was prepared by crushing the tablets of thiabendazole in the lipophilic base. All patients experienced a clinical resolution within a median of 48 hours. No adverse effects and no recurrence had occurred in any patient at 3 months' follow-up.

Treatment with topical thiabendazole ointment at 10% to 15% concentration in a hydrophilic vehicle has shown 98% efficacy within a median of 10 days of treatment.

Third-Line Therapies

• Topical albendazole	E
• Cryotherapy	E

Efficacy of albendazole ointment on cutaneous larva migrans in 2 young children

Caumes E. Clin Infect Dis 2004; 38: 1647–8.

Two 2-year-old patients were treated with a 10% albendazole ointment, prepared by crushing three 400-mg tablets of albendazole in 12 g of petroleum jelly. Treatment was applied three times daily for 10 days. The cutaneous lesions disappeared within a week. One patient had recurrence at 3 months, and the lesion disappeared within a week after repeated treatment. The author suggests that albendazole ointment is a safe and effective treatment for Hr-CLM in children.

A case of cutaneous larva migrans presenting in a pregnant patient

Kudrewicz K, Crittenden KN, Himes A. Dermatol Online J 2014;

20(10): 25526012.

Cryotherapy with liquid nitrogen resulted in complete resolution of her lesion and symptoms. Oral anthelmintic agents are contraindicated in pregnancy.

Cutaneous polyarteritis nodosa

Cindy E. Owen, and Jeffrey P. Callen

Polyarteritis nodosa (PAN) is a necrotizing vasculitis that involves small or medium-sized arterioles. Classic PAN is characterized by fever, weight loss, cutaneous ulcers, livedo reticularis, myalgias and weakness, arthralgias or arthritis, neuropathy, abdominal pain, ischemic bowel, testicular pain, hypertension, and renal failure. Microscopic polyarteritis (MPA) involves the same-sized vessels as

well as smaller vessels and manifests clinically as a glomerulonephritis and a pulmonary capillaritis with alveolar hemorrhage. Patients with MPA may develop small-vessel vasculitis (palpable purpura), livedo reticularis with or without nodules, and/or ulcerations of the skin. Cutaneous PAN (cPAN), sometimes termed *benign cutaneous polyarteritis*, is characterized by livedo reticularis, nodules, and ulceration, usually of the leg; it has been postulated to be a localized necrotizing arteritis that does not affect internal organs and runs a chronic but benign course. Many reports, however, have linked cPAN to inflammatory bowel disease, hairy cell leukemia, streptococcal upper respiratory infection, or hepatitis B or C infection. Occasional reports have linked cPAN to antiphospholipid antibodies, cryoproteins, or antineutrophil cytoplasmic antibodies (pANCA or atypical ANCA more commonly than cANCA). One recent report has demonstrated that interleukin-6 is elevated in roughly 40% of patients. A mutation in the *CERC1* gene leading to deficiency in the ADA2 protein has been identified in some patients with early cPAN and early-onset vasculopathy. Cases of cPAN have occurred in patients treated with propylthiouracil and minocycline. cPAN appears to be more prevalent in children. Although it is generally benign, there have been reports of associated neuropathy, as well as visceral involvement.

Management Strategy

cPAN causes pain and discomfort and may ulcerate, thereby causing disability. Therapy may include local measures, for example, *gradient pressure stockings*, or *systemic therapies*, including *systemic corticosteroids*, *methotrexate*, *azathioprine*, *pentoxifylline*, and *intravenous immunoglobulin (IVIG)*. Most of the reports are anecdotes or small case series.

Treatment is often indicated for underlying and associated conditions.

Specific Investigations

- Skin biopsy
- Serology for hepatitis B and C, assessment for tuberculosis, antistreptolysin O antibody titers, antineutrophil cytoplasmic

- antibodies, antiphospholipid antibodies, and cryoproteins
- Assessment for systemic involvement
- Assessment for inflammatory bowel disease
- Assessment for hairy cell leukemia
- Assessment for drugs that have been linked to cPAN
- In cases with early onset, measurement of ADA2 levels

Cutaneous periarteritis nodosa: a clinicopathological study of 79 cases

Daoud MS, Hutton KP, Gibson LE. *Br J Dermatol* 1997; 136: 706–13.

This analysis attempted to identify features that may distinguish those cases likely to have a prolonged course. Most patients (60%) had no associated medical condition. The disease course was prolonged but benign, and systemic PAN did not develop in any patient. The ulcerative form of disease was more prolonged and frequently associated with neuropathy. Therapy was varied, and the patients with nonulcerative disease responded better than those with ulcers. Corticosteroids, azathioprine, pentoxifylline, and hydroxychloroquine appeared effective in individual patients.

High titer of phosphatidylserine–prothrombin complex antibodies in patients with cutaneous polyarteritis nodosa

Kawakami T, Yamazaki M, Mizoguchi M, Soma Y. *Arthritis Rheum* 2007; 57: 1507–13.

Antiphosphatidylserine–prothrombin complex and/or anticardiolipin antibodies were positive in all 16 cPAN patients tested compared with none in the control group.

Epidemiological, clinical and laboratory profiles of cutaneous polyarteritis nodosa patients: report of 22 cases and literature review

Criado PR, Marques GF, Morita TC, Freire de Carvalho J. *Autoimmun Rev* 2016; 15: 558–63.

cPAN was more prevalent in women (77%) with a mean age at time of diagnosis of 39.4 years (range from 9–61 years). The clinical manifestations in decreasing order of frequency were ulcers, livedo racemose, subcutaneous nodules, atrophie blanche lesions, and purpura. Lower limbs were affected in all cases, but trunk and upper limbs were affected at equal frequency of 27%. No cases of cPAN

progressed to systemic PAN. Symptoms reported were pain (64%) and paresthesias (30%). Twenty-three percent were diagnosed with mononeuritis multiplex. The most common infectious agent in this study was *Mycobacterium tuberculosis*.

Tuberculosis testing should be performed in endemic areas in patients with cPAN.

Polyarteritis-like vasculitis in association with minocycline use: a single center case series

Kermani T, Ham E, Camilleri M, Warrington K. Semin Arthritis Rheum 2012; 42: 213–21.

Nine cases occurring in the context of minocycline use. Four had isolated cutaneous disease. All had positive pANCA. Minocycline was discontinued, and six patients required immunosuppressive therapy.

Vasculitic conditions mimicking cPAN have also been reported with isotretinoin and amphetamines.

First-Line Therapies

• Local measures (i.e., support stockings, local wound care)	E
• Nonsteroidal antiinflammatory drugs, penicillin (if antecedent streptococcal infection), systemic corticosteroids	E
• Immunosuppressants: azathioprine, methotrexate, mycophenolate mofetil, mizoribine	E

Low-dose weekly methotrexate for unusual neutrophilic vascular reactions: cutaneous polyarteritis nodosa and Behçet's disease

Jorizzo JL, White WL, Wise CM, Zanolli MD, Sherertz EF. J Am Acad Dermatol 1991; 24: 973–8.

Three patients responded dramatically.

Use of mizoribine in two patients with recalcitrant cutaneous polyarteritis nodosa

Kawakami T, Soma Y. J Am Acad Dermatol 2011; 64: 1213–4.

This antimetabolite/immunosuppressive agent is not available in the United States but has been regularly used in Japan for PAN and cPAN.

Ulcerative cutaneous polyarteritis nodosa treated with

mycophenolate mofetil and pentoxifylline

Kluger N, Guillot B, Bessis D. *J Dermatolog Treat* 2011; 22: 175–7.

This single case report combines a second-line and a third-line therapy.

Second-Line Therapies

• Intravenous immunoglobulin	E
• Pentoxifylline	E

Intravenous immunoglobulins as treatment of severe cutaneous polyarteritis nodosa

Marie I, Miranda S, Girszyn N, Soubrane JC, Vandhuick T, Levesque H. *Intern Med J* 2012; 42: 459–62.

Three patients with refractory cPAN resulting in painful ulcers involving the lower limbs and causing toe necrosis were treated with IVIG 1 g/kg/day for 2 days monthly. After the second infusion, skin signs dramatically improved and completely healed after the third infusion.

Successful treatment of cutaneous PAN with pentoxifylline

Calderon MJ, Landa N, Aguirre A, Diaz-Perez JL. *Br J Dermatol* 1993; 12: 706–8.

A patient who failed to respond to aspirin and penicillin was treated with pentoxifylline. Withdrawal of the pentoxifylline resulted in a relapse that again responded to therapy.

Third-Line Therapies

• Tamoxifen	E
• Infliximab	E
• Etanercept	D
• Rituximab	E
• Tonsillectomy	D
• Warfarin	E

Estrogen-sensitive cutaneous polyarteritis nodosa: response to tamoxifen

Cvancara JL, Meffert JJ, Elston DM. J Am Acad Dermatol 1998; 39: 643–6.

Tamoxifen, an antiestrogenic agent, at a dose of 10 to 20 mg daily, led to control of disease in a patient who seemed to worsen with conjugated estrogen therapy. Relapse occurred within 5 days of interruption of the therapy and rapidly responded with reinitiation of the tamoxifen.

Successful response to infliximab in a patient with undifferentiated spondyloarthropathy coexisting with polyarteritis nodosa-like cutaneous vasculitis

Garcia-Porrúa C, Gonzalez-Gay MA. Clin Exp Rheumatol 2003; 21: S138.

Remission induced by infliximab in a childhood polyarteritis nodosa refractory to convention immunosuppression and rituximab

Campanilho-Marques R, Ramos F. Joint Bone Spine 2014; 81: 267.

A 13-year-old boy responded to infliximab after failing prednisolone, methotrexate, cyclophosphamide, and rituximab.

Successful treatment of childhood cutaneous polyarteritis nodosa with infliximab

Vega Gutierrez J, Rodriguez Prieto MA, Garcia Ruiz JM. J Eur Acad Dermatol Venereol 2007; 21: 570–1.

A single case responding to infliximab.

A case of refractory cutaneous polyarteritis nodosa in a patient with hepatitis B carrier status successfully treated with tumor necrosis alpha blockade

Zoshima T, Matsumura M, Suzuki Y, Kakuchi Y, Mizushima I, Fujii H, et al. Mod Rheumatol. 2013; 23: 1029–33.

A case successfully treated with etanercept. The authors review five similar cases of response to this drug.

Young male patient diagnosed with cutaneous polyarteritis nodosa successfully treated with etanercept

Valor L, Monteagudo I, de la Torre I, Fernández CG, Montoro M, Longo JL, et al. Mod Rheumatol 2014; 24: 688–9.

A 7-year-old boy responded to etanercept after failing high-dose corticosteroids and cyclophosphamide.

Rituximab in refractory cutaneous polyarteritis

Krishnan S, Bhakuni DS, Kartik S. Int J Rheum Dis 2012; 15: e127.

A 34-year-old woman with cPAN refractory to prednisolone and cyclophosphamide developed digital gangrene of two fingers and was treated with rituximab (two courses) with complete healing of ulcers in 4 weeks. She had no recurrence over 6 months of follow-up on prednisolone and azathioprine.

Cutaneous polyarteritis nodosa: therapy and clinical course in four cases

Misago N, Mochizuki Y, Sekiyama-Kodera H, Shirotani M, Suzuki K, Inokuchi A, et al. J Dermatol 2001; 28: 719–27.

Two cases resolved after tonsillectomy. The authors proposed that chronic streptococcal disease might be responsible for cPAN.

Use of warfarin therapy at a target international normalized ratio of 3.0 for cutaneous polyarteritis nodosa

Kawakami T, Soma Y. J Am Acad Dermatol 2010; 63: 602–6.

Three patients with antiphosphatidylserine–prothrombin complex antibodies resolved on sustained warfarin therapy.

Darier disease

Genevieve A. Casey, and Susan M. Cooper

Courtesy of Dr Terence Casey.

Darier disease is a dominantly inherited condition, with an incidence 1:25,000 to 1:100,000, that is characterized by persistent greasy, hyperkeratotic papules. The disease is caused by mutations in the *ATP2A2* gene that encodes sarcoplasmic/endoplasmic reticulum calcium-ATPase type 2 (SERCA2).

Management Strategy

The warty, keratotic papules, which usually appear before the age of 20 years, can be malodorous, irritate, and look unsightly. The flexures can be a particular problem, as plaques here are frequently hypertrophic and may smell unpleasant. Initial treatment is aimed at controlling irritation. *Simple emollients, soap substitutes, and topical corticosteroid creams* are helpful. Keeping the skin cool by wearing comfortable cotton clothing helps. Sunscreen is recommended for those with a history of photoaggravation.

In mild disease or linear disease reflecting a genetic mosaicism, *topical retinoids* may be sufficient. These include topical isotretinoin (0.05%), tretinoin cream (0.05%), adapalene gel (0.1%), and tazarotene gel (0.1% short contact for 15 minutes). Treatment is applied on alternate days to begin with, increasing to once daily if possible, as irritation is common. The addition of a topical corticosteroid (alternating with the retinoid) may alleviate some of the side effects. Superinfection with viruses and bacteria is frequent, so combined corticosteroid/antibiotic preparations are logical.

In more extensive disease, an *oral retinoid* is required. Acitretin (10–25 mg daily and can be gradually increased), isotretinoin (0.5–1.0 mg/kg daily), and alitretinoin (30 mg daily) are effective. Teratogenicity is a problem, and pregnancy is contraindicated for 2 years after stopping treatment with acitretin and 1 month after isotretinoin or alitretinoin. For this reason, isotretinoin or alitretinoin is preferred in women of childbearing age. Treatment may be given either long term or as intermittent short courses.

The rare vesiculobullous form of the disease may respond to *prednisolone*. Hypertrophic flexural disease unresponsive to retinoids may require a surgical approach with *laser, electrosurgery, debridement, or excision*. Recurrence is a problem.

Oral lithium exacerbates the disease and should be avoided if possible.

Specific Investigations

- Skin biopsy. The characteristic finding is focal, suprabasal, acantholytic dyskeratosis.
- Skin swab/scraping for bacterial, viral, and fungal culture

Darier-White disease: a review of the clinical features in 163 patients

Burge SM, Wilkinson JD. J Am Acad Dermatol 1992; 27: 40–50.

Fourteen percent of patients in this series had herpes simplex complicating their disease.

Painful blisters arising in a patient with Darier disease are usually due to secondary infection with Staphylococcus aureus or herpes simplex.

First-Line Therapies

• Cool cotton clothing	E
• Emollients	D
• Topical corticosteroids	D
• Topical retinoids	D

Darier's disease

Cooper SM, Burge SM. Am J Clin Dermatol 2003; 4: 97–105.

A detailed review of the management of Darier disease.

Genetic counseling can be helpful, and written information is often appreciated.

Topical isotretinoin in Darier's disease

Burge SM, Buxton PK. Br J Dermatol 1995; 133: 924–8.

Six of 11 patients improved with 0.05% isotretinoin applied to a test patch. Erythema, burning, and irritation were common.

Successful treatment of Darier's disease with adapalene gel

Abe M, Inoue C, Yokoyama Y, Ishikawa O. Pediatr Dermatol 2011; 28: 197–8.

Adapalene gel 0.1% applied for 2 months to the abdomen of a 12-

year-old boy resulted in dramatic improvement.

Second-Line Therapies

• Oral retinoids	B
• Topical 5-fluorouracil 5%	E
• Topical tacrolimus 0.03%, 0.1%	E
• Topical diclofenac sodium 3%	E

Clinical and ultrastructural effects of acitretin in Darier's disease

Lauharanta J, Kanerva L, Turjanmaa K, Geiger JM. *Acta Dermatol Venereol* 1988; 68: 492–8.

Thirteen patients treated with acitretin starting at 30 mg daily for 16 weeks showed some improvement, but side effects included itching (5 patients) and hair loss (2 patients).

Isotretinoin treatment of Darier's disease

Dicken CH, Bauer EA, Hazen PG, Krueger GG, Marks Jr JG, McGuire JS, et al. *J Am Acad Dermatol* 1982; 6: 721–6.

This multicenter open study assessed the effect of short and longer courses of treatment. The starting dose was 0.5 mg/kg, but longer courses were adjusted according to symptoms. Isotretinoin was effective but did not give long-term remission. Some patients were maintained on alternate-day or alternate-week regimens.

Successful treatment with oral alitretinoin in women of childbearing potential with Darier's disease

Zamiri M, Munro CS. *Br J Dermatol* 2013; 169: 709–10.

Two women were treated with 30 mg daily, with improvement after 4 to 6 weeks. Relapse occurred upon stopping, and treatment was continued in one patient for 18 months.

A case of Darier's disease successfully treated with topical

tacrolimus

Rubegni P, Poggiali S, Sbanò P, Risulo M, Fimiani M. J Eur Acad Dermatol Venereol 2006; 20: 84–7.

Topical tacrolimus 0.1% ointment to the face and neck resulted in complete remission after 6 weeks, with no relapse 1 year later using maintenance therapy of 0.03%.

Improvement of Darier disease with diclofenac sodium 3% gel

Millan-Parrilla F, Rodrigo-Nicolas B, Moles-Poveda P, Armengot-Carbo M, Quecedo-Estebanez E, Gimeno-Carpio E. J Am Acad Dermatol 2014; 70: e89–90.

Third-Line Therapies

• Cyclosporine	E
• Oral prednisolone (vesiculobullous)	E
• Laser (CO ₂ , erbium:YAG, pulse-dye)	E
• Photodynamic therapy	D
• Botulinum toxin	E
• Electron beam radiation	E
• Dermabrasion	E
• Debridement	E
• Excision	E

Darier's disease: severe eczematization successfully treated with cyclosporine

Shahidullah H, Humphreys F, Beveridge GW. Br J Dermatol 1994; 131: 713–6.

Cyclosporine may be helpful in widespread eczematized Darier disease but had no effect on the underlying disease.

Vulval Darier's disease treated successfully with cyclosporine

Stewart LC, Yell J. J Obstet Gynaecol 2008; 28: 108–9.

A previously therapy-resistant case was treated with cyclosporine (initial dose 5 mg/kg) for 6 months with good response and was subsequently maintained on acitretin.

Vesiculobullous Darier's disease responsive to oral prednisolone

Speight EL. Br J Dermatol 1998; 139: 934–5.

A patient with the vesiculobullous form of the disease responded to a short course of oral prednisolone.

Prednisolone may also be useful in the eczematized form.

Extensive recalcitrant Darier disease successfully treated with laser ablation

Brown VL, Kelly SE, Burge SM, Walker NPJ. Br J Dermatol 2010; 162: 227–8.

Trunk, limbs and scalp were treated under general anaesthetic every 2 months with CO₂ laser. Wounds healed within 33 weeks, and the patient remained disease free in some areas for 9 years.

Darier-White disease treated with fractional CO₂ laser in two cases

Raszewska-Famielec M, Dudra-Jastrzebska M, Borzecki A, Chodorowska G. Dermatol Ther 2015; 24: 254–57.

Three sessions of fractional CO₂ laser resurfacing with 0.8- to 1- mm density every 6 weeks resulted in removal of papular lesions. Topical anesthetic (5% EMLA) cream was used. Some recurrence was observed after 6 months.

Efficacy of erbium:YAG laser ablation in Darier disease and Hailey-Hailey disease

Beier C, Kaufmann R. Arch Dermatol 1999; 135: 423–7.

Disease cleared in two patients, but follow-up was less than 2 years.

Successful treatment of Darier disease with the flashlamp-pumped pulse-dye laser

Roos S, Karsai S, Ockenfel HM, Raulin C. Arch Dermatol 2008; 144: 1073–5.

Submammary disease improved at 8 weeks post treatment, with no progression at 15 months.

Treatment of Darier's disease with photodynamic therapy

Exadaktylou D, Kurwa HA, Calonje E, Barlow RJ. Br J Dermatol 2003; 149: 606–10.

Six patients received photodynamic therapy with topical 5-aminolevulinic acid as a photosensitizer. One patient could not tolerate the treatment, but five experienced sustained improvement, with initial inflammatory response lasting 2 to 3 weeks.

Botulinum toxin type A: an alternative symptomatic management of Darier's disease

Kontochristopoulos G, Katsavou AN, Kalogirou O, Agelidis S, Zakopoulou N. Dermatol Surg 2007; 33: 882–3.

Submammary disease was treated with botulinum toxin as adjuvant therapy: 100 U were injected, with improvement sustained for 4 months. Reduced sweating may alleviate maceration and reduce bacterial colonization.

Treatment of recalcitrant Darier's disease with electron beam therapy

Kittridge A, Wahlgren C, Fuhrer R, Zirwas M, Patton T. Dermatol Ther 2010; 23: 302–4.

Electron beam radiation therapy to the inframammary folds resulted in initial severe local dermatitis, followed by complete resolution sustained for 18 months.

The surgical treatment of hypertrophic Darier's disease

Wheeland RG, Gilmore WA. J Dermatol Surg Oncol 1985; 11: 420–3.

Recalcitrant hypertrophic lesions were debrided under local anesthesia. Symptomatic and cosmetic improvement was maintained for 2 years.

Decubitus ulcers

Joseph A. Witkowski[†], Lawrence Charles Parish, Ayse Serap Karadag, and Jennifer L. Parish

The decubitus ulcer represents a defect in the skin that can extend through the subcutaneous tissue and muscle layer onto the underlying bone.

Management Strategy

Prevention

A patient in an ordinary bed who is at risk of developing a decubitus ulcer should be repositioned at frequent intervals; however, the correct timing for turning has never been established. The regularity is determined by the level of risk of developing an ulcer and the duration of blanchable erythema. Pillows and foam wedges are used to maintain position and to keep bony prominences apart. Completely immobile patients should have their heels raised from the bed by a pillow or boot and not be placed on their trochanters, unless a specialized bed is used. To avoid the latter, use a 30-degree position from the horizontal lying on the side. The head of the bed should not be raised more than 30 degrees from the horizontal for an extended period. The concept of repositioning every 2 hours is arbitrary and varies from country to country, even facility to facility.

Where possible, use lifting devices or draw sheets to reposition or to transfer patients. Finally, when appropriate, the patient should be placed on a pressure-reducing device such as a foam, alternating air, gel, or water mattress.

A patient sitting in a wheelchair should be repositioned frequently, perhaps every hour, and be taught to shift weight every 15 minutes. A pressure-reducing device made of foam, gel, air, or a combination of each is indicated. Unfortunately, even in paraplegics, the exact time interval for repositioning has never been accurately determined.

Theoretically, decubitus ulcers should be preventable, but despite these measures, many simply are not. If they are associated with immobility, sustained pressure, and the loss of pain sensibility, these problems can and should be addressed. In practice, successful prevention is often foiled by our limited understanding of the pathogenesis, as well as by complicating comorbidities. There is also some evidence that many deep ulcers are initiated by multiple microthromboses of deep tissues. This indicates that dehydration, along with any factor that might increase blood coagulability, should be addressed.

Management

The management of skin lesions caused by pressure is based on four

principles:

- Elimination of relative/sustained pressure
- Removal of necrotic debris
- Maintenance of a moist wound environment
- Correction of the underlying contributing factors

The patient should not lie on the ulcer. A patient who is at risk for developing additional ulcers and can assume a variety of positions without lying on the ulcer should be placed on a *static support surface* (i.e., *air, foam, or water*). If the patient cannot assume various positions without lying on the ulcer or bottoms out while on a static surface, or if the ulcer does not heal after 2 to 4 weeks of optimal care, place the patient on a *dynamic support surface* when possible—that is, *an alternating air overlay on the mattress, a low-air-loss bed, or an air-fluidized bed*. If a patient has large deep ulcers (stage III or IV) on multiple sleep surfaces or has excess moisture on intact skin, use a low-air-loss bed or an air-fluidized bed. A patient with an ulcer on the sitting surface should not sit, if possible.

Removal of Necrotic Debris

Surgical debridement is indicated for infected ulcers with necrotic debris and eschars other than those on the heel; however, the extent of tissue needing to be removed is highly variable. An eschar on the heel should be excised only if it is fluctuant, draining, or surrounded by cellulitis and if the patient is septic.

Major debridement is performed in the operating room, but serial sharp debridement can be performed at the bedside. The use of *systemic antimicrobials* should be considered to prevent bacteremia during significant debridement. A *bone biopsy* is recommended while debriding ulcers when bone is exposed and for nonhealing deep ulcers (stage III or IV) after 2 to 4 weeks of optimal therapy.

Other ulcers can be *debrided by the use of saline wet-to-dry gauze* every 4 to 6 hours, by the use of saline in a 35-mL syringe with an attached 19-gauge angiocatheter, or by whirlpool use. The use of enzymes should be reserved for ulcers that are not clinically infected. *Autolytic debridement* is indicated for noninfected ulcers that are not likely to become infected.

Debridement can also be indicated for staging of the ulcer. This assumes that staging is a requisite for treating the patient.

Maintenance of a Moist Wound Environment

The choice of a synthetic dressing depends on the presence of infection, amount of exudate, status of the periulcer skin, and amount of pain experienced by the patient. *Saline dressings* and *alginates* are indicated for infected ulcers. *Synthetic dressings (i.e., films)* are used on ulcers with minimal exudate, *hydrocolloid wafers* for moderate exudate, and *foam wafers* and *alginates* for ulcers with a large amount of exudate. Ulcers with fragile or dermatitic periulcer skin should be covered with *hydrogel wafers* or *nonadherent foam wafers*. All occlusive dressings relieve pain, when present, but the hydrogel wafers are best for this purpose.

Correction of the Underlying Contributing Factors

Attention to the medical status is important; diabetes mellitus, nutritional conditions (malnutrition, hypoproteinemia, anemia), peripheral vascular disease, cardiac disease, malignancy, mental health problems, and even Alzheimer disease may prevent any ulcer healing. Unfortunately, even the best medical care may not permit healing.

General Measures

Treatment of the decubitus ulcer can be simplified and made more effective if the following recommendations are considered:

- Saline should be used to clean most pressure lesions; soap and disinfectants are too irritating for more than occasional use. Scrubbing may prove too irritating, so gentle washing is indicated.
- When ulcers are not infected, synthetic dressings should be changed only if they become dislodged or wound fluid escapes from under the dressing.
- Periulcer skin must be kept dry not only to avoid maceration but also to permit the dressing to adhere to the skin.
- To obliterate dead space, *fill deep ulcers loosely with a hydrocolloid, a hydrogel wound filler, or an alginate rope* before applying a synthetic dressing. This same material should be placed under the edge of the ulcer when undermining is present. Bleeding after serial surgical debridement can often be controlled with an alginate

dressing. Moistening with saline can loosen an alginate dressing that adheres to granulation tissue.

- A clean ulcer failing to show signs of healing and revealing inflammatory signs of erythema, edema, and warmth; purulent discharge and persistent excessive exudate; discoloring or darkening of granulation tissue, giving off a foul odor; and presenting with heightened local pain should be treated with antibacterial agents, such as *1% silver sulfadiazine, cadexomer iodine, triple antibiotic, or retapamulin*, for 2 weeks to reduce the bacterial burden. However, topical antimicrobials may create the risk of resistant bacterial strains emerging. Metronidazole would be the exception, as the odor of an infected ulcer can often be eliminated by applying *metronidazole gel* to the ulcer bed. Increased bacterial burden may impede healing before clinical signs of infection become apparent. *Systemic antimicrobial agents* are indicated for patients with bacteremia, sepsis, advancing cellulitis, or osteomyelitis.
- Although most synthetic dressings relieve pain, treatment for moderate to severe pain can include *topical anesthetics (lidocaine), nonsteroidal antiinflammatory drugs (NSAIDs), opiates, antidepressants, and sedatives*.

Blanchable Erythema and Nonblanchable Erythema

Blanchable and nonblanchable erythema represent the initial development of the decubitus ulcer. The early lesions of nonblanchable erythema are bright red; later, they become dark red to purple. Both can be treated with *adherent synthetic dressings* to protect the lesion from friction and shear, *topical corticosteroids*, or *zinc oxide paste*. The bright red lesion can also be treated with *2% nitroglycerin ointment*; 0.5 to 1 cm of the ointment is applied over the lesion and covered with an impermeable plastic wrap (such as Saran Wrap) for 12 hours daily.

Decubitus Dermatitis

Decubitus dermatitis is treated with topical corticosteroids, Vaseline gauze, or a hydrogel wafer. Large bullae may be debrided before applying the dressing.

Superficial and Deep Ulcers

Superficial and deep ulcers without necrotic debris are treated with *saline wet-to-dry gauze* or an *adherent synthetic dressing*. Deep ulcers should be loosely filled with a *synthetic wound filler* before applying a synthetic dressing. The deep ulcer with necrotic debris requires debridement and is then treated as a clean ulcer.

Enzymatic debridement or the use of an *antimetabolite* can help manage the eschar. Covering the lesion with an adhesive occlusive dressing for several days after scarification will often soften the eschar before excision is undertaken. The firmly adherent dry eschar that is not attached to underlying bone can often be separated from the surrounding skin with 5% 5-fluorouracil cream. After scarification and application of zinc oxide paste to protect the surrounding skin, 5-fluorouracil is applied to the eschar, including its margin, and then covered with an impermeable plastic wrap. Application is repeated every 8 hours. When separation occurs, it can be excised.

Underlying Contributing Factors

Management of anemia, malnutrition, diabetes mellitus, hydration, and incontinence is essential. The patient should be ingesting approximately 30 to 35 calories/kg daily and 1.25 to 1.50 g protein/kg daily. Ascorbic acid 500 mg twice daily may enhance healing.

Specific Investigations

- Categorize patient
- Stage decubitus ulcer
- Total protein, serum albumin, and daily calorie intake
- Complete blood count
- Care for comorbid disorders

Clinical observation is the key to making the diagnosis. Cutaneous biopsies will not be helpful, although biopsies for aerobic and anaerobic bacteriology cultures could be useful if infection is suspected. Bacterial testing and analysis with thorough swabbing may only provide a portion of the necessary information. In clinical practice, infection, defined as a number of bacteria greater than 10^5 CFU/g of tissue, is of only limited relevance.

Categories of Patients

Patients at risk need to be considered in terms of the underlying disease process:

- Spinal cord injury in an otherwise healthy person
- Neurologic disease with no medical disease but a devastating condition, such as multiple sclerosis or a cerebral vascular accident compromising the body integrity
- Debilitation with a multitude of medical diseases affecting the patient (e.g., arteriosclerosis, diabetes mellitus, Parkinson disease, Alzheimer disease, malignancy, malnutrition, and peripheral vascular disease)
- Surgical procedures requiring lengthy positioning on the operating table for cardiovascular or orthopedic procedures

Grading or Evaluation

Grading or evaluation can be accomplished by dermatologic observation and staging. Bear in mind that ulcer staging is arbitrary and does not reflect the dynamics of ulcer formation.

Dermatologic Observation

Observe for:

- Blanchable erythema
- Nonblanchable erythema
- Decubitus dermatitis
- Superficial ulcer
- Deep ulcer
- Eschar
- Necrosis
- Gangrene

Staging

Stages are as follows:

- Stage I: nonblanchable erythema of intact skin
- Stage II: partial-thickness skin loss involving the epidermis and/or dermis
- Stage III: full-thickness skin loss with damage to the subcutaneous tissue that may extend down to, but not through, the underlying

fascia

- Stage IV: full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures
- Unstageable: full-thickness tissue loss, base of the ulcer being covered by slough and/or eschar, where the true depth of ulcer cannot be classified

Most superficial ulcers do not progress to stage II and IV ulcers. The concept of staging need not be thought of as a progression.

Accumulating evidence suggests that a number of ulcers (most stage III and IV) may initially originate in the deep tissue compartment and progress outward to the dermis and epidermis (inside-out theory).

Pathophysiology

Pathophysiology of acute wound healing

Li J, Chen J, Kirsner R. Clin Dermatol 2007; 25: 9–18.

Dilemmas about the decubitus ulcer: skin-fold ulcerations and apposition lesions

Parish LC, Lowthian PT. Exp Rev Dermatol 2008; 3: 287–91.

Decubitus ulcers continue to have an uncertain etiology.

Histology

Pressure ulcer tissue histology: an appraisal of current knowledge

Edsberg LE. Ostomy Wound Manage 2007; 53: 40–9.

Risk Assessment Tools

Predictive validity of pressure ulcer risk assessment tools for elderly: a meta-analysis

Park SH, Lee YS, Kwon YM. West J Nurs Res 2016; 38: 459–83.

Typical screening tools (Braden, Norton, and Waterlow scales) utilized for pressure ulcer risk are limited with regard to their validity and accuracy among older adults because of heterogeneity throughout studies.

25 years of pressure ulcers

Parish LC, Sibbald RG. *Adv Skin Wound Care* 2012; 25: 57–8.
Role of staging may provide more confusion than merit.

Pressure ulcer staging - revisited

Spear M. *Plast Surg Nurs* 2013; 33: 192–4.

The European Pressure Ulcer Advisory Panel developed a staging system in 1998 that is composed of four stages: Grade 1 to Grade 4. The classification system most popularly adopted and used is the one presented in 1989 by the National Pressure Ulcer Advisory Panel (NPUAP). This classification system has been updated and revised. A new stage, suspected deep tissue injury, was incorporated in 2007.

Factors Predicting Pressure Ulcers

Nutritional parameters predicting pressure ulcers and short-term mortality

Montalcini T, Moraca M, Ferro Y, Romeo S, Serra S, Raso MG, et al. *J Transl Med* 2015; 13: 305.

Lower hemoglobin and albumin were inversely related to pressure ulcers, where patients with lower albumin showed notably higher short-term mortality than patients with higher serum albumin.

Factors predicting the development of pressure ulcers in an at-risk population who receive standardized preventive care

Demarre L, Verhaeghe S, Van Hecke A, Clays E, Grypdonck M, Beeckman D. *J Adv Nurs* 2015; 71: 391–403.

Pressure ulcers in category II to IV were significantly related to nonblanchable erythema, urogenital disorders, and higher body temperature. Predictive factors having to do with superficial pressure ulcers were admittance to an internal medicine ward, incontinence-associated dermatitis, nonblanchable erythema, and a lower Braden score. Incontinence-associated dermatitis was greatly related to superficial sacral pressure ulcers.

Risk factors associated with pressure ulcer development in critically ill traumatic spinal cord injury patients

Wilczweski P, Grimm D, Gianakis A, Gill B, Sarver W, McNett M. *J Trauma Nurs* 2012; 19: 5–10.

Clinical variables associated with pressure ulcers were fecal management systems, incontinence, acidosis, support surfaces, steroids, and additional equipment, with hypotension as the strongest predictor of pressure ulcers in 94 spinal cord injury patients.

Predicting pressure ulcer development in clinical practice: evaluation of Braden scale scores and nutrition parameters

Miller N, Frankenfield D, Lehman E, Maguire M, Schirm V. J Wound Ostomy Continence Nurs 2016; 43: 133–9.

Patients admitted who showed signs of infection, trauma, gastrointestinal, urologic/renal, and neurologic diagnoses were associated with hospital-related pressure ulcer occurrences, whereas cardiovascular, respiratory, and hematology/oncologic diagnoses were not. A higher body mass index (BMI) may protect against the presence of hospital-associated pressure ulcers by cushioning pressure points over the sacrum.

Treatment

Revised National Pressure Ulcer Advisory Panel Pressure Injury Staging System: Revised Pressure Injury Staging System

Edsberg LE, Black JM, Goldberg M, McNichol L, Moore L, Sieggreen M. J Wound Ostomy Continence Nurs 2016; 43: 585–97.

In a consensus conference that involved 24 stakeholder organizations from various disciplines, it was unanimously agreed that pressure ulcers are largely preventable but not always avoidable.

Pressure ulcer treatment strategies: a systematic comparative effectiveness review

Smith ME, Totten A, Hickam DH, Fu R, Wasson N, Rahman B, et al. Ann Intern Med 2013; 159: 39–50.

Moderate-strength evidence shows that the use of air-fluidized beds, protein supplementation, radiant heat dressings, and electrical stimulation improved the healing of pressure ulcers in adults.

First-Line Therapies

• Elimination of pressure	C
• Pressure-reducing and pressure-relieving devices	C
• Palliative care	B
• Removal of necrotic debris	C
• Maintenance of a moist wound environment	C
• Synthetic dressings	B
• Topical antibacterials	B
• Cleansing	C
• Nutrition	C
• Dietary supplements	C

Eliminating Pressure and Relieving Devices

An Investigation of Geriatric Nursing Problems in Hospital

Norton D, McClaren R, Exton-Smith AN. London: Churchill Livingstone, 1975; 238.

Patients who developed fewer pressure sores were those who were turned every 2 to 3 hours.

This is based on a book published in 1916!

Shearing force as a factor in decubitus ulcers in paraplegics

Reichel SM. JAMA 1958; 166: 762–3.

As a result of shear, blood vessels in the sacral area become twisted and distorted, and the tissue may become ischemic and necrotic.

Drawsheets for prevention of decubitus ulcer

Witkowski JA, Parish LC. N Engl J Med 1981; 305: 1594.

Use of draw sheets reduces the incidence of friction burns.

Prevention of pressure ulcers among people with spinal cord injury: a systematic review

Groah SL, Schladen M, Pineda CG, Hsieh CH. PM&R 2015; 7: 613–36.

The evidence indicates staying away from the 90-degree lateral position due to high pressures and pressure ulcer risk over the trochanters. While sitting, pressures are linearly redistributed from the sitting area during recline and tilt; however, reclining has an increased risk of shear forces on this skin.

A randomized controlled clinical trial of repositioning, using the 30° tilt, for the prevention of pressure ulcers

Moore Z, Cowman S, Conroy RM. J Clin Nurs 2011; 20: 2633–44.

Older adults at risk of pressure ulcers should be repositioned every 3 hours throughout the night. Use of the 30-degree tilt minimizes the occurrence of pressure ulcers compared with usual care.

Repositioning for treating pressure ulcers

Moore ZE, Cowman S. Cochrane Database Syst Rev 2015; 1: CD006898.

Randomized trials that assess the impact of repositioning patients on the healing rates of pressure ulcers currently exist. The limited data derived from one economic evaluation suggest it remains undetermined as to whether repositioning every 3 hours using the 30-degree tilt is less expensive in terms of nursing time and more effective than standard care involving repositioning every 6 hours using a 90-degree tilt.

Palliative Care

Pressure ulceration and palliative care: prevention, treatment, policy and outcomes

Stephen-Haynes J. Int J Palliat Nurs 2012; 18: 9–16.

Nurses working in palliative care need to be aware of pressure ulcer development and to possess knowledge related to preventing and managing pressure ulceration.

How to reduce hospital-acquired pressure ulcers on a neuroscience unit with a skin and wound assessment team

McGuinness J, Persaud-Roberts S, Marra S, Ramos J, Toscano D, Policastro L, et al. Surg Neurol Int 2012; 3: 138.

Several changes were implemented in order to reduce hospital-

acquired pressure ulcers; turning patients every 1 to 2 hours, repositioning, specialty beds, and skin and wound teams that consisted of one or two expert nursing assistants/nurses who made rounds for all patients in the unit at least once a week.

Debridement

Collagenase in the treatment of dermal and decubitus ulcers

Rao DB, Sane PG, Georgiev EL. J Am Geriatr Soc 1975; 23: 22–30.

Enzymes can be used alone or in combination with other forms of debridement.

Debridement of cutaneous ulcer: medical and surgical aspects

Witkowski JA, Parish LC. Clin Dermatol 1991; 9: 585–93.

Debridement can be accomplished by cold steel cutting, by chemical application, or by autohemolytic destruction under an occlusive dressing.

Maggot debridement therapy: a systematic review

Shi E, Shofler D. Br J Community Nurs 2014; Suppl Wound Care: S6–13.

Maggot debridement therapy, as unappetizing as it may be, promotes wound healing through debridement, disinfection, and growth-promoting activity. It may be utilized for the debridement of nonhealing necrotic skin and soft tissue wounds, especially pressure ulcers, and diabetic foot ulcers.

The role of surgical debridement in healing of diabetic foot ulcers

Gordon KA, Lebrun EA, Tomic-Canic M, Kirsner RS. Skinmed 2012; 10: 24–6.

Evidence to support debridement in enhancing healing is scarce, and there are insufficient data to support debridement for venous ulcers and pressure ulcers.

Cleansing

Cleansing the traumatic wound by high pressure syringe irrigation

Stevenson TR, Thacker JG, Rodeheaver GT, Bacchetta C, Edgerton MT, Edlich RF. J Am Coll Emerg Phys 1976; 5: 17–21.

Cleansing provides enough force to remove bacteria and other debris and loosen eschar.

Wound cleansing for pressure ulcers

Moore ZE, Cowman S. Cochrane Database Syst Rev 2013; 3: CD004983.

Studies that used saline spray containing aloe vera, silver chloride, and decyl glucoside; isotonic saline solution; and pulsatile lavage, water, and sham (the lavage flow was directed into a wash basin positioned adjacent to the wound and not visible to the participants).

There currently is no promising trial evidence to advocate for the use of a specific wound cleansing solution or technique for pressure ulcers.

Wound cleansing, topical antiseptics and wound healing

Atiyeh BS, Dibo SA, Hayek SN. Int Wound J 2009; 6: 420–30.

Wound cleansers, povidone-iodine, chlorhexidine, alcohol, acetate, hydrogen peroxide, boric acid, silver nitrate, silver sulfadiazine, and sodium hypochlorite may affect normal human cells and may be antimitotic, adversely affecting normal tissue repair. Negative outcomes may occur with repeated and excessive wound treatment with antiseptics without proper indications; however, when applied at the appropriate times and concentrations, some classes of antiseptics may function as a tool for the clinician to steer the wound bed in specific directions.

Antimicrobial Agents

Topical metronidazole for odor control in pressure ulcers

Lyvers E, Elliott DP. Consult Pharm 2015; 30: 523–6.

When metronidazole was applied to the wound two or three times daily, 0.75% and 1% creams, gels, lotions, and intravenous solutions of metronidazole were effective with nearly complete odor resolution in 2 to 7 days. Although there was the risk for systemic absorption, almost no systemic adverse events were reported in the literature. Monitoring is still required, as nausea, gastrointestinal distress, and neural toxicities from long-term use are still possible.

Which medical device and/or which local treatment are to be used, as of 2012, in patients with infected pressure sore?
Developing French guidelines for clinical practice

Arzt H, Fromantin I, Ribinik P, Barrois B, Colin D, Michel JM, et al. *Ann Phys Rehabil Med* 2012; 55: 498–507.

The studies do not indicate that one particular topical product is better than another for wound cleaning. Local antimicrobial treatment may be applied when there are indications of local infection. Systemic antimicrobial treatment should be used when general medical signs of infection exist. The draining of exudates and pus is ensured by alginate dressings, carboxymethyl cellulose (CMC) fiber, draining, or irrigoabsorbent compresses covered, if possible, by a nonocclusive dressing until the signs of infection regress.

Bacteriology of pressure ulcers in individuals with spinal cord injury: what we know and what we should know

Dana AN, Bauman WA. *J Spinal Cord Med* 2015; 38: 147–60.

Staphylococcus aureus, *Proteus mirabilis*, *Pseudomonas aeruginosa*, and *Enterococcus fecalis* were the organisms most frequently identified in pressure ulcers.

Nutrition

A nutritional formula enriched with arginine, zinc, and antioxidants for the healing of pressure ulcers: a randomized trial

Cereda E, Klersy C, Seriola M, Crespi A, D'Andrea F; OligoElement Sore Trial Study Group. *Ann Intern Med* 2015; 162: 167–74.

Supplementation with arginine, zinc, and antioxidants within a high-calorie, high-protein formula may improve pressure ulcer healing with a 20% higher reduction in pressure ulcer area after 8 weeks of intervention.

The role of nutrition for pressure ulcer management: National Pressure Ulcer Advisory Panel, European Pressure Ulcer Advisory Panel, and Pan Pacific Pressure Injury Alliance white paper

Posthauer ME, Banks M, Dorner B, Schols JM. *Adv Skin Wound Care* 2015; 28: 175–88.

Adults who are underweight or who have experienced notable unintended weight loss may require additional energy intake. Provide fortified foods and/or high-calorie, high-protein oral nutritional supplements between meals if nutritional requirements remain deficient by dietary intake means. Consider enteral or parenteral nutritional support when oral intake is inadequate.

Synthetic Dressing

Successful treatment of unstageable pressure ulcers by using advanced wound dressing

Sunarti S. Med Indones 2015; 47: 251–2.

The stages of healing are cleaning, granulation, and epithelialization. Alginate dressing, dextranomer dressing, hydrofiber dressing, flax dressing, silver-supplemented dressing, or enzyme-supplemented dressing are the proposed dressings for the cleaning phase, whereas for the granulation phase, alginate dressing, hydrocolloid dressing, flax dressing, polyurethane foam dressing, or tender wet dressing should be utilized. For the epithelization phase, hydrofiber dressing, hydrocolloid dressing, hydrogel dressing, flax dressing, and semipermeable dressing may be used.

Second-Line Therapies

• Hydrocolloid wafer dressing	C
• Hydrogel	C
• Synthetic dressing	C

Using transparent polyurethane film and hydrocolloid dressings to prevent pressure ulcers

Dutra RA, Salomé GM, Alves JR, Pereira VO, Miranda FD, Vallim VB, et al. Wound Care 2015; 24: 268, 270–1, 273–5.

The transparent polyurethane film (8.7%) performed better and was

more effective than the hydrocolloid dressing (15%) in preventing pressure ulcer development, as evidenced in 160 patients.

Hydrogel dressing for treating pressure ulcers

Dumville JC, Stubbs N, Keogh SJ, Walker RM, Liu Z. Cochrane Database Syst Rev 2015; 2: CD011226.

It is not explicit if hydrogel dressings are more or less effective than other treatments in healing pressure ulcers or if different hydrogels have contrasting effects. Most trials that have been performed in this area are very small and poorly reported, so the risk of bias is uncertain.

Dressings and topical agents for preventing pressure ulcers

Moore ZE, Webster J. Cochrane Database Syst Rev 2013; 8: CD009362.

Although the occurrence of pressure ulcers was reduced when dressings were employed to protect the skin, results were compromised by the low quality of the included trials. These trials contained considerable risk of bias and clinical heterogeneity (variations in population and intervention techniques); consequently, results should be interpreted as inconclusive.

Third-Line Therapies

• Nitroglycerin ointment	D
• Becaplermin gel	A
• 5-Fluorouracil cream	D
• Hyperbaric oxygen	E
• Honey	B
• Platelet-rich plasma	B
• Electrical stimulation	C
• Negative pressure wound therapy	C
• Surgical management	D

Hyperbaric oxygen therapy for chronic wounds

Kranke P, Bennett MH, Martyn-St James M, Schnabel A, Debus S. Cochrane Database Syst Rev 2012; 4: CD004123.

There are no satisfactory studies available to prove that hyperbaric oxygen is useful in decubitus or arterial ulcers.

Nonpharmacologic interventions to heal pressure ulcers in older patients: an overview of systematic reviews (the SENATOR-ONTOP series)

Vélez-Díaz-Pallarés M, Lozano-Montoya I, Abraha I, Cherubini A, Soiza RL, O'Mahony D, et al. J Am Med Dir Assoc 2015; 16: 448–69.

The most frequent interventions investigated in these trials were support surfaces (13 studies), nutrition (8), and electrotherapy (6). The evidence grade is too low or insufficient to support the utilization of any support surface, nutrition intervention, multicomponent interventions, repositioning, or other adjunctive therapy (ultrasound, negative pressure, laser, electromagnetic, light, shock wave, hydrotherapy, radiofrequency, or vibration therapy) to increase the

rates of pressure ulcers healing in older patients. Electrotherapy may demonstrate some beneficial effect in the treatment of pressure ulcers, although the quality of evidence is low.

Honey as a topical treatment for wounds

Jull AB, Cullum N, Dumville JC, Westby MJ, Deshpande S, Walker N. Cochrane Database Syst Rev 2015; 3: CD005083.

Honey has become in vogue for healing partial-thickness burns more quickly than conventional treatment (which included polyurethane film, paraffin gauze, soframycin-impregnated gauze, sterile linen, and leaving the burns exposed) and healing infected postoperative wounds more quickly than antiseptics and gauze, but the evidence remains unconvincing.

Role of local application of autologous platelet-rich plasma in the management of pressure ulcers in spinal cord injury patients

Singh R, Rohilla RK, Dhayal RK, Sen R, Sehgal PK. Spinal Cord 2014; 52: 809–16.

Using local applications of platelet-rich plasma (PRP) may be deemed a promising alternative to standard saline dressings in 25 grade IV spinal cord injury patients with pressure ulcers healing.

Negative pressure wound therapy for treating pressure ulcers

Dumville JC, Webster J, Evans D, Land L. Cochrane Database Syst Rev 2015; 5: CD011334.

There is currently no rigorous randomized controlled trial (RCT) evidence available regarding the effects of negative pressure wound therapy (NPWT) compared with alternatives for the treatment of pressure ulcers.

Phototherapy for treating pressure ulcers

Chen C, Hou WH, Chan ES, Yeh ML, Lo HL. Cochrane Database Syst Rev 2014; 7: CD009224.

Trials compared the use of phototherapy with standard care only (six trials) or sham phototherapy (one trial). Among five studies reporting the rate of change in ulcer area, three studies found no statistically remarkable difference between the two groups. These are very uncertain as to the effects of phototherapy in treating pressure ulcers. The quality of evidence is very low due to the unclear risk of bias and small number of trials available for analysis.

Electromagnetic therapy for treating pressure ulcers

Aziz Z, Bell-Syer SE. Cochrane Database Syst Rev 2015; 9: CD002930.

There is no strong evidence indicating benefits of using electromagnetic therapy (EMT) to treat pressure ulcers; however, the possibility of a beneficial or harmful effect cannot be eliminated, because there were only two included trials, both with methodological limitations and small numbers of participants.

A review of the surgical management of heel pressure ulcers in the 21st century

Bosanquet DC, Wright AM, White RD, Williams IM. Int Wound J 2016; 13: 9–16.

Surgical interventions, such as simple debridement, partial or total calcanectomy, arterial revascularization in the context of coexisting peripheral vascular disease, or using free tissue flaps may be the only means of encountering successful healing in stage IV pressure ulcers. Amputation may be necessary for failed surgical intervention or as a definitive first-line procedure in certain high-risk or poor-prognosis patient groups.

[†] deceased

Delusions of parasitosis

Mio Nakamura, Jillian W. Wong Millsop, and John Y.M. Koo

Delusions of parasitosis is a form of delusional disorder, somatic type (also known as a *monosymptomatic hypochondriacal psychosis*), in which patients have cutaneous dysesthesia that causes them to pick at their skin continuously in order to “extract” an organism or “foreign

body” they believe is present in their skin. The cutaneous findings that result from these attempts to dig out the suspected parasites range from normal skin to excoriations, picker’s nodules, and frank ulcerations. Patients develop elaborate and complex delusional ideations associated with their condition, and their fixed beliefs cannot be argued with reason. These patients often collect “samples” in bottles, Ziploc bags, jars, or slides of what is often lint, hair, debris, dead skin, and even common insects found in the home, using these specimens to provide “evidence” to physicians of the alleged underlying cause of their condition. Many of these patients can also have tactile hallucinatory experiences that are compatible with their delusion. The most characteristic hallucinatory symptom they may experience is formication, which manifests as sensations of cutaneous crawling, biting, or stinging. Many also complain of pruritus.

The condition has a bimodal age distribution, occurring in younger adults (men and women) and the elderly (mostly women). There can be secondary psychopathologies in delusions of parasitosis, such as depression and anxiety; these can be severe enough to cause the patient to commit suicide.

Management Strategy

First, it is imperative that the dermatologist carry out a detailed medical history to exclude a frank skin condition (e.g., scabies incognito) or other possible organic conditions, such as substance abuse (e.g., cocaine), neurologic (e.g., multiple sclerosis), endocrine (e.g., diabetes mellitus), hematologic/oncologic (e.g., lymphoma), nutritional (e.g., B₁₂ or folate deficiency), infectious (e.g., Human Immunodeficiency Virus), cardiovascular (e.g., congestive heart failure), or renal (e.g., uremic pruritus) disorders. The condition can also develop after the patient, relative, or pet has had a true parasitic infection, and so ruling out the presence of a real infestation is warranted. Importantly, when patients do *not* know the reason why they are itching, the clinician should consider a diagnosis other than delusions of parasitosis because patients with delusions typically “know” that a particular infestation is causing their symptoms.

Second, a thorough physical examination should be performed, including examining various “specimens” that the patient may bring to the dermatologist’s office. These specimens can be observed under

the microscope, which will demonstrate to the patient that his or her concerns are being taken seriously. One should not make any comments that may reinforce their delusional ideation, such as a statement that an organism responsible for the condition was found; this may ultimately render the patient more difficult to deal with by making him or her even more firmly fixated on the erroneous beliefs. On the other hand, by definition, rational argument or trying to talk a patient out of a delusion is both not possible (if the patient has a real delusion) and counterproductive. Dermatologists can acknowledge the patient's sensations and suffering as real and that they will do everything they can to help.

It is also important for the dermatologist to treat secondary skin changes in these patients. By doing so, the dermatologist will help to forge a therapeutic alliance with the patient. Dermatologists should consider soothing baths and topical agents such as steroid–anesthetic combinations or creams with menthol.

The most effective way to reverse delusional ideation is to start the patient on an *antipsychotic medication*. If this is described as an antipsychotic agent, however, few patients will accept the treatment. On the other hand, if this option is offered in a neutral way, emphasizing possible symptom reduction, such as reduced crawling, biting, or stinging sensations, while avoiding discussing pathophysiology or the mechanism of action of these medications, patients may be willing to accept.

The medication traditionally used to treat delusions of parasitosis is pimozide, a neuroleptic. This medication generally works very well, whether patients have classic delusions of parasitosis or formication without delusions. The starting dose of pimozide is deliberately kept low at 0.5 to 1 mg/day to minimize risks of side effects. The dose is gradually increased until the optimal clinical response is attained, as evidenced by reduced formication, mental preoccupation, and agitation. The dose of pimozide can be increased by as little as 0.5- to 1-mg increments and as slowly as on a biweekly to monthly basis until significant clinical response is noted, which is usually evident at a dose of 3 to 5 mg daily. It is very rare that a patient will require a dose of more than 5 mg daily, and the use of more than 10 mg daily is almost unheard of in the treatment of delusions of parasitosis. Once the patient reaches a stable, well-tolerated dose and agitation, mental preoccupation, and symptoms of formication have subsided, this dose should be maintained for a few months. During this time, if the

patient continues to experience improvement, the dosage of pimozide can then be gradually reduced by as little as 1 mg every 2 to 4 weeks until the minimum necessary dosage is determined or the patient is slowly tapered off the pimozide altogether.

If the clinical state deteriorates again in the future with a new episode of a delusional belief system and formication, the patient can be restarted on pimozide and again treated on a time-limited fashion to control the particular episode. Most patients can be treated on an episodic basis and can be tapered off pimozide after several months, but some require long-term low-dose maintenance treatment.

Because pimozide blocks dopaminergic receptors, there is the possibility that extrapyramidal side effects such as stiffness in the muscles or akathisia, an inner sensation of restlessness, may develop. Acute dystonic reaction and tardive dyskinesia are other potential adverse consequences associated with pimozide, although with the relatively low dosages used to treat delusions of parasitosis, these side effects are rarely encountered. If they do develop, however, they can usually be controlled with anticholinergic agents such as benztropine (Cogentin) 1 to 2 mg up to four times a day as needed, or diphenhydramine (Benadryl) 25 mg four times a day as needed for stiffness or restlessness. Akathisia and pseudoparkinsonian side effects are not a reason for discontinuing treatment with pimozide provided they are kept under control with one of these agents.

Because pimozide can theoretically prolong the QT interval or cause ventricular arrhythmias, it is advisable to consider checking electrocardiograms (ECGs) pretreatment and, periodically, during treatment, especially in older patients or those with a history of cardiac arrhythmia. It should be noted that in most cases, the risk of ECG abnormalities, including prolongation of the QT interval, is minimal with doses at or less than 5 mg daily, provided that they are not elderly and have no history of arrhythmia. Caution must also be exercised in prescribing pimozide for those with hepatic or renal dysfunction.

Atypical antipsychotics, such as *risperidone* and *olanzapine*, have also been used successfully to treat patients with delusions of parasitosis. Atypical antipsychotics block more 5-HT₂ (serotonin) receptors than D₂ receptors. Serotonin has been shown to be a key player in some states of psychosis, most cases of obsessive-compulsive disorder, and self-mutilation, which can all potentially manifest in patients with delusions of parasitosis. Thus atypical antipsychotics, by blocking

both serotonin and dopaminergic receptors, are thought theoretically to be an effective choice for treating this condition. Furthermore, the burden of side effects with atypical antipsychotics may be reduced compared with that of older typical antipsychotics. Having the patient agree to go on risperidone or olanzapine, however, may be more difficult than pimozide, because pimozide's primary indication is Tourette syndrome, whereas the primary indication for risperidone and olanzapine is schizophrenia, with the latter indication being unacceptable to most patients with delusions of parasitosis.

Nevertheless, over the past several years, clinicians have reported many successful cases using atypical antipsychotics. It is usually advisable to start at low doses and titrate upward as needed. (For example, for risperidone, start from 0.5 mg once to twice daily up to the usual maximum dose of 5 mg daily.) To date, however, there have been no randomized, double-blind, placebo-controlled trials comparing the efficacy of pimozide with the atypical antipsychotics, and most of the medical literature on atypical antipsychotics is limited to case reports.

At any point, if feasible, it may be beneficial to try to refer the patient to a psychiatrist. However, many of these patients cannot be managed by psychiatrists because of their refusal to believe their condition is psychiatric in nature. Therefore, a dermatologist willing to use antipsychotic medications is likely to be the only way that most of these patients can receive the treatment they need. At the same time, the most difficult aspect of managing patients with delusions of parasitosis is trying to obtain their cooperation in taking the medication. This difficulty arises as a result of the difference between the patients' belief system and the physician's understanding of the patient's experience. Even with all the interpersonal skillfulness as described earlier, patients may be reluctant to take a psychotropic medication. It may be helpful to emphasize to them that these medications have worked well with patients with similar symptoms and that, in light of their suffering, they have nothing to lose by trying the medication with the spirit of "trial and error" as long as the patient is adequately supervised for safety. Even though managing psychotic patients in dermatologic settings has many challenges, when a dermatologist manages to connect with at least some of these patients and dramatically reverse their very miserable situation, these patients often turn out to be the most grateful patients one can have in a dermatologist's career.

Specific Investigations

These additional tests may be considered, depending on the patient's clinical presentation:

- Complete blood count
- Complete metabolic panel, including liver function tests
- Thyroid function tests
- Serum B₁₂, ferritin
- ECG before initiation of pimozide and periodically while on pimozide, if indicated
- Drug screen

Clinical, epidemiologic, histopathologic and molecular features of an unexplained dermopathy

Pearson ML, Selby JV, Katz KA, Cantrell V, Braden CR, Parise ME, et al. PLoS ONE 2012; 7: e29908.

This is a study by Kaiser Permanente Northern California that was funded by the Centers for Disease Control of 115 patients with self-reported fibers, threads, granules, and other solid substances coming out of their skin. The study included collection of epidemiologic data, clinical evaluations, and analysis of solid materials. The final conclusion of the study was that the patients studied appeared to have a psychiatric disorder consistent with delusions of parasitosis.

Contemporary Diagnosis and Management in Advanced Psychodermatology

Nguyen CM, Beroukhim K, Danesh MJ, Koo JYM. Longboat Key: Handbooks in Health Care, 2015.

This is a comprehensive handbook on psychodermatology, including diagnosis and management of patients with delusions of parasitosis.

Delusions of parasitosis: ethical and clinical considerations

Fabbro S, Aultman JM, Mostow N. J Am Acad Dermatol 2013; 69: 156–9.

A case is presented that demonstrates the dermatologist's dilemma when treating patients with primary psychiatric disease. There is a discussion on the best clinical and ethical action, using principle- and narrative-based approaches in ethical reasoning.

Delusional infestation is typically comorbid with other psychiatric diagnoses: review of 54 patients receiving psychiatric evaluation at Mayo Clinic

Hylwa SA, Foster AA, Bury JE, Davis MD, Pittelkow MR, Bostwick JM. Psychosomatics 2012; 53: 258–65.

This retrospective study found that 74% of patients with delusional infestation have multiple coexisting or underlying psychiatric disorders. Therefore evaluation by a psychiatrist, when possible, is advised for all patients with delusional infestation.

Diffuse pruritic lesions in a 37-year-old man after sleeping in an abandoned building

Dunn J, Murphy MB, Fox KM. Am J Psychiatry 2007; 164: 1166–72.

This is an excellent case presentation of a patient with delusions of parasitosis and contains a thorough discussion of the differential diagnosis.

First-Line Therapy

• Pimozide	B
------------	----------

Pimozide in dermatologic practice: a comprehensive review

Lorenzo CR, Koo J. Am J Clin Dermatol 2004; 5: 339–49.

This article reviews the utility of pimozide in dermatologic conditions.

Delusional parasitosis: a dermatologic, psychiatric, and pharmacologic approach

Driscoll MS, Rothe MJ, Grant-Kels JM, Hale MS. J Am Acad Dermatol 1993; 29: 1023–33.

Pimozide is suggested as the first line of therapy for this psychodermatologic condition. Relapse often occurs upon discontinuation of the drug.

Neurotropic and psychotropic drugs in dermatology

Tennyson H, Levine N. *Dermatol Clin* 2001; 19: 179–97.

This is a review article discussing the use of psychotropic drugs for psychodermatologic conditions such as delusions of parasitosis.

Second-Line Therapies

• Risperidone	D
• Olanzapine	D
• Quetiapine	E
• Aripiprazole	E
• Ziprasidone	E
• Trifluoperazine	E
• Haloperidol	E
• Sulpiride	E
• Fluphenazine	E
• Flupenthixol	E
• Promazine	E

Second-generation antipsychotics in primary and secondary delusional parasitosis: outcome and efficacy

Freudenmann RW, Lepping P. J Clin Psychopharmacol 2008; 28: 500–8.

The first retrospective case-based analysis of 63 cases from 434 available publications to determine the efficacy and outcome of second-generation antipsychotic agents. It was found that risperidone and olanzapine were the most frequently used of these agents, with full or partial remission in 69% and 72% of cases, respectively.

Therapeutic update: use of risperidone for the treatment of monosymptomatic hypochondriacal psychosis

Elmer KB, George RM, Peterson K. J Am Acad Dermatol 2000; 43: 683–6.

The authors discuss risperidone as being highly effective for delusions of parasitosis while avoiding the negative long-term side effects of pimozide (as discussed earlier).

Primary delusional parasitosis treated with olanzapine

Freudenmann RW, Schönfeldt-Lecuona C, Lepping P. Int Psychogeriatr 2007; 19: 1161–8.

A case report of an elderly woman with delusions of parasitosis successfully and safely treated with olanzapine monotherapy. The authors also present a review of all articles that report the use of atypical antipsychotics for delusions of parasitosis.

Aripiprazole as a viable alternative for treating delusions of parasitosis

Ladizinski B, Busse KL, Bhutani T, Koo JY. J Drugs Dermatol 2010; 9: 1531–2.

A case report of using aripiprazole as a safe and effective treatment for delusions of parasitosis.

Ziprasidone in the treatment of delusional parasitosis

Contreras-Ferrer P, de Paz NM, Cejas-Mendez MR, Rodriguez-Martin M, Souto R, Bustiduy MG. Case Rep Dermatol 2012; 4: 150–3.

This is a case report of successful treatment of delusions of parasitosis with pimozide and ziprasidone.

Promazine in the treatment of delusional parasitosis

Cubala WJ, Jakuszkowiak-Wojten K, Burkiewicz A, Wrońska A. *Psychiatria Danubina* 2011; 23: 198–9.

This case report demonstrates efficacy and safety of promazine in an elderly patient with delusions of parasitosis.

Antipsychotic treatment of primary delusional parasitosis: systematic review

Lepping P, Russell I, Freudenmann RW. *Br J Psychiatry* 2007; 191: 198–205.

This article is a systematic review of the use of typical and atypical antipsychotics in patients with delusions of parasitosis. Analyses showed that both typical and atypical antipsychotics were effective in the majority of patients. Particularly effective antipsychotics resulting in full or partial remission were pimozide, trifluoperazine, haloperidol, sulpiride, fluphenazine, and flupenthixol.

Dermatitis artefacta

Tian Hao Zhu, Jillian W. Wong Millsop, and John Y.M. Koo

Dermatitis artefacta (DA), also known as *factitious dermatitis*, is a rare psychiatric condition in which patients self-induce a variety of skin lesions. The motive for creating the lesions is often a conscious or unconscious psychological need to seek attention or medical care,

possibly due to childhood feelings of abandonment or neglect. Currently the disorder is found to occur in a 4-to-1 ratio of female-to-male patients with the average age at presentation of 12.5 years. Recent studies suggest that a large proportion of patients with dermatitis artefacta may also have comorbid generalized anxiety, major depression, or borderline personality disorder.

The method used to inflict the lesions is typically more elaborate than simple excoriations. The appearance of the lesions depends on the manner in which they are created and can range from minor cuts to large areas of trauma but is usually characterized by abnormally shaped superficial erosions surrounded by normal-looking skin within easily reachable areas. Chemical or thermal burns, injection of foreign materials, circulatory occlusion, and tampering with old lesions, such as existing scars or prior surgical incision sites, are some common methods of self-injury. More serious wounds can result in abscesses, gangrene, or even life-threatening infection.

Interestingly, when the patient is asked about the manner in which the skin condition evolved, he or she will invariably deny responsibility for the injury and is often vague, generally unmoved, and cannot provide sufficient detail, a unique aspect of the illness termed the *hollow history*.

Management Strategy

It is important to first rule out malingering as the etiology of the skin lesions. If the skin lesions are created deliberately for secondary gain, such as to obtain disability or insurance benefits, the case is no longer considered psychiatrically based. Rather, it is now considered a criminal act and may eventually need to be dealt with legally. On the other hand, if the lesions are created without underlying material or personal gain, then the condition is considered an illness, and medical/psychiatric intervention is warranted.

Most treatment for dermatitis artefacta is symptomatic and supportive. *Protective dressings*, such as an Unna boot, may be used to occlude the involved areas and protect against further self-injurious behavior.

Antidepressant medications, such as *selective serotonin reuptake inhibitors (SSRIs)*, may be helpful for patients with dermatitis artefacta who have primary or secondary depression. If there is clinical evidence of a psychotic process, *pimozide* could be considered. There

have also been recent case reports of patients responding to the atypical antipsychotic *olanzapine* when other modes of therapy, including antidepressants and other antipsychotics, have failed.

Importantly, physicians should be aware that patients presenting with dermatitis artefacta have a psychiatric illness, and the skin lesions are often an appeal for help. However, suggesting that the illness is psychiatrically based often has a negative effect on patient rapport. Direct confrontation should be avoided, if possible, and instead, *a supportive environment* and a *stable physician–patient therapeutic alliance* should be fostered, often initially through short (so as not to “burn out” the dermatologist) but frequent (so as to satisfy the patient) office visits. The clinician should be nonjudgmental; empathize with the patient’s pain, discomfort, and restrictions imposed by the skin lesions; and potentially explore possible stressors in the patient’s life.

In the case of an adolescent, the clinician should encourage the parents to become involved in identifying psychosocial stressors and helping to modify the patient’s environment to meet his or her needs. Certain parents may be resistant to their child’s diagnosis and can become angry and critical toward the clinician, so great discretion is recommended. If there is intense antagonism (“power struggle”) between the adolescent patient and the parents, it may be advisable to see the patient alone, without the parents, to optimize the possibility of developing therapeutic rapport with the patient. Once the patient establishes trust in the physician by means of a stable relationship, the physician may help the patient recognize the psychosocial impact of the disorder and *recommend consultation with a psychiatrist* or *psychotherapy*. However, this approach should be attempted only if the clinician feels that the therapeutic rapport is strong enough to achieve possibility of success rather than being misinterpreted negatively and defensively by the patient.

Most patients with dermatitis artefacta will have a chronic waxing and waning course of disease. Thus even when the condition is under control, the physician should still follow the patient at regular intervals to ensure that the self-destructive behavior does not relapse. *Regular visits*, whether or not lesions are present, will help the patient feel cared for and diminish the need for self-mutilation as a call for help.

Specific Investigations

- Rule out malingering
- Rule out any organic dermatologic disease
- Assess for associated psychiatric disorders (e.g., depression)

Factitious Dermatitis

Contemporary Diagnosis and Management in Advanced Psychodermatology

Nguyen C, Beroukheim K, Danesh M, Koo J. 2015; 21–2.

This handbook is an up-to-date review of the diagnosis and treatment of dermatitis artefacta.

Self-induced skin lesions: a review of dermatitis artefacta

Gattu S, Rashid RM, Khachemoune A. *Cutis* 2009; 84: 247–51.

This article is an up-to-date review of dermatitis artefacta.

Cutaneous manifestations of psychiatric disease that commonly present to the dermatologist – diagnosis and treatment

Koblenzer CS. *Int J Psychiatry Med* 1992; 22: 47–63.

This article describes common dermatologic presentations of psychopathology, including dermatitis artefacta.

Dermatitis artefacta in pediatric patients: experience at the National Institute of Pediatrics

Saez-de-Ocariz M, Orozco-Covarrubias L, Mora-Magaña I, Duran-McKinster C, Tamayo-Sanchez L, Gutierrez-Castrellon P, et al. *Pediatr Dermatol* 2004; 21: 205–11.

In this study, the incidence of dermatitis artefacta was 1:23,000. It is considered rare in children; 12 of the 29 patients reported had an associated chronic illness, and 7 exhibited mild mental retardation.

Diagnostic clues to dermatitis artefacta

Joe EK, Li VW, Magro CM, Arndt KA, Bowers KE. *Cutis* 1999; 63: 209–14.

The clinical and histopathologic features, diagnostic aids, approach to therapy, and prognosis for dermatitis artefacta are discussed in this case report.

First-Line Therapies

• Occlusive dressings	D
• Psychotropic agents	D
• Psychotherapy (even if only supportive)	D
• Management of secondary cutaneous complications	D

Self-inflicted skin diseases. A retrospective analysis of 57 patients with dermatitis artefacta seen in a dermatology department

Nielsen K, Jeppesen M, Simmelsgaard L, Rasmussen M, Thestrup-Pedersen K. *Acta Derm Venereol* 2005; 85: 512–5.

This retrospective analysis of 57 patients reported the following findings: when self-infliction was suggested as the potential cause of illness to patients ($n = 30$), only one patient agreed to see a psychiatrist, and two thirds denied self-infliction or discontinued treatment. Ten patients had a psychiatric diagnosis. The most common subjective complaints were “pain” (59%) and “itching” (37%). The three most common lesion types were skin ulcers (72%), excoriations (46%), and erythema (30%). Of the 57 patients, 61% were treated with anxiolytic or antidepressant medications. In 32 patients, occlusive dressings were administered, and the lesions showed improvement except in two cases.

Training future dermatologists in psychodermatology

Van Moffaert M. *Gen Hosp Psychiatry* 1986; 8: 115–8.

Palliative dermatologic measures such as occlusive bandages, ointments, or placebo drugs, as well as hospitalization that includes bathing and massaging by nurses, can have a therapeutic impact on the psychiatric problem by symbolizing the medical attention and care the patient with dermatitis artefacta is craving.

Dermatitis artefacta. Clinical features and approach to treatment

Koblenzer CS. *Am J Clin Dermatol* 2000; 1: 47–55.

A good review article.

The current management of delusional parasitosis and dermatitis artefacta

Koblenzer CS. Skin Therapy Lett 2010; 15: 1–3.

This article briefly reviews treatment for dermatitis artefacta, including the use of aripiprazole.

Second-Line Therapy

• Olanzapine	D
--------------	---

Treatment of self-mutilation with olanzapine

Garnis-Jones S, Collins S, Rosenthal D. J Cutan Med Surg 2000; 4: 161–3.

Three patients were successfully treated with low-dose olanzapine when multiple other therapies (including antidepressants and other antipsychotics) failed.

Dermatitis herpetiformis

John J. Zone

Dermatitis herpetiformis (DH) is a cutaneous manifestation of celiac disease. Rare exceptions have been reported, especially in the Japanese population. More than 85% of patients have an associated celiac disease that spans the spectrum of intestinal histologic severity.

Both the skin disease and intestinal inflammation respond to dietary gluten restriction independent of the severity of the intestinal inflammation. The skin disease also presents with a spectrum of severity, ranging from minimal pruritic papules on the elbows and knees to severe, intensely pruritic vesicular lesions over multiple extensor surfaces. The prevalence of DH is approximately 10 to 39 per 100,000 persons in the Caucasian population. One in six patients diagnosed with celiac disease has DH. DH is distinguished from other bullous diseases by characteristic histologic, immunologic, and associated gastrointestinal findings. Histologically, vesicle formation at the dermal-epidermal junction and infiltration of dermal papillary tips with neutrophils occurs in two thirds of the cases, but other cases may show only nonspecific inflammatory findings. Direct immunofluorescence shows granular or fibrillar IgA localized in the dermal papillary tips or along the basement membrane of perilesional skin.

Management Strategy

The course of DH depends on the therapeutic choices that are made at the time of diagnosis. If patients choose a strict gluten-free diet and adopt a conscientious change in eating habits, they are likely to have a long-term remission. Associated intestinal symptoms are also minimized. Relapses are usually associated with dietary indiscretions. Elevated levels of IgA antibodies to tissue transglutaminase are characteristic of celiac disease, correlate with the degree of intestinal inflammation, and decrease with gluten restriction. Elevated levels of IgA epidermal transglutaminase antibodies are characteristic of DH and are responsible for the diagnostic IgA deposits in skin. If medical therapy with dapsone or sulfapyridine is chosen, the cutaneous lesions can be well controlled. However, attention must be paid to potential side effects of medications. Intestinal symptoms, if present, will continue. Occasionally, some patients (10%–20%) will enjoy a spontaneous remission without medication or dietary restriction. The reason for such remission is unclear.

Dapsone is the drug of choice for DH and is currently the only drug approved by the U.S. Food and Drug Administration (FDA) for use in this disease. Initial treatment with dapsone 25 mg daily will improve pruritus within 24 to 48 hours and the papulovesicular lesions within 1 week in adults. The skin disease recurs within 24 to 72 hours if

dapsone is discontinued. Correspondingly smaller doses (0.5–1 mg/kg) should be used in children. Maintenance therapy is then adjusted on a weekly basis to maintain adequate suppression of symptoms. The average maintenance dose is 0.5 to 1.0 mg/kg daily. Despite adequate dapsone dosages, outbreaks of facial and scalp lesions are common. The most common cause of poor response to dapsone therapy is incorrect diagnosis.

Adherence to a gluten-free diet (GFD) improves clinical symptoms in patients with DH. The advantages of gluten restriction include a reduction of dapsone dosage and its attendant complications, improvement of gastrointestinal symptoms (which range from cramping pain to overt diarrhea), and a therapy aimed at the cause rather than the symptoms of the disease. The increased risk of lymphoma incident to DH and celiac disease is also reduced with a GFD, but not with dapsone. Dapsone improves the cutaneous lesions but has no effect on intestinal disease. Strict adherence to a GFD is challenging, and reintroduction of gluten can exacerbate symptoms. Extremely rare patients will not respond to gluten restriction. In the author's opinion, a useful therapeutic strategy is the initial control of DH symptoms with dapsone coincident with a GFD, with subsequent monthly tapering of dapsone as gluten restriction gradually improves the cutaneous symptoms. Oats have been found to be nontoxic in most patients with DH and may broaden the dietary options. Recently gluten-free foods have become more available, and patient support groups offer extensive information.

Sulfapyridine is an alternative choice in patients who are intolerant to dapsone and has been shown to result in significant therapeutic efficacy. Sulfapyridine is started at 500 mg three times a day and is usually increased to a maximum maintenance dose of 1.5 g three times a day. Sulfapyridine is not commercially available in the United States and must be compounded. Sulfasalazine can be used as a substitute. It is metabolized by intestinal bacteria to sulfapyridine and 5-amino salicylate. Recommended doses are 500 to 1000 mg twice daily.

Other agents that have been reported to have a therapeutic benefit in DH include *nicotinamide*, *tetracycline* (or a combination of the two), *heparin*, *ciclosporin*, *azathioprine*, *mycophenolate*, *colchicine*, and *systemic corticosteroids*. Rituximab has recently been shown to be effective for both DH and the underlying celiac disease. *Topical corticosteroid application* is generally inadequate when used alone to control DH

symptoms. However, potent corticosteroids in gel form applied frequently may provide relief for occasional lesions that develop on otherwise adequate dapsone or GFD therapy. This allows patients to treat lesions without increasing the dosage of dapsone.

Specific Investigations

- Biopsy for histology and direct immunofluorescence
- Complete blood count and liver function tests
- Glucose-6-phosphate dehydrogenase levels
- IgA tissue transglutaminase antibodies
- IgA epidermal transglutaminase antibodies

Dermatitis herpetiformis: a cutaneous manifestation of coeliac disease

Collin P, Salmi TT, Hervn K, Kaukinen K, Reunala T. Ann Med 2016; 8: 1–25.

DH is a manifestation of celiac disease in virtually all cases. Not all cases have abnormal IgA TG2 antibodies or abnormal small intestinal biopsies, but nearly all cases respond slowly to dietary gluten restriction. Five percent of first-degree relatives of DH patients will have celiac disease if tested.

Deposition of granular IgA relative to clinical lesions in dermatitis herpetiformis

Zone JJ, Meyer LJ, Petersen MJ. Arch Dermatol 1996; 132: 912–8.

It is accepted that granular IgA deposition in perilesional, clinically normal-appearing skin is the most reliable diagnostic criterion for DH. Although the combination of characteristic clinical and pathologic features is highly suggestive of DH, the diagnosis should not be made without the identification of granular IgA in dermal papillae. If direct immunofluorescence is negative and histology is suggestive of DH, a repeat biopsy for direct immunofluorescence is recommended.

First-Line Therapies

• Dapsone	B
• Gluten-free diet	B

Suggested guidelines for patient monitoring: hepatic and hematologic toxicity attributable to systemic dermatologic drugs

Wolverton SE, Remlinger K. *Dermatol Clin* 2007; 25: 195–205.

Dapsone may produce a drug hypersensitivity syndrome with liver toxicity in the first 3 to 12 weeks. Monitoring of the aspartate transaminase (AST), alanine transaminase (ALT), and eosinophil count is indicated. Hepatocellular toxicity may also occur in a dose-related fashion, especially with doses greater than 2 mg/kg. AST and ALT should be monitored when the dosage is increased. There are three main hematologic toxicities of dapsone: hemolysis, methoglobinemia, and agranulocytosis. Methoglobinemia is usually mild and not problematic unless the patient has underlying cardiopulmonary problems. Agranulocytosis is rare and usually occurs in the first 3 to 12 weeks of therapy. Symptoms demanding attention include pharyngitis, fever, and oral ulcerations. Virtually all patients have at least some degree of hemolysis, and a fall of the hemoglobin of 1 to 3 g/dL is to be expected. A compensatory reticulocytosis occurs and may be monitored with a reticulocyte count. Hemolysis may be severe in patients with glucose-6-phosphate dehydrogenase deficiency. Glucose-6-phosphate dehydrogenase levels should be evaluated in blacks and those of Southern Mediterranean origin before the initiation of therapy to avoid potentially catastrophic hemolytic anemia.

Complete blood count and liver function tests should be checked every 2 to 3 weeks for the first 3 months and then every 3 to 6 months thereafter.

Celiac disease and the gluten-free diet: consequences and recommendations for improvement

Theethira TG, Dennis M. *Dig Dis* 2015; 33: 175–82.

GFD is the cornerstone of treatment for celiac disease and

dermatitis herpetiformis. This review addresses the improvements in nutrition in celiac patients on a GFD and also potential problems that may develop on a GFD with deficiencies of fiber, iron, and trace minerals. They also review the issue of weight gain in celiac patients adhering to a GFD because of the high caloric content of commercially available gluten-free foods.

The GFD is complex, and patients need comprehensive nutrition education from a skilled dietitian. Patient support groups frequently provide answers to specific dietary questions.

A long-term gluten-free diet as an alternative treatment in severe forms of dermatitis herpetiformis

Nino M, Ciacci C, Delfino M. J Dermatolog Treat 2007; 18: 10–2.

This study evaluated the efficacy of treating severe skin manifestations of DH with a GFD alone and compared the results to treatment with GFD and dapsone. Eighty-seven percent of patients on GFD alone had complete remission in 18 months (67% of severe patients). A total of 89% of patients on diet and dapsone had remission of skin disease (70% of severe patients), and 11% were improved.

Second-Line Therapies

• Sulfapyridine and sulfasalazine	E
• Elemental diet	C

Management of dermatitis herpetiformis

Cardones AR, Hall RP. Immunol Allergy Clin North Am 2012; 32: 275–81.

Sulfapyridine is not readily available in the United States but can be prescribed through compounding pharmacies. Sulfasalazine, which is more readily available, is metabolized to 5-amino-salicylic acid and sulfapyridine. Patients have been reported to respond to sulfasalazine, 2 to 4 g/day administered twice daily.

The effect of elemental diet with and without gluten on disease activity in dermatitis herpetiformis

Kadunce DP, McMurry MP, Avots-Avotins A, Chandler JP, Meyer LJ, Zone JJ. J Invest Dermatol 1991; 97: 175–82.

In severe refractory cases of DH elemental diet therapy is effective and produces dramatic clinical improvement within 2 to 4 weeks. It involves the ingestion of amino acid and carbohydrate alone and is commercially available as Vivonex. It produces rapid healing of the intestine and relief of cutaneous symptoms but was designed for tube feeding and is considered unpalatable by many.

In this author's experience, elemental diet containing short-chain polypeptides is less effective.

Third-Line Therapies

• Tetracycline and nicotinamide	E
• Heparin	E
• Ciclosporin	E
• Colchicine	E
• Systemic corticosteroids	E
• Rituximab	E

Dermatitis herpetiformis effectively treated with heparin, tetracycline and nicotinamide

Shah SAA, Ormerond AD. Clin Exp Dermatol 2000; 25: 204–5.

This is a case report of a patient with severe DH who was intolerant to dapsone and sulfapyridine. The DH lesions resolved with a combination treatment consisting of subcutaneous low-dose heparin, nicotinamide 1.5 g daily in divided doses, and tetracycline 2 g daily.

The patient was, however, on a GFD.

A rare case of dermatitis herpetiformis requiring parenteral heparin for long-term control

Tan CC, Sale JE, Brammer C, Irons RP, Freeman JG. *Dermatology* 1996; 192: 185–6.

A patient with severe DH who was intolerant of dapsone and sulfapyridine was treated with parenteral heparin, with complete resolution of her skin lesions within 1 week of therapy. This treatment is not practical for long-term management.

Efficacy of ciclosporin in two patients with dermatitis herpetiformis resistant to conventional therapy

Stenveld HJ, Starink TM, van Joost T, Stoof TJ. *J Am Acad Dermatol* 1993; 28: 1014–5.

Two patients with severe DH who were intolerant and/or unresponsive to conventional therapy were treated with ciclosporin (5–7 mg/kg daily) with resolution of skin lesions.

Treatment of dermatitis herpetiformis with colchicine

Silver DN, Juhlin EA, Berczeller PH, McSorley J. *Arch Dermatol* 1980; 116: 1373–84.

Oral colchicine resulted in a significant improvement of skin lesions in three of four patients with DH. The authors suggest that colchicine may be used when dapsone or sulfapyridine is contraindicated.

Rituximab treatment for recalcitrant dermatitis herpetiformis

Albers LN, Zone JJ, Stoff BK, Feldman RJ. *JAMA Dermatol*. 2017; 153: 315–8.

A single patient with refractory DH had a complete clinical response to rituximab 1000 mg on days 1 and 15 with a remission that was documented by normalization of IgA antibody levels to both tissue and epidermal transglutaminase.

Dermatofibrosarcoma protuberans

Daniel Bernstein, Kate Kleydman, and Hooman Khorasani

Dermatofibrosarcoma protuberans (DFSP) is a rare, low-grade, soft tissue, undifferentiated, CD34-positive, factor XIII-negative, mesenchymal tumor that arises in the dermis and characteristically invades deeper underlying soft tissue. It is associated with a high risk

for local recurrence and widespread subclinical extension. The incidence of DFSP is 0.1% of all cancers and 1.8% of all soft tissue sarcomas. It occurs most often in adults aged 20 to 50 years; pediatric and infantile cases, particularly when congenital, are rare. The tumor most commonly involves the trunk (50%–60%) or upper limbs (25%). Head and neck sites account for an additional 10% to 15% of DFSP cases and may not always be completely resectable. If left untreated, the tumor often grows slowly, invading surrounding tissue and neurovascular bundles. Although DFSP can be locally destructive, the tumor rarely metastasizes.

Management Strategy

Surgical excision remains the mainstay of treatment for DFSP. Because DFSP commonly has an infiltrating growth pattern that extends far beyond the clinical margins, a wide excision is recommended, with margins of 2 to 3 cm or more beyond clinically identifiable tumor, down to and including fascia. Despite treatment with wide local excision, local recurrence rates vary significantly in the literature from 10% to 80%. Tumor size and location help determine the appropriate surgical procedure because generous margins are not always practical, particularly for tumors of acral location. The prognosis of DFSP has been investigated, and reduced recurrence-free survival was found to be most associated with acral tumors, whereas overall survival was reduced in cases with metastasis.

Because these neoplasms have a high tendency for local recurrence after surgical excision, a superior cure rate (an overall average recurrence rate of 1.3% among 463 cases reported) and tissue conservation are seen when Mohs micrographic surgery (MMS) is used; thus, *Mohs micrographic surgery* may be considered the treatment of choice. Mohs surgery with continuous histologic margin control requires less tissue removal, allows complete margin assessment, has low recurrence rates, and is rapidly emerging as a first-line treatment modality for this condition. A recent systematic review of the literature found that despite a lack of randomized prospective evidence, margin control via MMS has tended to produce superior results compared with conventional surgery. Alternatively, some dermatologic surgeons have adopted modified Mohs techniques, or so-called *slow Mohs*, by using rush paraffin sections instead of a fresh

tissue technique.

Cytogenetically, DFSP is characterized by a t(17;22)(22;q13) aberration with fusion of the collagen type 1 α (COL1A1) gene on chromosome 17 with the platelet-derived growth factor- β (PDGFB) gene on chromosome 22, which renders these tumors responsive to targeted therapy with tyrosine kinase inhibitors, such as *imatinib mesylate*. Originally approved for the treatment of chronic myelogenous leukemia, imatinib mesylate has been found to have significant therapeutic value in the treatment of DFSP. In 2006 the Food and Drug Administration (FDA) granted approval for imatinib mesylate (*Gleevec*) as a single agent for the treatment of adult patients with unresectable, recurrent, and/or metastatic DFSP at a recommended oral dose of 800 mg/day. Before starting imatinib therapy, cytogenetic studies to confirm PDGFB gene rearrangement may help predict clinical response, and it is recommended that all cases be evaluated before treatment is started.

Neoadjuvant imatinib therapy for DFSP has also been proposed in recent studies. It has been used as a preoperative therapy agent in locally advanced or recurrent DFSPs. This therapeutic strategy may decrease tumor load, promote tumor cell apoptosis, and subsequently reduce the extent of surgery.

Adjuvant radiotherapy, administered either before or after surgery, significantly reduces the risk of local recurrence in patients who have or who are likely to have close or positive margins. This appears to be true for radiation alone or postoperatively for margin-positive disease (primary or recurrent).

DFSP is a radioresponsive tumor, and radiation to doses of 50 to 60 Gy should be considered. Radiation is not recommended in younger patients (under the age of 50 because of increased risk of radiodermatitis and scarring) or in patients with a previous history of radiation therapy. Radiation is also contraindicated in patients with connective tissue diseases or genetic conditions predisposing to skin cancer (e.g., patients with Gorlin syndrome or xeroderma pigmentosum). Combined conservation resection and postoperative radiation should also be considered for situations where adequate wide excision alone would result in major cosmetic or functional morbidity.

Specific Investigations

- Skin biopsy
- Genetic studies

Dermatofibrosarcoma protuberans is a unique fibrohistiocytic tumor expressing CD34

Aiba S, Tabata N, Ishii H, Ootani H, Tagami H. Br J Dermatol 1992; 127: 79–84.

DFSP can be misdiagnosed as a keloid. Histopathology may help differentiate the two, but expression of CD34 by tumor cells occurs only in DFSP. CD34 expression by the tumor cells can be an extremely useful marker in establishing a definitive diagnosis of DFSP.

Stromelysin-3 (ST3) expression in the differential diagnosis of dermatofibroma (DF) and dermatofibrosarcoma protuberans: comparison with factor XIIIa and CD34

Kim HJ, Lee JY, Kim SH, Seo YJ, Lee JH, Park JK, et al. Br J Dermatol 2007; 157: 319–24.

Recent studies demonstrated that dermatofibromas (DFs) expressed ST3, whereas DFSPs were only rarely ST3 positive. ST3 staining might be more reliable than factor XIIIa staining in differential diagnosis of DF and DFSP.

First-Line Therapies

• Mohs micrographic surgery	B
• Wide local excision	C

Dermatofibrosarcoma protuberans: a report on 29 patients treated by Mohs micrographic surgery (MMS) with long-term follow-up and review of the literature

Snow SN, Gordon EM, Larson PO, Bagheri MM, Bentz ML, Sable DB. Cancer 2004; 101: 28–38.

A retrospective review of a series of 29 patients with DFSP and, in an accompanying update of the medical literature, 136 patients with DFSP underwent MMS with over 5 years of follow-up. There were no regional and/or distant metastases. However, late recurrences beyond the usual recommended 5-year follow-up may occur.

Dermatofibrosarcoma protuberans: wide local excision vs. Mohs micrographic surgery

Paradisi A, Abeni D, Rusciani A, Cigna E, Wolter M, Scuderi N, et al. *Cancer Treat Rev* 2008; 34: 728–36.

The records of 79 patients with DFSP who underwent wide local excision (WLE; $n = 38$) or MMS ($n = 41$) between 1990 and 2005 were reviewed retrospectively. Five of the 38 WLE patients (follow-up = 4.8 years) had recurrences (13.2%, 95% confidence interval (CI): 4.4%–28.1%) as opposed to none (95% CI: 0%–8.6%) of the 41 MMS patients (follow-up = 5.4 years).

Outcomes in 11 patients with dermatofibrosarcoma protuberans treated with Mohs micrographic surgery

Galimberti G, Montaña AP, Kowalczyk A, Ferrario D, Galimberti R. *Int J Dermatol* 2012; 51: 89–93.

A retrospective chart review carried out for patients treated with MMS during a 6-year period. MMS with continuous histologic margin control allows for maximum tissue preservation and low recurrence rates and is rapidly emerging as a first-line treatment modality for this condition.

Dermatofibrosarcoma protuberans: 35 patients treated with Mohs micrographic surgery using paraffin sections

Tan WP, Barlow RJ, Robson A, Kurwa HA, McKenna J, Mallipeddi R. *Br J Dermatol* 2011; 164: 363–6.

A case review of 35 patients with DFSP treated with “slow” MMS using paraffin-embedded sections. Seventeen patients required one horizontal layer to clear their tumor, 10 patients needed two, and 8 patients needed three layers or more. Tumor persistence has not been observed in any of our patients after a median follow-up duration of 29.5 months.

Current treatment options in dermatofibrosarcoma protuberans

Lemm D, Mügge LO, Mentzel T, Höffken K. *J Cancer Res Clin Oncol*

2009; 135:653–65.

A literature review of DFSP to review modalities of diagnosis, including CD34 positivity and the unique molecular translocation involving chromosomes 17 and 22 t(17;22)(22;q13), in addition to an investigation of outcomes based on treatment. Although surgical excision remains the mainstay of treatment, MMS has been found to yield improved margin control and is associated with reduced recurrence rates. Adjuvant therapy with radiation or imatinib may be necessary in selected patients, especially when unresectable tumors are being addressed. Chemotherapy seems to be of little or no benefit.

Dermatofibrosarcoma protuberans treated with wide local excision and followed at a cancer hospital: prognostic significance of clinicopathologic variables

Erdem O, Wyatt AJ, Lin E, Wang X, Prieto VG. Am J Dermatopathol 2012; 34: 24–34.

A retrospective review of 122 patients with DFSP, including multivariate analysis of recurrence rates and overall survival, when comparing various methods of surgical excision. Whereas reduced recurrence-free survival was found to be most associated with acral location, overall survival was only decreased in cases of metastatic disease.

Surgical treatment of Darier-Ferrand dermatofibrosarcoma: a systematic review

Pallure V, Dupin N, Guillot B; Association for Recommendations in Dermatology. Dermatol Surg. 2013; 39: 1417–33.

A systematic literature review of DFSP to establish a consensus for lateral margin control. Despite a general lack of formal evidence, margins over 3 cm had decreased recurrence rates compared with margins less than 3 cm; MMS tended to yield the best clinical results. Patients should be followed for a minimum of 10 years postoperatively, and ideally indefinitely, to monitor for recurrences.

Mohs micrographic surgery for dermatofibrosarcoma protuberans (DFSP): a single-center series of 76 patients treated by frozen-section Mohs micrographic surgery with a review of the literature

Loghdey MS, Varma S, Rajpara SM, Al-Rawi H, Perks G, Perkins W. J Plast Reconstr Aesthet Surg 2014; 67: 1315–21.

A retrospective review of 76 cases in addition to a literature review of DFSP to review outcomes when comparing various excision margins. Clearance of tumor required varying margins of tissue, but the asymmetric nature of DFSP seems most suited for procedures that ensure complete margin control. These conclusions support the use of MMS, which is correlated with reduced recurrence rates. Furthermore, positive or narrow margins may be considered for adjuvant radiation or imatinib therapy.

Second-Line Therapies

• Imatinib mesylate (Gleevec)	B
• Radiation	B

Treatment of advanced dermatofibrosarcoma protuberans with imatinib mesylate with or without surgical resection

Rutkowski P, Dębiec-Rychter M, Nowecki Z, Michej W, Symonides M, Ptaszynski K, et al. J Eur Acad Dermatol Venereol 2011; 25: 264–70.

Data of 15 patients with locally advanced/initially inoperable and/or metastatic DFSP treated with imatinib 400 to 800 mg daily were analyzed. A 2-year progression-free survival rate was 60%, and a 2-year overall survival rate was 78%.

Using imatinib as neoadjuvant therapy in dermatofibrosarcoma protuberans: potential pluses and minuses

Johnson-Jahangir H, Sherman W, Ratner D. J Natl Compr Cancer Netw 2010; 8: 881–5.

Neoadjuvant imatinib mesylate therapy has been shown to reduce preoperative tumor size and lessen surgical morbidity associated with the removal of residual DFSP. Use of neoadjuvant imatinib before surgery, however, requires appropriate patient selection and careful weighing of the potential risks and benefits of this treatment.

Imatinib mesylate as a preoperative therapy in dermatofibrosarcoma: results of a multicenter phase II study on

25 patients

Kérob D, Porcher R, Vérola O, Dalle S, Maubec E, Aubin F, et al. Clin Cancer Res 2010; 16: 3288–95.

Twenty-five adults suffering from primary or recurrent DFSP were included in a phase II multicenter study. Percentage of clinical response was defined to a 2-month preoperative daily administration of 600 mg of imatinib mesylate before WLE. A clinical response was achieved in nine (36%) patients (95% CI: 18.9–57.5). The median relative tumoral decrease was 20.0% (range, –12.5–100). Apart from expected grade II or III side effects, one grade III neutropenia, one grade III maculopapular rash, and one grade IV transient transaminitis were observed.

Radiation in management of patients with dermatofibrosarcoma protuberans

Suit H, Spiro I, Mankin HJ, Efird J, Rosenberg AE. J Clin Oncol 1996; 14: 2365–9.

The outcome of treatment of 18 patients with DFSP by radiation alone and radiation and surgery was assessed. Local control was realized in the three patients treated by radiation alone, with follow-up periods of at least 9 years. Among 15 patients treated by radiation and surgery, there have been three local failures.

Dermatofibrosarcoma protuberans: treatment results of 35 cases

Sun LM, Wang CJ, Huang CC, Leung SW, Chen HC, Fang FM, et al. Radiother Oncol 2000; 57: 175–81.

A retrospective study examined 35 consecutive patients, over a 10-year period, with pathologically proved DFSP who received surgery with or without radiation therapy. Adjuvant radiation therapy was given to 11 patients, with a dose ranging from 46 to 68 Gy (1 preoperative, 10 postoperative). At a median follow-up of 50 months, there were 11 patients (9 patients without radiation therapy) who developed local failure. After all patients underwent excision with or without radiation, 10 achieved disease control.

Dermatomyositis

Ruth Ann Vleugels, and Jeffrey P. Callen

Dermatomyositis (DM) is an idiopathic inflammatory myopathy characterized by cutaneous disease, including a heliotrope eruption, Gottron papules, photodistributed erythema and poikiloderma, and/or periungual changes. Patients with cutaneous lesions of DM often have weakness of the proximal muscles; elevated enzymes such as creatine kinase or aldolase; or abnormal electromyogram, magnetic resonance imaging, or muscle biopsy findings. Some, however, have

cutaneous disease that either precedes the onset of demonstrable muscle disease or occurs in its absence (clinically amyopathic DM). In addition, many patients have persistent cutaneous manifestations long after their muscle disease is adequately controlled. DM in children and adolescents may be complicated by calcinosis, particularly when treatment is delayed. Adults with DM have an increased risk of having or developing a malignancy, usually within the first 3 years after diagnosis.

Management Strategy

Before treatment the patient should be thoroughly evaluated to assess the severity of both skin and muscle disease; the presence of systemic involvement such as pulmonary, cardiac, or gastrointestinal involvement; and the presence of malignancy.

The goal of management is to *reverse the weakness, prevent contractures*, and allow the patient to return to normal functional status. The *prevention or treatment of calcinosis* is usually an issue in the management of children and adolescents but may occur in adults as well. Patients with cutaneous disease are troubled by intense *pruritus*, *photosensitivity*, and *the appearance of their skin* and may therefore require treatment even when the muscle disease has been effectively managed or is absent.

For the myopathy, systemic *corticosteroids*, most often in conjunction with an immunosuppressive agent, is standard treatment. Most patients respond to this strategy, but for those who do not, *high-dose intravenous immune globulin (IVIG)* may be of benefit. Patients with cutaneous disease are photosensitive and are treated with *sunscreens*, *photoprotective clothing*, *behavior modification*, *topical corticosteroids*, and *occasionally topical calcineurin inhibitors*, *oral antimalarials*, and often an immunosuppressive agent. *High-dose IVIG* may also be used for recalcitrant cutaneous disease. Ultimately, the therapeutic goal is to provide relief from the cutaneous inflammation and associated symptoms utilizing a combination of topical and/or systemic medications selected after considering a patient's comorbidities.

One of the problems with many of the reports published to date regarding therapeutic options for cutaneous DM is the lack of the use of a validated measure to assess the activity of skin disease and response to therapy. To this end, three such measures have been developed: the Cutaneous Dermatomyositis Area and Severity Index

(CDASI) (Arch Dermatol Res 2008; 300: 3–9, and Br J Dermatol 2012; 162: 669–73), the Dermatomyositis Skin Severity Index (DSSI) (Br J Dermatol 2008; 158: 345–50), and a cutaneous assessment tool in juvenile dermatomyositis (Arthritis Rheum 2008; 59: 352–6).

Unfortunately, none of these measures has routinely been used in studies investigating therapeutic interventions for DM; however, the tools are being utilized more frequently and will ideally become incorporated as standard practice in the future as a means to assess cutaneous disease response.

Specific Investigations

- A thorough evaluation to exclude other causes of myopathy
- Malignancy evaluation, including computed tomography (CT) scans of chest, abdomen, and pelvis; transvaginal pelvic ultrasound; stool occult blood testing and age-appropriate endoscopy; Papanicolaou smear; mammography; complete blood count; comprehensive metabolic panel; CA-125; CA 19-9; urinalysis; and full physical examination
- Serum creatine kinase and aldolase
- Electromyogram, magnetic resonance imaging, or ultrasound of muscle
- Muscle biopsy
- Assessment for the presence of systemic involvement (e.g., pulmonary, esophageal, and cardiac)
- Myositis-specific antibodies

Treatment

Scalp involvement in dermatomyositis. Often overlooked or misdiagnosed

Kasteler JS, Callen JP. JAMA 1994; 272: 1939–41.

Skin lesions in patients with DM, particularly those of the scalp, are often confused with psoriasis or seborrheic dermatitis. Additionally, DM skin disease may simulate cutaneous lupus erythematosus or lichen planus.

Influence of age on characteristics of polymyositis and dermatomyositis in adults

Marie I, Hatron PY, Levesque H, Hachulla E, Hellot MF, Michon-Pasturel U, et al. *Medicine (Baltimore)* 1999; 78: 139–47.

This group compared characteristics of younger versus older adults and found that the incidence of malignancy was much higher in the older population, resulting in a poorer prognosis for this subset of patients.

Frequency of specific cancer types in dermatomyositis and polymyositis: a population-based study

Hill CL, Zhang Y, Sigurgeirsson B, Pukkala E, Mellemkjaer L, Airio A, et al. *Lancet* 2001; 357: 96–100.

This study demonstrated that malignancies of the ovaries, pancreas, stomach, colon and rectum, and non-Hodgkin lymphoma were overrepresented in patients with DM. The malignancy risk decreased with each passing year after DM diagnosis and approached background levels at 3 years.

Malignancy evaluations should be directed by abnormalities found on history, physical findings, or routine laboratory testing. The initial search should include CT scans of the chest, abdomen, and pelvis in most patients, and these scans should be repeated annually for at least 3 years. Malignancy screening should also include annual physical examinations.

Positron emission tomography (PET)-CT scanning is under evaluation in dermatomyositis.

A new approach to the classification of idiopathic inflammatory myopathy: myositis-specific autoantibodies define useful homogeneous patient groups

Love LA, Leff RL, Fraser DD, Targoff IN, Dalakas M, Plotz PH, et al. *Medicine (Baltimore)* 1991; 70: 360–74.

This study compared the usefulness of myositis-specific autoantibodies (antiaminoacyl-tRNA synthetases, antisingnaling recognition particle [anti-SRP], and anti-Mi-2) to the standard clinical categories (polymyositis, DM, overlap myositis, cancer-associated myositis, and inclusion body myositis) in predicting clinical signs and symptoms and prognosis in 212 adult patients. Compared with those without these antibodies, patients with antiaminoacyl-tRNA synthetase autoantibodies ($n = 47$) had significantly more frequent arthritis, fever, interstitial lung disease, and “mechanic’s hands”; higher mean prednisone dose at survey; higher proportion of patients receiving cytotoxic drugs; and higher death rates. Those with anti-

SRP antibodies ($n = 7$) had more frequent palpitations, myalgias, severe refractory disease, and higher death rates. Patients with anti-Mi-2 antibodies ($n = 10$) had increased “V-sign” and “shawl-sign” rashes and cuticular overgrowth, as well as a good response to therapy. These findings suggest that myositis-specific autoantibody status is a more useful guide than clinical group in assessing patients with myositis.

Currently only the anti-aminoacyl-tRNA synthetase autoantibodies are frequently incorporated into clinical practice.

A novel dermato-pulmonary syndrome associated with MDA-5 antibodies: report of 2 cases and review of the literature

Chaisson NF, Park J, Orbai AM, Casciola-Rosen L, Fiorentino D, Danoff S, et al. *Medicine* (Baltimore) 2012; 91: 220–8.

This work describes the clinical features typically associated with a novel autoantibody termed *melanoma differentiation-associated protein 5* (MDA-5), including interstitial lung disease that can be rapidly progressive, arthritis, and a characteristic cutaneous phenotype, including ulcerations in Gottron papules; Gottron sign; and along the lateral nailfold, painful palmar papules, and prominent alopecia (this phenotype was first described in 2011 by Fiorentino et al. The mucocutaneous and systemic phenotype of dermatomyositis patients with antibodies to MDA5 (CADM-140): a retrospective study. *J Am Acad Dermatol* 2011; 65: 25–34). Most patients with the MDA-5 antibody have clinically amyopathic DM. Although this entity was first recognized in Asian populations, it has since been described in other populations as well.

Most patients with cancer-associated dermatomyositis have antibodies to nuclear matrix protein NXP-2 or transcription intermediary factor 1- γ

Fiorentino DF, Chung LS, Christopher-Stone L, Zaba L, Li S, Mammen AL, et al. *Arthritis Rheum* 2013; 65: 2954–62.

In two large DM cohorts, reactivity against either transcription intermediary factor-1 γ (TIF-1 γ) or NXP-2 identified 83% of patients with cancer-associated DM. In these cohorts, malignancy was associated with older age, male sex, and antibodies to either TIF-1 γ or NXP-2 on multivariate analysis (OR 3.78).

The MDA-5 and TIF-1-gamma autoantibodies are largely considered investigational at present and are not routinely available in commercial

laboratories. They are currently available through two laboratories in the United States (Johns Hopkins and Oklahoma Medical Research Foundation Myositis Testing Laboratory). These autoantibodies seem to define distinct clinical subsets and therefore may be useful in predicting patient outcomes in DM. The primary purpose of these autoantibodies is not in making a diagnosis of dermatomyositis but to potentially help prognosticate and alter screening practices for patients with DM in the future.

Interstitial lung disease in classic and skin-predominant dermatomyositis: a retrospective study with screening recommendations

Morganroth PA, Kreider ME, Okawa J, Taylor L, Werth VP. Arch Dermatol 2010; 146: 729–38.

In this retrospective cohort study, 23% of patients had interstitial lung disease (ILD) based on CT findings, and all of these had a reduced diffusion capacity (DLCO) on pulmonary function tests as well. Prevalence of ILD was not statistically different between patients with and without muscle disease. The authors conclude that serial DLCO testing is reasonable in all patients with DM to screen for pulmonary involvement.

Incidence of dermatomyositis and clinically amyopathic dermatomyositis: a population-based study in Olmstead County, Minnesota

Bendewald MJ, Wetter DA, Li X, Davis MD. Arch Dermatol 2010; 146: 26–30.

This retrospective population-based study found an overall age- and sex-adjusted incidence of dermatomyositis, including all subtypes, to be 9.63 (95% CI: 6.09–13.17) per 1 million persons, whereas the incidence of clinically amyopathic dermatomyositis was 2.08 (95% CI: 0.39–3.77) per 1 million persons. Twenty percent of the dermatomyositis cases were amyopathic in this population.

This epidemiologic study supports other data demonstrating that 20% to 30% of adult DM patients lack muscle involvement.

First-Line Therapies

For cutaneous disease

• Sunscreens	E
• Topical corticosteroids	E
• Antimalarials – hydroxychloroquine (HCQ) or chloroquine (CQ)	D
• Combination antimalarial therapy (quinacrine plus either HCQ or CQ)	E
• Methotrexate	D

For muscle disease

• Systemic corticosteroids	B
• Immunosuppressive agents – methotrexate, mycophenolate mofetil, azathioprine	A

The use of pulse corticosteroid therapy for juvenile dermatomyositis

Paller AS. *Pediatr Dermatol* 1996; 13: 347–8.

This report notes that pulse administration of systemic corticosteroids might result in less toxicity, and further that this therapy aids in the prevention of calcinosis.

Cutaneous lesions of dermatomyositis are improved by hydroxychloroquine

Woo TY, Callen JP, Voorhees JJ, Bickers D, Hanno R. *J Am Acad Dermatol* 1984; 10: 592–600.

Seven patients with cutaneous lesions of DM that had not responded to therapy with corticosteroids and/or immunosuppressive agents were treated with hydroxychloroquine 200 mg once or twice daily in an open study. The response to the addition of hydroxychloroquine was good in all patients, and three had total resolution of their skin lesions. In two patients the corticosteroid dosage could be tapered. Therapy with hydroxychloroquine did not appear to have any beneficial effect on the myositis.

Combination antimalarials in the treatment of cutaneous dermatomyositis: a retrospective study

Ang GC, Werth VP. *Arch Dermatol* 2005; 141: 855–9.

In this retrospective analysis, 7 of 17 patients experienced at least near clearance of cutaneous symptoms with the use of antimalarial

therapy alone: 4 of them required combination therapy (hydroxychloroquine sulfate 200 mg once or twice daily + quinacrine hydrochloride 100 mg daily; or chloroquine phosphate 250 mg daily + quinacrine 100 mg daily), and 3 of them responded well to antimalarial monotherapy. The median time required to efficacy was 3 months.

When considering combination antimalarial agents as a therapeutic option, it is critical to use quinacrine in addition to either hydroxychloroquine or chloroquine, given that quinacrine lacks ocular toxicity. Hydroxychloroquine and chloroquine both have ocular toxicity and should not be given concurrently.

Adverse cutaneous reactions to hydroxychloroquine are more common in patients with dermatomyositis than in patients with cutaneous lupus erythematosus

Pelle MT, Callen JP. Arch Dermatol 2002; 138: 1231–3.

In this case-control study, 31% of patients with dermatomyositis developed a cutaneous reaction to hydroxychloroquine, compared with 2.5% of those with cutaneous lupus.

Given the fact that hydroxychloroquine is utilized as a first-line therapy for cutaneous DM, awareness of the increased risk of cutaneous reactions in approximately one third of DM patients is critical, as this can lead to worsening of the cutaneous DM and warrants cessation of hydroxychloroquine. A pretreatment warning is helpful in order to allow patients to alert the clinician to the development of a cutaneous reaction.

Second-Line Therapies

For cutaneous disease

• Topical calcineurin inhibitors (tacrolimus or pimecrolimus)	D
• Mycophenolate mofetil	D
• IVIG	A

For muscle disease

• Other immunosuppressive agents – cyclophosphamide, chlorambucil, cyclosporine, tacrolimus	D
• IVIG	A
• Rituximab	A

Topical tacrolimus 0.1% ointment for refractory skin disease in dermatomyositis: a pilot study

Hollar CB, Jorizzo JL. J Dermatol Treat 2004; 15: 35–9.

This open-label study of six patients with cutaneous DM treated with topical tacrolimus noted a very good to excellent response in two patients, a moderate response in one, and essentially no response in three.

This agent is worthy of a trial but does not seem to be highly effective.

Low-dose methotrexate administered weekly is an effective corticosteroid-sparing agent for the treatment of the cutaneous manifestations of dermatomyositis

Kasteler JS, Callen JP. J Am Acad Dermatol 1997; 36: 67–71.

The records of 13 patients who received oral methotrexate in doses ranging from 2.5 to 30 mg weekly were reviewed. Their skin lesions had not been completely responsive to sunscreens, topical corticosteroids, oral prednisone, oral antimalarial therapy, or, in 1 patient each, chlorambucil and azathioprine. Four of these 13 patients had complete clearance of cutaneous manifestations, and another 4 had almost complete clearance. In the remaining 5 patients, methotrexate induced moderate clearing of their cutaneous lesions. In all patients, the addition of methotrexate allowed a reduction in or discontinuation of other therapies, including prednisone.

Mycophenolate mofetil as an effective corticosteroid-sparing therapy for recalcitrant dermatomyositis

Edge JC, Outland JD, Dempsey JR, Callen JP. Arch Dermatol 2006; 142: 65–9.

Mycophenolate mofetil in dermatomyositis: is it safe?

Rowin J, Amato AA, Deisher N, Cursio J, Meriggioli MN. Neurology 2006; 66: 1245–7.

These two open-label studies suggest that in 60% to 75% of patients with myositis, mycophenolate mofetil 1 to 1.5 g twice daily is an effective steroid-sparing agent for skin and muscle disease. Toxicity

was noted in these relatively small case series, including an Epstein–Barr virus–associated lymphoma of the central nervous system in the former study, which resolved upon cessation of therapy, and opportunistic infections in the latter study, one of which was fatal.

This agent appears to be useful in some patients with refractory DM yet needs careful monitoring for the development of infection and potentially neoplasia.

A controlled trial of high-dose intravenous immune globulin infusions as treatment for dermatomyositis

Dalakas MC, Illa I, Dambrosia JM. N Engl J Med 1993; 329: 1993–2000.

These authors conducted a double-blind, placebo-controlled trial of IVIG in 15 patients with biopsy-proven treatment-resistant DM. The patients continued to receive prednisone (mean daily dose 25 mg) and were randomly assigned to receive one infusion of immunoglobulin (2 g/kg body weight) or placebo monthly for 3 months, with the option of crossing over to the alternative therapy for 3 more months. The 8 patients assigned to immunoglobulin showed a significant improvement in scores of muscle strength ($p < 0.018$) and neuromuscular symptoms ($p < 0.035$), whereas the 7 patients assigned to placebo did not. With crossovers, a total of 12 patients received immunoglobulin. Of these, 9 with severe disabilities showed a major improvement to near-normal function. Of 11 placebo-treated patients, none had a major improvement, 3 had a mild improvement, 3 had no change in their condition, and the condition of 5 worsened. Skin disease also responded in the treated patients, with 8 of 12 demonstrating “marked clearance” of cutaneous disease as assessed through clinical photographs.

Intravenous immunoglobulin for refractory cutaneous dermatomyositis: a retrospective analysis from an academic medical center

Femia AN, Eastham AB, Lam C, Merola JF, Qureshi AA, Vleugels RA. J Am Acad Dermatol 2013; 69: 654–7.

Clinical efficacy of intravenous immunoglobulins for the treatment of dermatomyositis skin lesions without muscle disease

Bounfour T, Bouaziz JD, Bezier M, Cordoliani F, Saussine A, Petit A, et al. J Eur Acad Dermatol Venereol 2014; 28: 1150–7.

Since the time of the small randomized controlled trial by Dalakas et al., two retrospective studies investigated the role of IVIG specifically in refractory cutaneous DM. The first study (Femia et al.) included 13 patients who received IVIG to specifically treat cutaneous DM. All patients, except 2, had previously been treated with various systemic immunosuppressive and immunomodulatory therapies, photoprotection, and topical agents. The validated CDASI was utilized when available to determine treatment response, in addition to review of clinical photography. All 13 patients demonstrated improvement on IVIG, with a complete clinical response noted in 8 patients. IVIG allowed for discontinuation of all concurrent immunosuppressive medications except in 2 patients.

A second retrospective study (Bounfour et al.) of 27 patients treated with IVIG for refractory cutaneous DM also found promising results. Utilizing clinical examination and photography, 19 of 27 patients were determined to have a major response to therapy, 4 demonstrated a partial response, and 4 had no response.

Chlorambucil. An effective corticosteroid-sparing agent for patients with recalcitrant dermatomyositis

Sinoway PA, Callen JP. *Arthritis Rheum* 1993; 36: 319–24.

Five patients with recalcitrant DM were treated with oral chlorambucil, 4 mg daily, after discontinuation of another immunosuppressive agent. Beneficial effects were noted within 4 to 6 weeks in all five patients, and corticosteroids were eventually discontinued in four. The chlorambucil was stopped after 13 to 30 months of treatment in four patients, and their disease remained in remission. Minimal chlorambucil toxicity was noted, consisting of leukopenia in two patients.

Although chlorambucil was effective, its potential for subsequent malignancy makes it a less desirable choice.

Cyclosporine A and intravenous immunoglobulin treatment in polymyositis/dermatomyositis

Danieli MG, Malcangi G, Palmieri C, Logullo F, Salvi A, Piani M, et al. *Ann Rheum Dis* 2002; 61: 37–41.

This is a retrospective review of 20 patients, including 12 with DM. It suggests that combining prednisone, cyclosporine, and IVIG was the most useful regimen.

A pilot trial of rituximab in the treatment of patients with dermatomyositis

Chung L, Genovese MC, Fiorentino DF. Arch Dermatol 2007; 143: 763–7.

In this open-label pilot study with seven evaluable patients who received 1-g infusions administered 2 weeks apart, only three had partial response of their muscle disease. Skin disease using the validated DSSI did not demonstrate notable improvement over the study period.

Rituximab in the treatment of refractory adult and juvenile dermatomyositis (DM) and adult polymyositis (PM): a randomized, placebo-phase trial (the RIM Study)

Oddis CV, Reed AM, Aggarwal R, Ascherman DP, Barohn RJ, Feldman BM, et al. Arthritis Rheum 2013; 65: 314.

This multicenter randomized controlled trial of 200 participants, including 76 with DM, 48 with juvenile DM, and 76 with polymyositis, randomized participants to either a “rituximab early” arm, receiving drug at weeks 0 and 1 and placebo at weeks 8 and 9, or a “rituximab late” arm, receiving placebo at weeks 0 and 1 and rituximab at weeks 8 and 9. The primary end point, time to achieve improvement based on specifically defined muscle parameters, was not met, nor were the secondary end points, which were also based on muscle involvement. Despite this, 83% of patients met the definition of improvement (DOI) by week 44. In addition, a steroid-sparing effect of rituximab was noted in both groups. The authors propose that the trial design, particularly the short placebo phase of 8 weeks, may have reduced the ability to detect differences between the groups given the median time to DOI from rituximab. Of note, a validated DM skin index was not used in the rituximab for inflammatory myopathy (RIM Study).

Although design concerns with the RIM Study make recommendations regarding the use of rituximab in DM challenging, it is used for refractory muscle disease. At this time, however, there is little data to support the use of rituximab for cutaneous dermatomyositis specifically.

Third-Line Therapies

• Dapsone for cutaneous disease	E
• Thalidomide for cutaneous disease	E
• Antiestrogen medication for cutaneous disease	E
• Diltiazem for calcinosis	D
• Total body irradiation	D
• Rituximab for cutaneous disease	D
• Leflunomide	E
• Sirolimus	E
• Tocilizumab	E
• Anakinra	D
• Sifalimumab	D
• Tofacitinib, ruxolitinib (JAK inhibitors)	D, E
• Stem cell transplantation	D

Calcinosis cutis occurring in association with autoimmune connective tissue disease: the Mayo Clinic experience with 78 patients, 1996 to 2009

Balin SJ, Wetter DA, Andersen LK, Davis MD. Arch Dermatol 2012; 148: 455–62.

This retrospective study found that DM and systemic sclerosis were the most common autoimmune connective tissue diseases associated with calcinosis cutis. Therapy with diltiazem resulted in partial benefit in 9 of 17 patients. Of 28 patients who had surgical excision of one or more lesions, 22 noted complete response, 5 had partial response, and 1 patient did not respond.

A wide variety of agents have been used in the treatment of DM-associated calcinosis, although none is uniformly effective.

Open-label trial of anti-TNF-alpha in dermato- and polymyositis treated concomitantly with methotrexate

Hengstman GJ, De Bleecker JL, Feist E, Vissing J, Denton CP, Manoussakis MN, et al. Eur Neurol 2008; 59: 159–63.

Although case series and reports have suggested that anti-tumor necrosis factor alpha (TNF- α) agents may be useful in DM, this open-label trial found differing results. The trial was terminated prematurely due to low rate of patient enrollment, as well as poor responses in many patients. The authors conclude that TNF antagonists do not have a place in the therapeutic armamentarium of dermatomyositis.

A randomized, pilot trial of etanercept in dermatomyositis

Amato A. Ann Neurol 2011; 70: 427–36.

In this randomized double-blind placebo-controlled trial of 16 participants with DM on prednisone (11 randomized to etanercept arm 50 mg subcutaneously weekly for 52 weeks and 5 to placebo arm), a steroid-sparing effect was demonstrated in 5 patients in the treatment arm. There was no statistically significant difference in skin disease response assessed by CDASI between the groups. In addition, cutaneous disease worsened in five etanercept-treated patients.

In addition to the potential worsening of muscle disease in patients with DM treated with anti-TNF- α therapy, reports of TNF inhibitor-associated DM have been reported. For these reasons, anti-TNF therapy is utilized with caution in patients with DM, and some experts suggest that the use of these agents in DM should occur only in the setting of approved clinical trials.

Improvement in dermatomyositis rash associated with the use of antiestrogen medication

Sereda D, Werth VP. Arch Dermatol 2006; 142: 70–2.

In this report, two women experienced improvement in their DM-associated skin eruptions while taking antiestrogen medication, either tamoxifen, a selective estrogen receptor modulator, or anastrozole, an aromatase inhibitor. When tamoxifen therapy was discontinued after 4 years of use in the first patient, her cutaneous DM worsened and remained difficult to control with conventional immunosuppressive agents

This observation offers a novel approach to consider for women with DM; however, no further reports of either medication have appeared in the literature.

Rapamycin (sirolimus) as a steroid-sparing agent in

dermatomyositis

Nadiminti U, Arbiser JL. J Am Acad Dermatol 2005; 52: 17–9.

A single case of dermatomyositis that was recalcitrant to prior therapies responded to this antirejection agent 5 mg/day for 2 weeks, then 2 mg/day. Both muscle disease and skin manifestations were noted to improve.

Anakinra treatment in patients with refractory inflammatory myopathies and possible predictive response biomarkers: a mechanistic study with 12 months of follow-up

Zong M, Dorph C, Dastmalchi M, Alexanderson H, Pieper J, Amoudruz P, et al. Ann Rheum Dis 2014; 73: 913–20.

An open-label trial of 15 patients with refractory myositis, 4 of whom had DM, received anakinra for a 12-month period. Three of the four DM patients had improvement in their cutaneous disease, but no validated skin index was used.

Remission of recalcitrant dermatomyositis treated with ruxolitinib

Hournung T, Janzen V, Heidgen FJ, Wolf D, Bieber T, Wenzel J. N Engl J Med 2014; 371: 2537–8.

A case of refractory DM was incidentally noted to have complete resolution of both muscle weakness and cutaneous disease based on CDASI scores after being treated with ruxolitinib, a JAK 1 and 2 selective inhibitor, for concurrent myelofibrosis. The patient was able to discontinue systemic corticosteroids, mycophenolate mofetil, and IVIG while taking ruxolitinib.

Future studies or observations of this and other JAK inhibitors might add another agent to our therapeutic armamentarium for DM.

Efficacy of allogeneic mesenchymal stem cell transplantation in patients with drug-resistant polymyositis and dermatomyositis

Wang D, Zhang H, Cao M, Tang Y, Liang J, Feng X. J Ann Rheum Dis 2011; 70: 1285–8.

An open study of 10 patients with refractory DM ($n = 4$) or polymyositis who underwent stem cell transplantation (SCT) noted recurrence of disease in 3 patients and death in 2 patients. The remaining patients had improvement in muscle disease, pulmonary disease, and chronic cutaneous ulcers.

Other reports of patients with adult and juvenile DM have noted

improvement in both skin disease and calcinosis after SCT in severe cases. Given infection risks, SCT is considered only in highly refractory cases at this time.

Diaper dermatitis

Catalina Matiz, and Lawrence F. Eichenfield

Diaper (napkin) dermatitis encompasses a broad set of conditions, although the most common form is irritant contact dermatitis. Irritant diaper dermatitis usually presents as erythema and mild scaling on the convex surfaces of the inner upper thigh, lower abdomen, and buttock areas, classically sparing the inguinal folds where the skin is not in contact with irritants. It usually presents as early as a few days after birth to as late as several years of age, whereas diaper use in

older disabled and geriatric patients may be identical in pathogenesis and physical findings. Many other dermatoses such as psoriasis, seborrheic dermatitis, allergic contact dermatitis, acrodermatitis enteropathica, infections (*Candida*, *Staphylococcus*, and *Streptococcus*), and Langerhans cell histiocytosis can affect the diaper area and may need to be excluded.

Management Strategy

Irritant diaper dermatitis is triggered by irritants present in the area covered by the diaper, which acts as an occlusive surface. Moisture from urine and feces increases the friction coefficient of the skin, causing frictional damage. Skin integrity is further compromised by the increased pH from urine and fecal enzymes and the physical erosive effects of these activated enzymes. The reduction in skin barrier function and increase in pH contribute to the increased susceptibility to infections with microorganisms such as *C. albicans*, which further increases the severity of diaper dermatitis. Therefore management should aim at preventing overhydration and frictional damage in the diaper area.

Frequent diaper changes, particularly after defecation, reduce moisture and prevent the build-up of irritants. This is therefore one of the most important steps in the management of diaper dermatitis. Disposable diapers containing superabsorbent gelling materials and breathable backsheets are preferred to those without. Cloth diapers should be avoided, as they have been shown to be associated with an increased incidence of irritant diaper dermatitis compared with disposable diapers.

The skin in the area may be cleaned with water alone, with mild soap, or with commercial wipes. Optimally, wipes should not contain fragrance, isothiazolinones, iodopropyl butylcarbamate, or alcohol. Rubbing of the area can cause damage to the skin and should be avoided.

A *barrier cream* may be applied at every diaper change. This can provide a barrier between the skin and irritants in order to reduce friction and contact with stool and urine.

A *low-potency topical steroid* such as hydrocortisone 1% ointment can be used in more severe cases of diaper dermatitis, but must be used sparingly to avoid skin atrophy and systemic absorption. High-potency steroids should be avoided in diaper dermatitis, including

the use of compound formulations containing potent steroids and antimicrobial agents.

Topical antifungal preparations are recommended for use in proven or suspected cases of *C. albicans* infection.

Specific Investigations

- Inquiry about recent antibiotic usage (predisposing to *Candida*)

In selected cases:

- KOH preparation, fungal and bacterial cultures
- Serum zinc and biotin levels
- Skin biopsy
- Patch testing

Diaper dermatitis: clinical characteristics and differential diagnosis

Coughlin CC, Eichenfield LF, Frieden IJ. *Pediatr Dermatol* 2014; 31(Suppl 1):19–24.

This article characterizes three subgroups: skin conditions caused by the presence of the diaper, eruptions exacerbated by the diaper, and rashes present regardless of the presence of the diaper. Those caused by the presence of the diaper include irritant diaper dermatitis and its different presentations, as well as allergic contact dermatitis. The conditions exacerbated by the diaper include infectious causes (yeast and bacteria), seborrheic dermatitis, and psoriasis. The third group includes infantile hemangiomas, Langerhans cell histiocytosis, zinc deficiency, Kawasaki disease, and Coxsackie virus.

Potential allergens in disposable diaper wipes, topical diaper preparations and disposable diapers: under-recognized etiology of pediatric perineal dermatitis

Yu J, Treat J, Chaney K, Brod B. *Dermatitis* 2016; 27: 110–8.

Botanical extracts, which include members of the Compositae family, were the top potential allergens in both diaper wipes and topical preparations. Others identified include tocopherol, fragrances, propylene glycol, parabens, iodopropynyl butylcarbamate, and lanolin.

Patch test series for allergic perineal dermatitis in the diapered infant

Yu J, Treat J, Brod B. *Dermatitis* 2017; 28: 70–5.

Two suggested allergen panels for evaluation of perineal dermatitis in children.

The role of allergic contact dermatitis in diaper dermatitis

Smith WJ, Jacob SE. *Pediatr Dermatol* 2009; 26: 369–70.

Allergens to consider include many chemicals added to diapers, as well as preservatives in baby wipes. For example, sorbitan sesquioleate, fragrances, and disperse dye have been increasingly reported to cause contact dermatitis in the diaper area. Cyclohexyl thiophthalimide and mercaptobenzothiazole, which are rubber additives, tend to cause “lucky Luke” dermatitis, a pattern that resembles a cowboy’s holster due to elastic bands coming into contact with the skin. The authors suggest patch testing in diaper dermatitis that fails to improve despite treatment.

First-Line Therapies

• Water-repellant barrier cream	A
• Frequent changing of diapers	B
• Superabsorbent disposable diapers	A

Modern diaper performance: construction, materials, and safety review

Dey S, Kenneally D, Odio M, Hatzopoulos I. *Int J Dermatol* 2016; 55(Suppl 1): 18–20.

Typical modern diapers do not contain concerning ingredients such as latex and disperse dyes, but use spandex and pigments with a favorable safety profile. Today’s disposable diapers are designed with layers and liners for optimal urine and feces absorption.

Prevention, diagnosis, and management of diaper dermatitis

Nield LS, Kamat D. Clin Pediatr (Philadelphia) 2007; 46: 480–6.

Differential diagnoses, prevention, and management strategies of diaper dermatitis in a stepwise, tabular format. The key prevention strategy is to keep the area dry. This can be accomplished by using superabsorbent disposable diapers, frequent diaper changes, eliminating irritants (e.g., avoiding baby wipes that contain fragrance and alcohol), using a water-impermeable topical barrier, and allowing for daily diaper-free time.

Diaper dermatitis and advances in diaper technology

Odio M, Friedlander SF. Curr Opin Pediatr 2000; 12: 342–6.

Absorbent gelling materials (AGM) have been proved to reduce skin overhydration and reduce the frequency and severity of diaper dermatitis compared with cellulose-only disposable diapers. In a study with nearly 4000 children, a temporal association between the introduction of AGM and a reduction in the incidence of severe diaper dermatitis was found. Polymeric covers or films, commonly known as *breathable backsheets*, allow moisture vapor to flow out of the diaper and significantly reduce overhydration in the area. The inner lining of diapers designed to deliver a petrolatum-based formulation to the skin continuously during use has been shown to be associated with a statistically significant and sustained reduction in the severity of diaper dermatitis.

Clinical approaches to skin cleansing of the diaper area: practice and challenges

Coughlin CC, Frieden IJ, Eichenfield LF. Pediatr Dermatol 2014; 31(Suppl 1): 1–4.

The authors very nicely review important factors in diaper area care, including skin pH, the local microbiome, irritant and allergic potential of certain products, and application of topical agents. The use of wet wipes is concluded to be a widespread practice, which is well tolerated and effective in several populations, including preterm infants.

Second-Line Therapies

• 1% hydrocortisone ointment	D
• Topical antifungal agent (miconazole, clotrimazole, nystatin, ketoconazole)	A

A prospective 2-year assessment of miconazole resistance in *Candida* spp. with repeated treatment with 0.25% miconazole nitrate ointment in neonates and infants with moderate to severe diaper dermatitis complicated by cutaneous candidiasis

Blanco D, van Rossem K. *Pediatr Dermatol* 2013; 30: 717–24.

This multicenter, open-label, long-term, phase IV study investigated the potential resistance of *Candida* spp. to repeated topical use of 0.25% miconazole nitrate in infants age 15 months and younger with moderate to severe diaper dermatitis complicated with cutaneous candidiasis. Results of the study showed that about half of the patients achieved clinical cure, 45.8% achieved a mycologic cure, and 29.2% achieved an overall cure (clinical and mycologic). The treatment with 0.25% miconazole nitrate ointment was effective and generally well tolerated. There was no evidence of resistance to miconazole in candida.

Efficacy and safety of two different antifungal pastes in infants with diaper dermatitis: a randomized, controlled study

Hoeger PH, Stark S, Jost G. *J Eur Acad Dermatol Venereol* 2010; 24: 1094–8.

This double-blinded, multicenter trial compared 1% clotrimazole versus nystatin with 20% zinc oxide for the treatment of diaper dermatitis complicated by *Candida* infection. Clotrimazole was superior to nystatin in symptom reduction. Both clotrimazole and nystatin had microbiologic cure rates of 100%, and both were safe and well tolerated.

Absorption and efficacy of miconazole nitrate 0.25% ointment in infants with diaper dermatitis

Eichenfield LF, Bogen ML. *J Drugs Dermatol* 2007; 6: 522–6.

Twenty-four infants with moderate to severe diaper dermatitis were evaluated for relative safety from systemic absorption of topical miconazole. Nineteen received 0.25% miconazole nitrate ointment, and five received 2% miconazole nitrate cream for 7 days. Blood concentrations in the 0.25% miconazole nitrate treatment group were

undetectable in 83% and minimal in 17%, thereby demonstrating its safety as a treatment for diaper dermatitis.

Pediatricians who prescribe clotrimazole-betamethasone dipropionate (Lotrisone) often utilize it in inappropriate settings regardless of their knowledge of the drug's potency

Railan D, Wilson JK, Feldman SR, Fleischer AB. *Dermatol Online J* 2002; 8: 3.

High-potency topical corticosteroids can cause skin atrophy and systemic absorption. Products combining antibiotics with high-potency corticosteroids should be avoided in the diaper area.

Third-Line Therapies

• Continuous administration of petrolatum and zinc oxide by disposable diaper	A
• Oral antifungal agent	E

Skin benefits from continuous topical administration of a zinc oxide/petrolatum formulation by a novel disposable diaper

Baldwin S, Odio MR, Haines SL, O'Connor RJ, Englehart JS, Lane AT. *J Eur Acad Dermatol Venereol* 2001; 1: 5–11.

A double-blind, randomized trial comparing regular diapers to diapers designed to continuously deliver zinc oxide and petrolatum in 268 infants over a 4-week period. The ointment formulation was effectively transferred to the skin, and a significant reduction in skin erythema and rash was observed in the treatment group compared with controls.

Contact dermatitis

Friedlander SF. *Pediatr Rev* 1998; 19: 166–71.

Some diaper dermatitis persists despite first- and second-line therapies. In these recalcitrant cases oral Mycostatin may be beneficial. In addition, an evaluation of the mother for infections of the nipples or genital tract should be considered, as continuous reinoculation of the infant is possible. If positive, a short course of oral fluconazole (5–7 days) can help eradicate the infection.

Discoid (Nummular) eczema

Ian H. Coulson

Discoid eczema comprises relatively well-defined, usually multiple, coin-sized plaques. In the acute stages they often weep or ooze; in the chronic phase lesions are discrete, hyperkeratotic, or lichenified. Itching is usual. It primarily affects the limbs (especially the legs), sometimes the trunk, and rarely the face or flexures.

Management Strategy

Discoid eczema (nummular dermatitis) has many causes. It is usually idiopathic in older patients, but similar lesions may occur due to contact allergic reactions, as a pattern of hand and foot eczema, in atopic dermatitis (AD), as an “id” eruption related to venous eczema, or locally (e.g., after trauma, insect bite reactions, “halo eczema” around melanocytic nevi). Discoid eczema has been reported as a manifestation of drug reaction to gold, tumor necrosis factor (TNF) antagonists, interferon, and retinoids. Comparisons among studies may be limited if the site(s) and etiology are not stated or represent a mixed spectrum.

There are few publications on the pathophysiology of discoid eczema to inform treatment. An association with dry skin (xerosis) is documented, and discoid lesions may appear during treatment with isotretinoin (which reduces sebum secretion). However, dry skin is not consistently present, and the morphology of discoid eczema differs from that of xerosis or asteatotic eczema.

One study suggested that patients with discoid eczema have a degree of xerosis similar to that of age-matched controls but have stronger delayed hypersensitivity to allergens that permeate the skin as a result of scratching. A link with atopy has been proposed, but serum IgE levels are generally normal.

Occult infections (e.g., dental abscess) and infections causing dry skin (e.g., leprosy) have rarely been linked with discoid eczema. *Helicobacter pylori* has been implicated, but the evidence is weak.

It is difficult to provide specific therapeutic strategies because of the various different causes and the paucity of pertinent publications; most reports are retrospective from individual departments or are anecdotal, rather than formal, trials. The main therapeutic issues are:

- Other disorders may need to be excluded, especially mycoses, psoriasis, Bowen disease, mycosis fungoides, and sarcoidosis.
- A medication and alcohol history should be taken.
- Patch testing may be useful; metals and medicaments (such as fusidic acid, lanolin, neomycin, and cetostearyl alcohol) are most implicated.
- The management of discoid eczema is generally similar to that of other eczemas; *emollients* appear to be helpful due to the link with dry skin.
- The mainstay of treatment is *topical corticosteroids*. Severe itch in

discoid eczema usually dictates that strong agents are applied; this is safe because the individual lesions are small, rarely affect thin skin sites such as the face or flexures, and usually respond to this approach. Chronic lichenified lesions may respond better to steroid-impregnated tapes or by using a potent steroid with hydrocolloid dressing or paste bandage occlusion.

- *Calcineurin antagonists* have been used successfully both as monotherapy and in combination with topical steroids, but trials specifically looking at efficacy in discoid eczema exclusively, rather than atopic eczema generally, are lacking.
- If weeping is present, the use of soaks (with, e.g., 1 in 10,000 *potassium permanganate* solution) will help dry lesions up and prevent lesions from sticking to clothes or dressings.
- Secondary impetiginization, particularly in the exudative phase, is common, and combining a *topical antibiotic or antiseptic*, or the use of an *oral antistaphylococcal antibiotic*, helps.
- *Tar-based treatments* and impregnated bandages to minimize the effects of scratching may help.
- *Sedating antihistamines* before retiring will help nocturnal scratching and minimize excoriation.
- *Systemic immunosuppressive therapies* are usually not required. Newer drugs such as *biological agents* (dupilumab) and small molecules such as *apremilast* and *topical PDE 4 antagonists* show efficacy in atopic eczema, but specific reports relating to discoid eczema are lacking to date.

Specific Investigations

- None usually required, except to exclude differential diagnoses
- Consider medications as a cause
- Consider mycology
- Consider patch testing
- Bacteriology if secondary infection likely
- Consider occult infections in resistant cases

Pityriasis rosea and discoid eczema: dose related reactions to treatment with gold

Wilkinson SM, Smith AG, Davis MJ, Matthey D, Dawes PT. Ann Rheum Dis 1992; 51: 881–4.

Discoid eczematous lesions occur in up to 30% of patients on gold therapy and may be dose related.

Severe, generalized nummular eczema secondary to interferon alpha-2b plus ribavirin combination therapy in a patient with chronic hepatitis C virus infection

Moore MM, Elpern J, Carter DJ. Arch Dermatol 2004; 140: 215–7.

Cutaneous disease and alcohol misuse

Higgins EM, du Vivier AW. Br Med Bull 1994; 50: 85–98.

Documents a strong link between discoid eczema and alcohol consumption.

Patch testing in discoid eczema

Fleming C, Parry E, Forsyth A, Kemmett D. Contact Dermatitis 1997; 36: 261–4.

Retrospective study of persistent and severe discoid eczema; 24 of 48 cases were positive (16 relevant) to rubber chemicals, formaldehyde, neomycin, chromate, and nickel.

Patch testing in discoid eczema

Khurana S, Jain VK, Aggarwal K, Gupta S. J Dermatol 2002; 29: 763–7.

Positive tests in 28 of 50 patients with relatively chronic discoid eczema, mainly to dichromate, nickel, cobalt, and fragrance.

However, 44% had a purely hand-and-foot pattern and only 12% a trunk and limb distribution.

Challenge with metal salts. (II). Various types of eczema

Veien NK, Hattel T, Justesen O, Nørholm A. Contact Dermatitis 1983; 9: 407–10.

Patch testing can be helpful. Larger series suggest a 50% positive test rate, with clinical relevance in many. However, these are based on testing patients with chronic or therapy-resistant discoid eczema (i.e., a selected, potentially unrepresentative group); most reports are anecdotal. Implicated agents include chromate, nickel, mercury, thimerosal, rubber chemicals, formaldehyde, neomycin, fragrances, aloe, ethylene diamine, cyanoacrylate glue, textile dyes, and epoxy resin. Oral metal challenge tests rarely induce flares of discoid eczema. Irritants may also cause discoid eczema.

Dental infection associated with nummular eczema as an overlooked focal infection

Tanaka T, Satoh T, Yokozeki H. J Dermatol 2009; 36: 462–5.

Thirteen cases of extensive discoid eczema with moderate to severe odontogenic infections detected by panoramic x-ray screening test. In 11 patients, skin lesions partially or completely improved after the dental treatment.

First-Line Therapies

• Topical corticosteroids ± antibacterial agents	C
• Emollients	C
• Tar-based preparations	C
• Oral antibiotics	C
• Oral antihistamines	C
• Topical doxepin	A

Most of these are standard treatments for discoid eczema; however, in terms of evidence grading, most studies include a variety of different eczemas, few specifically identify results for discoid eczema, and no comparative trials have been identified.

Successful treatment of therapy-resistant atopic dermatitis with clobetasol propionate and a hydrocolloid occlusive dressing

Volden G. Acta Derm Venereol 1992; 176: 126–8.

Nummular AD lesions cleared rapidly.

Topical corticosteroids are the usual first-line therapy. Trial evidence is limited to pharmaceutically sponsored studies that are not specific to discoid eczema.

Nummular eczema. A review, follow-up and analysis of a series of 325 cases

Cowan MA. Acta Derm Venereol 1961; 41: 453–60.

Tar preparations were the main treatment. Recurrent crops of lesions occurred in 25% of cases, and relapse occurred when treatment was discontinued in 53% of patients, presumably representing the natural history of the disease, but possibly reflecting the limitations of therapy available at the time (other options were hydrocortisone or superficial x-ray therapy).

Tar preparations, historically used in the treatment of discoid eczema, have been largely superseded by potent topical corticosteroids as first-line therapy.

The antipruritic effect of 5% doxepin cream in patients with eczematous dermatitis

Drake LA, Millikan LE. Arch Dermatol 1995; 131: 1403–8.

Significant improvement in itch after 1 day, not at 7 days.

Studies suggest that doxepin has a short-term effect on itch only.

The use of antibacterial agents (e.g., clioquinol) or antibiotics is based on the fact that lesions are often moist and crusted. Secondary staphylococcal infection, as in AD, may aggravate the eczematous process.

Occlusion over a topical corticosteroid has been reported to lead to lesion clearance in previously therapy-resistant patients with discoid lesions due to AD; soaking in water for 20 minutes before treatment application has been recommended for a range of eczemas.

As with other itchy dermatoses, sedating antihistamines may help symptoms; the increase in mast cells in lesions provides the rationale for this approach. However, histamine itself has not been shown to be important.

Second-Line Therapies

• Phototherapy (broadband or narrowband UVB, 311 nm)	E
• Photochemotherapy (psoralen plus UVA, PUVA)	E
• Topical immune modulators	E
• Ciclosporin	E
• Intralesional corticosteroid injection	E
• Oral corticosteroids	E

Formal trials of these treatments in discoid eczema are lacking, and therefore the evidence gradings are weak; however, all are useful in AD or other dermatitis (see gradings in Atopic dermatitis, [Chapter 17](#)) and are therefore likely to be effective in discoid eczema. Personal experience is that narrowband UVB or ciclosporin is useful if required.

Photochemotherapy beyond psoriasis

Honig B, Morison WL, Karp D. J Am Acad Dermatol 1994; 31: 775–90.

Review article. Nothing specific to discoid eczema, but several eczemas respond to PUVA.

Half-side comparison study on the efficacy of 8-methoxypsoralen bath–PUVA versus narrow-band ultraviolet B phototherapy in patients with severe chronic atopic dermatitis

Der-Petrossian M, Seeber A, Honigsmann H, Tanew A. Br J Dermatol 2000; 142: 39–43.

Both were equivalent (at equi-erythemogenic doses) in AD.

Phototherapies also reduce staphylococci and superantigens and therefore may improve eczema with weeping and infection.

Antimicrobial effects of phototherapy and photochemotherapy in vivo and in vitro

Yoshimura M, Namura S, Akamatsu H, Horio T. Br J Dermatol 1996; 135: 528–32.

Antimicrobial effects are apparent after a single exposure.

Suppressive effect of ultraviolet (UVB and PUVA) radiation on superantigen production by *Staphylococcus aureus*

Yoshimura-Mishima M, Namura S, Akamatsu H, Horio T. J Dermatol Sci 1999; 19: 31–6.

Hand dermatitis: a review of clinical features, therapeutic options, and long-term outcomes

Warshaw E, Lee G, Storrs FJ. Am J Contact Dermat 2003; 14: 119–37.

One review recommends topical tacrolimus or pimecrolimus for nummular hand dermatitis. No evaluable evidence presented.

Long-term efficacy and safety of ciclosporin in severe adult atopic dermatitis

Berth-Jones J, Graham-Brown RA, Marks R, Camp RD, English JS, Freeman K, et al. Br J Dermatol 1997; 136: 76–81.

An open study of 100 patients with AD, with mostly good responses.

Side effects (drug interactions, hypertension, nephrotoxicity) limit ciclosporin therapy in older patients with discoid eczema, compared with AD. It is possibly useful for intermittent short-term treatment.

Oral corticosteroids are generally unnecessary. Intralesional corticosteroid injection is impractical, except in patients who have a small number of persistent thickened lesions.

Third-Line Therapies

• Azathioprine	E
• Methotrexate	C
• Mycophenolate mofetil	E
• Hypnosis	D
• Relaxation therapy	D

As for second-line therapies, formal trials of these treatments in discoid eczema are lacking, and therefore the evidence gradings are weak; however, all are useful in AD or other dermatitis (see gradings in atopic dermatitis, [Chapter 17](#)) and are therefore likely to be effective in discoid eczema.

Azathioprine in dermatologic practice. An overview with special emphasis on its use in nonbullous inflammatory dermatoses

Scerri L. Adv Exp Med Biol 1999; 445: 343–8.

Documents the efficacy of azathioprine in AD and pompholyx.

Azathioprine in dermatology: a survey of current practice in the UK

Tan BB, Lear JT, Gawkrödger DJ, English JSC. Br J Dermatol 1997; 136: 351–5.

A questionnaire to 248 dermatologists showed that none was using azathioprine for discoid eczema.

Azathioprine is used in the treatment of several dermatoses, including various eczemas. It is likely to be beneficial in discoid eczema, although a study of azathioprine prescribing by UK dermatologists did not identify this as a current indication.

Methotrexate is a safe and effective treatment for pediatric discoid (nummular) eczema: a case series of 25 children

Roberts H, Orchard D. Australas J Dermatol 2010; 51: 128–30.

Sixteen out of 25 children completely cleared their eczema after an average of 10.5 months of methotrexate at a dose of 5 to 10 mg a week. A further three patients responded well but incompletely. Treatment was well tolerated, so it should be considered for recalcitrant or disabling disease.

Hypnosis in dermatology

Shenefelt PD. Arch Dermatol 2000; 136: 393–9.

Hypnosis as a complementary therapy may improve lesions or itch in discoid eczema.

Treatment of atopic dermatitis: a comparison of psychological and dermatologic approaches to relapse prevention

Ehlers A, Stangier U, Gieler J. Consult Clin Psychol 1995; 63: 624–35.

Although this study related to adults with atopic eczema, it may be applicable to discoid eczema too. Relaxation therapy produced a sustained benefit over a year and significantly reduced topical steroid use.

Discoid lupus erythematosus

Bruce H. Thiers

Discoid lupus erythematosus (DLE) is the most common form of chronic cutaneous lupus erythematosus (CCLE). Lesions predominate in sun-exposed areas, especially the face, scalp, upper chest, upper back, and extensor arms. Early lesions consist of sharply demarcated,

erythematous, often hyperpigmented, hyperkeratotic papules and small plaques with adherent scale. The individual lesions spread peripherally, resulting in atrophy and central scarring, which may be associated with alopecia, telangiectasia, and depigmentation.

Management Strategy

The lesions of DLE are quite characteristic, especially in their later stages. When the diagnosis is in doubt, a skin biopsy should be performed. The histologic findings are usually diagnostic, although direct immunofluorescence examination can be obtained in questionable cases. A complete history and physical examination should be performed, looking for signs of systemic disease.

Laboratory examinations to be obtained include a complete blood count with differential, erythrocyte sedimentation rate, serum chemistry profile, and urinalysis. Serum should be screened for antinuclear antibodies (ANAs) and Ro(SSA)/La(SSB) antibodies. It should be emphasized that although, as mentioned earlier, DLE is the most common form of CCLE, most patients do not have systemic involvement. Risk factors for systemic disease include widespread skin lesions, anemia or leukopenia, and a positive ANA, especially when the titer is high. Despite the relative infrequency of internal involvement, aggressive treatment of DLE is warranted because the scarring from the disease can be devastating. The characteristic “carpet tack” scale associated with lesions indicates follicular involvement, and the disease can result in permanent scarring alopecia. Moreover, the depigmentation in fully evolved lesions can be disfiguring, especially in dark-skinned individuals. The goal of therapy is to halt the inflammatory process quickly and effectively to prevent these changes. The predominance of lesions in exposed areas emphasizes the urgency for prompt effective therapy.

Patients should be counseled on the role of ultraviolet (UV) light in the provocation of skin lesions, and a program of sun avoidance and sunscreen use should be instituted. Corticosteroids, either topical or intralesional, are the cornerstone of initial therapy for patients with limited involvement. Hydroxychloroquine and other antimalarial drugs appear to afford a measure of photoprotection and are often quite effective, although their onset of action is relatively slow. Systemic retinoids are useful, especially for hyperkeratotic lesions. Cytotoxic agents are generally reserved for refractory cases. The role

of thalidomide and its analog, lenalidomide, in the treatment of DLE is evolving.

Specific Investigations

- Autoantibody studies
- Indicators of systemic disease

Cutaneous lupus erythematosus: an update on pathogenesis, diagnosis and treatment

Hejazi EZ, Werth VP. Am J Clin Dermatol 2016; 17: 135–46.

This article reviews the three recognized subtypes of cutaneous lupus erythematosus, including the acute, subacute, and chronic forms, as well as the nonspecific cutaneous manifestations of the disease. Diagnostic strategies that encompass histopathology, immunopathology, serology, and other laboratory studies are discussed, and an overview of treatment is provided.

First-Line Therapies

• Sunscreens	B
• Topical or intralesional corticosteroids	B
• Topical calcineurin inhibitors	B

A multicenter photoprovocation study to identify potential biomarkers by global peptide profiling in cutaneous lupus erythematosus

Calderon C, Zucht HD, Kuhn A, Wozniacka A, Szepietowski JC, Nyberg F, et al. Lupus 2015; 24: 1406–20.

Cutaneous lupus erythematosus can be precipitated and aggravated by exposure to UV light. Attempts have been made to identify biomarkers for predicting photosensitivity. Recommendation for use of a broad-spectrum sunscreen that includes protection against both UVB (sun protection factor 15 or higher) and UVA (e.g.,

containing oxybenzone, avobenzone, or ecamsule) is an essential disease management strategy.

Efficacy of tacrolimus 0.1% ointment in cutaneous lupus erythematosus: a multicenter, randomized, double-blind, vehicle controlled trial

Kuhn A, Gensch K, Haust M, Schneider SW, Bonsmann G, Gaebelein-Wissing N, et al. J Am Acad Dermatol 2011; 65: 54–64.

Effectiveness of topical calcineurin inhibitors as monotherapy or in combination with hydroxychloroquine in cutaneous lupus erythematosus

Avgerinou G, Papafragkaki DK, Nasiopoulou A, Arapaki A, Katsambas A, Stavropoulos PG. J Eur Acad Dermatol Venereol 2012; 26: 762–7.

The macrolactam immunosuppressive agents, tacrolimus and pimecrolimus, have been reported to be effective in the topical treatment of lesions of DLE, although most reports have consisted of uncontrolled case studies. These trials confirm that they may provide at least temporary benefit for patients with acute, edematous, nonhyperkeratotic lesions, particularly when cutaneous atrophy, either disease or treatment related, is a concern. Hypertrophic lesions may not respond well to calcineurin inhibitors or to other topical therapies, presumably because of limited penetration. Topical calcineurin inhibitors can also be used in combination with systemic therapy (e.g., hydroxychloroquine).

Second-Line Therapies

• Antimalarial drugs	B
• Systemic retinoids	B

Updated recommendations on the use of hydroxychloroquine in

dermatologic practice

Anthony P. Fernandez. *J Am Acad Dermatol* 2017; 76:1176-1182.

Recommendations on Screening for Chloroquine and Hydroxychloroquine Retinopathy (2016 Revision). Marmor MF, Kellner U, Lai TY, Melles RB, Mieler WF, American Academy of Ophthalmology. *Ophthalmology* 2016; 123: 1386-94.

Long-term response to hydroxychloroquine in patients with discoid lupus erythematosus

Wahie S, Meggitt SJ. *Br J Dermatol* 2013; 169: 653–9.

The effect of increasing the dose of hydroxychloroquine (HCQ) in patients with refractory cutaneous lupus erythematosus (CLE): an open-label prospective pilot study

Chasset F, Arnaud L, Costedoat-Chalumeau N, Zahr N, Bessis D, Francés C. *J Am Acad Dermatol* 2016; 74: 693–9.

Influence of smoking on the efficacy of antimalarials in cutaneous lupus: a meta-analysis of the literature

Chasset F, Francés C, Barete S, Amoura Z, Arnaud L. *J Am Acad Dermatol* 2015; 72: 634–9.

Antimalarial drugs are favored for long-term treatment of DLE and are effective in many patients for whom topical therapy alone is unsuccessful or impractical, although in some series the long-term response rate is <50%. In most patients, 6 weeks of treatment is needed before they begin to exert their effect. Hydroxychloroquine (200 mg once or twice daily) is most often used, chloroquine (250–500 mg daily) being reserved for unresponsive patients. Quinacrine was widely used in the past but has become increasingly difficult to obtain. Baseline lupus severity may predict response to hydroxychloroquine, whereas the deleterious role of cigarette smoking on the efficacy of antimalarial drugs is controversial. Treatment failure may be associated with subtherapeutic blood concentrations of the drug, which may be managed by increasing the daily dose of hydroxychloroquine to reach blood concentrations >750 ng/mL.

Drugs for discoid lupus erythematosus

Jessop S, Whitelaw DA, Delamere FM. *Cochrane Database Syst Rev* 2009; 4: CD002954.

Oral retinoids, either isotretinoin (1 mg/kg/d in two divided doses) or acitretin (25–50 mg daily in one or two divided doses), are useful in the treatment of DLE, particularly the hypertrophic variety. Their teratogenic effects must be respected, especially because patients with DLE are often women of childbearing age. The long-term adverse effects of retinoids, including hypertriglyceridemia and possible bony abnormalities, must also be considered in constructing a treatment plan. As with other treatments for DLE, the disease occasionally flares, even with continued treatment.

Third-Line Therapies

• Cytotoxic agents	D
• Immune response–modifying agents	D
• Topical salbutamol	B

Treatment of cutaneous lupus erythematosus: current practice variations

Reich A, Werth VP, Furukawa F, Kuhn A, Szczęch J, Samotij D, et al. *Lupus* 2016; 25: 964-72.

Evidence-based data to support the efficacy of drugs commonly used to treat DLE is lacking, with few randomized, controlled trials. Case reports have claimed efficacy for a variety of systemic drugs with diverse mechanisms of action, including antibiotics (e.g., sulfasalazine, dapsone) and biologic agents (e.g., etanercept, infliximab, rituximab), as well as older and newer immune-response modifiers (e.g., clofazimine, apremilast, fumaric acid esters). Immunosuppressive drugs (e.g., azathioprine, methotrexate, mycophenolate mofetil) have also been used in patients with disease refractory to conventional treatment, as has the pulsed dye laser.

Thalidomide and lenalidomide for the treatment of refractory dermatologic conditions

Nahmias Z, Nambudiri VE, Vleugels RA. *J Am Acad Dermatol* 2016;

75: 210-2.

Lenalidomide treatment of cutaneous lupus erythematosus: the Mayo Clinic experience

Kindle SA, Wetter DA, Davis MD, Pittelkow MR, Sciallis GF. *Int J Dermatol* 2016; 55: e431-9.

Lenalidomide for refractory chronic and subacute cutaneous lupus erythematosus

Fennira F, Chasset F, Soubrier M, Cordel N, Petit A, Francès C. *J Am Acad Dermatol* 2016; 74: 1248-51.

Thalidomide (20 - 100 mg daily) has been used in the treatment of patients with cutaneous lupus erythematosus refractory to other modalities. The response is variable but may be quite favorable. It must be emphasized that the disease typically affects young women of childbearing age; thus the teratogenic potential of the drug should not be ignored. Sensory neuropathy and thromboembolic events are other potential complications of thalidomide administration. Some reports suggest that lenalidomide, an analog of thalidomide, may be a viable alternative, despite its similar adverse event profile.

A randomized controlled trial of R-salbutamol for topical treatment of discoid lupus erythematosus

Jemec GB, Ullman S, Goodfield M, Bygum A, Olesen AB, Berth-Jones J, et al. *Br J Dermatol* 2009; 161: 1365–70.

Salbutamol has antiinflammatory properties, and although not yet commercially developed, this study demonstrated promising results from a 0.5% cream applied twice daily for 8 weeks.

Dissecting cellulitis of the scalp

Vikram Rajkomar, and Matt Harries

Dissecting cellulitis (*perifolliculitis capitis abscedens et suffodiens*) is a rare inflammatory disease of the scalp characterized by multiple fluctuant nodules and abscesses over the vertex and occipital region associated with interconnecting sinus tract formation and purulent discharge. Dissecting cellulitis of the scalp (DCS) follows a progressive relapsing course eventually resulting in permanent hair

loss and hypertrophic scarring. The condition predominantly affects men aged 20 to 40 and is more common in those of African descent. Dissecting cellulitis may occur in association with hidradenitis suppurativa (HS) and acne conglobata to form the “follicular occlusion triad.” The suggested common pathogenic mechanism is of follicular occlusion triggering a folliculitis with neutrophilic or granulomatous inflammation in the dermis and subcutis, leading to formation of sinus tracts, abscesses, and progressive fibrosis. An abnormal host response to (possibly commensal) bacteria may also be a factor in disease development.

Management Strategy

Dissecting cellulitis is characterized by a chronic, progressive course with temporary improvement on treatment followed by relapses when treatment is discontinued. There are no large therapeutic clinical trials, and recommendations for therapy are based on case reports or case series. Inflammatory tinea capitis and the very rare complication of squamous cell carcinoma should be excluded. Although no specific pathogenic organisms have been isolated, swabs should be obtained for bacteriology and the antibiotic sensitivity of organisms reviewed.

In mild cases or when disease is limited, *improved scalp hygiene* and the use of *antiseptics, topical antibiotics, intralesional corticosteroid injections, and aspiration of fluctuant lesions* may be adequate. At an early stage, *systemic antibiotics* such as *tetracyclines* reduce inflammation and can control disease. In more severe cases a *combination of systemic antibiotics such as clindamycin with rifampicin, with or without corticosteroids*, may be effective. However, recognition that *oral isotretinoin* can provide sustained remission has led many to now regard it as first-line therapy in DCS. Oral *zinc sulfate* has received anecdotal reports of benefit when used long term. Recent reports highlight success with anti-tumor necrosis factor (TNF) therapy in those unresponsive to standard treatment. *Alitretinoin* and *photodynamic therapy* are new additions to the therapeutic armamentarium.

In those unresponsive to medical therapy a surgical approach may be considered. *X-ray epilation* of affected areas has largely been superseded by *laser epilation* techniques. The most resistant cases may require *surgical excision and skin grafting*.

Specific Investigations

- Swabs for bacteriology
- Scrapings and plucked hairs for mycology
- Scalp biopsy for histology and fungal culture

Inflammatory tinea capitis (kerion) mimicking dissecting cellulitis

Sperling LC, Major MC. Int J Dermatol 1991; 30: 190–2.

Two cases of inflammatory tinea capitis mimicking DCS are reported. If initial mycology is negative, consider biopsy for histology and fungal culture.

Squamous cell carcinoma arising in dissecting perifolliculitis of the scalp

Curry SS, Gaither DH, King LE. J Am Acad Dermatol 1981; 4: 673–8.

The rare complication of squamous cell carcinoma arising in DCS is presented.

First-Line Therapy

• Isotretinoin (oral)	D
-----------------------	----------

Dissecting cellulitis of the scalp: response to isotretinoin

Scerri L, Williams HC, Allen BR. Br J Dermatol 1996; 134: 1105–8.

Three patients with DCS showed a sustained response to isotretinoin. The authors recommend isotretinoin initially at 1 mg/kg daily and maintained at 0.75 mg/kg daily for at least 4 months after clinical remission is achieved.

Dissecting cellulitis of the scalp: a retrospective study of 7 cases confirming the efficacy of oral isotretinoin

Koudoukpo C, Abdennader S, Cavelier-Balloy B, Gasnier C, Yédomon H. Ann Dermatol Venereol 2014; 141: 500–6.

Dissecting cellulitis of the scalp: a retrospective study of 51 patients and review of literature

Badaoui A, Reygagne P, Cavelier-Balloy B, Pinquier L, Deschamps L, Crickx B, et al. Br J Dermatol 2016; 174: 421–3.

A retrospective analysis of 51 patients with DCS treated from 1996 to 2013. Thirty-five patients received treatment with isotretinoin at 0.5 to 0.8 mg/kg/day with complete remission being achieved in 92%.

Second-Line Therapies

• Systemic antibiotics	D
• Intralesional corticosteroid injection	D
• Incision and drainage	D
• Topical antibiotic/retinoid	E
• Systemic corticosteroids	E
• Oral zinc	E

Dissecting cellulitis of the scalp responding to oral quinolones

Greenblatt DT, Sheth N, Teixeira F. Clin Exp Dermatol 2008; 33: 99–100.

Dissecting cellulitis (perifolliculitis capitis abscedens et suffodiens): a comprehensive review focusing on new treatments and findings of the last decade with commentary comparing the therapies and causes of dissecting cellulitis to hidradenitis suppurativa

Scheinfeld N. Dermatol Online J 2014; 20: 22692.

Various treatment strategies for DCS are reviewed. Oral antibiotics and oral isotretinoin, either as monotherapy or in combination, represent the mainstay of treatment. Addition of intralesional corticosteroids or incision and drainage may improve local control.

Reported antibiotic regimens include rifampicin 300 mg BID and clindamycin 300 mg BID, tetracyclines (e.g., doxycycline 100–200 mg/day), ciprofloxacin 250 to 500 mg BID, and trimethoprim-sulfamethoxazole 960 mg BID. Responses and relapse rates are variable and depend on the regimen chosen.

Perifolliculitis capitis abscedens et suffodiens successfully controlled with topical isotretinoin

Karpouzis A, Giatromanolaki A, Sivridis E, Kouskoukis C. Eur J Dermatol 2003; 13: 192–5.

A case of DCS controlled with topical isotretinoin and clindamycin gel.

Perifolliculitis capitis: successful control with alternate day corticosteroids

Adrian RM, Arndt KA. Ann Plast Surg 1980; 4: 166–9.

Successful control of DCS was achieved using high-dose oral prednisolone and maintained with alternate-day 5 mg prednisolone for 2 years.

Successful treatment of dissecting cellulitis and acne conglobata with oral zinc

Kobayashi H, Aiba S, Tagami H. Br J Dermatol 1999; 141: 1136–8.

A patient with DCS and acne conglobata responded to oral zinc sulfate 135 mg three times a day for 12 weeks followed by a reduced maintenance dose.

Third-Line Therapies

• Excision and grafting	E
• Laser epilation	E
• Radiotherapy epilation	E
• Dapsone	E
• PDT	E
• Alitretinoin	E
• Infliximab/adalimumab	E

Dissecting cellulitis of the scalp

Williams CN, Cohen M, Ronan SG, Lewandowski CA. *Plast Reconstruct Surg* 1986; 77: 378–82.

Four patients with extensive scalp disease responded to wide excision and split-thickness skin grafting.

Dissecting cellulitis treated with the long-pulsed Nd:YAG laser

Krasner BD, Hamzavi FH, Murakawa GJ, Hamzavi IH. *Dermatol Surg* 2006; 32: 1039–44.

Four patients achieved sustained improvement at 1 year, with some regrowth of hair at treated sites.

Use of an 800-nm pulsed-diode laser in the treatment of recalcitrant dissecting cellulitis of the scalp

Boyd AS, Binhlam JQ. *Arch Dermatol* 2002; 138: 1291–3.

Complete clearance of recalcitrant disease after four monthly treatments, with remission maintained at 6 months.

Modern external beam radiation therapy for refractory dissecting cellulitis of the scalp

Chinnalayan P, Tena LB, Brenner MJ, Welsh JS. Br J Dermatol 2005; 152: 777–9.

Rapid improvement in four cases treated with electron beam therapy. No relapses reported after 4- to 13-year follow-up.

Successful treatment of recalcitrant dissecting cellulitis of the scalp with ALA-PDT: case report and literature review

Liu Y, Ma Y, Xiang LH. Photodiagnosis Photodyn Ther 2013; 10: 410–3.

The authors report complete response using ALA-PDT weekly for 6 weeks in recalcitrant DCS. Remission was maintained at 5 months' follow-up.

Successful treatment with alitretinoin of dissecting cellulitis of the scalp in keratitis-ichthyosis-deafness syndrome

Prasad SC, Bygum A. Acta Derm Venereol 2013; 93: 473–4.

Alitretinoin was given at 10 mg daily for 2 months followed by 20 mg daily in a patient with DCS and keratitis, ichthyosis, deafness (KID) syndrome. Significant improvement was noted after 5 months of therapy.

Perifolliculitis capitis abscedens et suffodiens successfully controlled with infliximab

Brandt HRC, Malheiros APR, Teixeira MG, Machado MCR. Br J Dermatol 2008; 159: 506–7.

Sustained response to infliximab given 8 weekly for 12 months in a case of DCS refractory to antibiotics and isotretinoin.

Three cases of dissecting cellulitis of the scalp treated with adalimumab

Navarini AA, Trüeb RM. Arch Dermatol 2010; 146: 517–20.

Rapid improvement with adalimumab, but relapse occurred on stopping treatment due to persistent underlying structural disease. The authors suggest continuous therapy or surgical excision of involved areas to prevent recurrence.

Drug eruptions

Roni P. Dodiuk-Gad, and Neil H. Shear

Drug eruptions are among the most frequent adverse reactions in patients receiving drug therapy. They have a wide spectrum of clinical manifestations, are caused by various drugs, and result from varied pathophysiologic mechanisms. Hence, their diagnosis and management are challenging. Drug eruptions can range from a mild,

simple eruption involving only the skin to severe complex eruptions with systemic involvement, such as toxic epidermal necrolysis. Systemic involvement should be explored even in a mild cutaneous eruption due to a drug because the severity of skin manifestation does not necessarily mirror the severity of the systemic involvement. The image shows a widespread eruption of erythematous macules and papules coalescent into ill-defined plaques on the trunk—maculopapular morphology of cutaneous drug eruption. This can be localized to the skin with no systemic involvement (simple drug eruption) or be associated with systemic involvement (complex drug eruption).

Management Strategy

The following is the authors' protocol to approach a patient with a drug eruption: **4Ds. Diagnosis** of the adverse event is based on three key clinical elements: 1) Appearance: the morphology of the drug eruption based on four main categories of the primary lesion: maculopapular, urticarial, bullous, and pustular. 2) Systemic signs that differentiate between a simple reaction involving only the skin and a complex reaction that comprises systemic involvement in addition to the skin. Systemic involvement is evaluated by assessing the patient's symptoms such as fever, facial edema, malaise, chills, dyspnea, cough, palpitations, nausea, vomiting, diarrhea, sore throat, and arthralgia and a basic laboratory screen, which includes a full blood count, liver and renal function tests, and urine analysis. 3) Histology: histopathology and, if relevant, direct immunofluorescence studies of skin biopsies to confirm the clinical impression and to distinguish between a drug eruption and other skin diseases. In addition, it is valuable to use validated diagnostic criteria of specific types of drug eruptions, if available. Currently, only acute generalized exanthematous pustulosis (AGEP) and drug reaction with eosinophilia and systemic symptoms (DRESS) have published validated diagnostic criteria.

Differential diagnosis

Establishing a differential diagnosis that takes into account all possible diagnoses is essential.

Drug exposure (timing)

All medications, regardless of route of administration, must be considered, particularly new drugs taken in the 8 weeks before the drug eruption. Assessment of the lag period, the time between initiation of the drug and onset of the cutaneous reaction, is essential in view of the different lag times for different drug eruptions. A recommended method for drug exposure analysis is to chart a timeline in order to visualize the chronology and facilitate comprehension of the event.

Determine probabilities

An important step in assessing a drug eruption is to establish whether there is a causal relationship between the suspected drug and the clinical event. The following methods are helpful: 1) Patient history: the patient should be questioned about previous drug eruptions and whether dechallenge with the drug improved the eruption. 2) Analysis of the literature: PubMed (<http://www.ncbi.nlm.nih.gov/pubmed/>) and Litt's D.E.R.M. Drug Eruptions and Reactions Manual and database (<http://www.drugeruptiondata.com/>). 3) In vitro and in vivo diagnostic assessments, including human leukocyte antigen (HLA) genetic tests. An important progress in the underlying mechanisms of several types of drug eruptions has been achieved by the discovery of an association between a specific HLA allele, a drug, an ethnic background, and a drug eruption. These tests are best utilized as genetic screening before drug prescription. However, they may serve as a simple, safe, and reliable method for establishing causality in specific cases of drug eruptions such as toxic epidermal necrolysis and DRESS induced by specific drugs such as carbamazepine and allopurinol. Other in vitro tests may include lymphocyte transformation test and basophil activation test. Patch test is an important in vivo test that may be used in assessment of a drug eruption. Caution should always be exercised regarding false-positive and false-negative results of these in vitro and in vivo tests, and no test should be used as justification for rechallenge.

After the diagnosis of a drug eruption, the physician must provide the patient with clear information on the drug eruption, the name of the offending drug, potential cross-reacting drugs, and drugs that can

be safely taken as an alternative to the offending drug. In cases of complex reactions, it is also necessary to explain to the patient the possible long-term medical complications, to provide him or her with information on medical follow-up and support groups, and to conduct family counseling because the predisposition may be genetic. The physician must also report the event to the patient's health care provider, the manufacturer, and regulatory agencies.

Specific Investigations

- Determination of the morphology of the primary lesion based on four main categories: maculopapular, urticarial, bullous, and pustular
- Assessment of systemic involvement based on patient's vital signs and symptoms
- Assessment of systemic involvement based on basic laboratory screen: full blood count, liver and renal function tests, and urine analysis
- Skin biopsy for histopathology and, if relevant, direct immunofluorescence studies
- Usage of validated diagnostic criteria, if available
- Establishment of a differential diagnosis that takes into account all possible diagnoses
- Drug exposure analysis: determination of the lag period and creation of a timeline
- Determination of probabilities for the associations between the suspected drug and the clinical event according to the patient's history, literature, and in vitro and in vivo diagnostic assessments, including HLA genetic tests

Phenotype standardization for immune-mediated drug-induced skin injury

Pirmohamed M, Friedmann PS, Molokhia M, Loke YK, Smith C, Phillips E, et al. Clin Pharmacol Ther 2011; 89: 896–901.

A drug-induced skin injury (DISI) expert working group comprising participants with varied expertise defined the minimum phenotypic criteria for selected forms of DISI (SJS/TEN, AGEP, and DRESS). In addition, an algorithm to aid appropriate clinical categorization of patients with DISI is presented.

Acute generalized exanthematous pustulosis (AGEP)—a clinical reaction pattern

Sidoroff A, Halevy S, Bavinck JN, Vaillant L, Roujeau JC. *J Cutan Pathol* 2001; 28: 113–19.

An algorithm for validating cases of AGEP is presented in this manuscript.

Variability in the clinical pattern of cutaneous side-effects of drugs with systemic symptoms: does a DRESS syndrome really exist?

Kardaun SH, Sidoroff A, Valeyrie-Allanore L, Halevy S, Davidovici BB, Mockenhaupt M, et al. *Br J Dermatol* 2007; 156: 609–11.

Scoring system for classifying DRESS cases is presented in this manuscript.

The lymphocyte transformation test in the diagnosis of drug hypersensitivity

Pichler WJ, Tilch J. *Allergy* 2004; 59: 809–20.

The lymphocyte transformation test (LTT) measures the proliferation of T cells to a drug in vitro. The main advantage of this test is its applicability with many different drugs in different immune reactions. Its main disadvantages are that the test is technically demanding and with limited sensitivity.

A multicentre study to determine the value and safety of drug patch tests for the three main classes of severe cutaneous adverse drug reactions

Barbaud A, Collet E, Milpied B, Assier H, Staumont D, Avenel-Audran M, et al. *Toxidermies group of the French Society of Dermatology. Br J Dermatol* 2013; 168: 555–62.

In a multicenter study, patch tests were conducted on patients referred for AGEP, DRESS, and SJS/TEN. It was found that patch tests are useful and safe for identifying severe cutaneous drug eruptions, and the value of patch tests depended on the type of drug and the type of drug eruption. Testing for all possible agents is recommended in order to identify responsible products that are normally not suspected.

HLA associations and clinical implications in T-cell mediated drug hypersensitivity reactions: an updated review

Cheng CY, Su SC, Chen CH, Chen WL, Deng ST, Chung WH. J Immunol Res 2014; 2014: 565320.

Recent advances in pharmacogenetic studies show strong genetic associations between HLA alleles and susceptibility to drug hypersensitivity. This review summarizes the literature on recent progress in pharmacogenetic studies and clinical application of pharmacogenetic screening.

*Various associations between a specific HLA and drug hypersensitivity were found. The following are the current most important associations related to severe cutaneous adverse drug reactions: HLA-B*1502 and carbamazepine-induced SJS/TEN in Asians, HLA-A*31:01 and carbamazepine-induced DRESS in both Caucasians and Asians, HLA-B*5701 and abacavir hypersensitivity in Caucasians, and HLA-B*5801 and allopurinol-induced SJS/TEN or DRESS in both Caucasians and Asians.*

First-Line Therapies

• Discontinue the offending drug	D
• Supportive care	E
• Simple drug eruption (involving only the skin): oral antihistamines and topical corticosteroids	E
• Complex drug eruption (systemic involvement in addition to the skin): specific treatments based on the type of the drug eruption	E

Clinical practice. Exanthematous drug eruptions

Stern RS. N Engl J Med 2012; 366: 2492–501.

Identifying and discontinuing the causative drug are the most important steps in management of a drug eruption. In simple drug eruptions, symptomatic treatment with antihistamines and potent topical glucocorticoids may be helpful. A decision can be made to continue the drug and offer symptomatic treatment if the drug is of paramount importance, but the risk:benefit ratio of this option has to be carefully weighed, and the evolution of the eruption must be meticulously monitored. In cases of complex drug eruptions, it is always essential to discontinue the drug.

Second-Line Therapies

• Cyclosporine	B
• Intravenous immunoglobulin G	E
• TNF inhibitors	E
• Mucous membrane treatment	E
• Skin treatment	E
• Pain control	E

Open trial of cyclosporine treatment for Stevens-Johnson syndrome and toxic epidermal necrolysis

Valeyrie-Allanore L, Wolkenstein P, Brochard L, Ortonne N, Maitre B, Revuz J, et al. *Br J Derm* 2010; 163: 847–53.

Death rate and progression of detachment appeared lower than expected in 29 patients with a diagnosis of SJS or TEN who received cyclosporine (3 mg/kg/day for 10 days and tapered over a month).

Stevens-Johnson syndrome and toxic epidermal necrolysis: an update

Dodiuk-Gad RP, Chung WH, Valeyrie-Allanore L, Shear NH. *Am J Clin Dermatol* 2015; 16: 475–93.

This review summarizes up-to-date insights on SJS/TEN and describes a protocol for assessment and treatment.

Management of drug reaction with eosinophilia and systemic symptoms (DRESS)

Descamps V, Ben Saïd B, Sassolas B, Truchetet F, Avenel-Audran M, Girardin P, et al. *Groupe Toxidermies de la Société française de dermatologie. Ann Dermatol Venereol* 2010; 137: 703–8.

This manuscript describes the management protocol for DRESS based on the consensus of experts from the French Society of Dermatology. A decisional tree of treatment options is proposed, based on the severity of visceral manifestations.

Other Therapies

• Counsel the patient and family	E
• Report the event to the patient's health care provider, the manufacturer, and regulatory agencies	E

Eosinophilic fasciitis

Jamie R. Manning, Shaheen H. Ensanyat, Amir A. Larian, Brian S. Fuchs, and Marsha L. Gordon

Eosinophilic fasciitis (EF), also known as *Shulman syndrome*, is a rare fibrosing disorder characterized by the rapid onset of symmetric induration of the extremities. The trunk and neck can be affected, with typical sparing of the hands, feet, and face. Clinically, the progression of EF is marked by edema and erythema followed by dimpling of the skin and a *peau d'orange* appearance evolving into

woody induration and stiffness of the limbs. Depressions over superficial veins produce the “gutter” or “groove” sign. Laboratory investigations often reveal hypergammaglobulinemia, an elevated erythrocyte sedimentation rate, and peripheral blood eosinophilia but are not essential in securing a diagnosis, given their transient levels. Histologically, EF presents with severe fascial thickening associated with an inflammatory infiltrate composed of plasma cells, eosinophils, histiocytes, and lymphocytes that can ultimately lead to dermal sclerosis. Although the etiology remains unknown, vigorous physical activity and infection have been reported before the onset of EF in many cases, presumably triggering an aberrant immune response.

Management Strategy

Whether a distinct entity or variant of scleroderma, EF is differentiated by the relative absence of sclerodactyly, Raynaud phenomenon, and serologic markers. Unlike scleroderma, patients with EF typically demonstrate a more rapid onset with normal nail fold capillaries, infrequent visceral involvement, and response to corticosteroid therapy. Although organ involvement is not prominent in EF, rare cases have reported significant proteinuria, possibly representing an underestimated systemic feature. EF must also be distinguished from the eosinophilia–myalgia syndrome, which is characterized by diffuse muscle pain and weakness, polyneuropathy, respiratory and pulmonary problems, and most notably a history of contaminated L-tryptophan ingestion.

EF has been reported in association with hematologic disorders, including aplastic anemia, hemolytic anemia, thrombocytopenia, leukemias, and lymphomas. In addition, EF has to a lesser extent been linked to administration of simvastatin or exposure to trichloroethylene; these should be checked for in the patient history.

Clinical and laboratory findings help identify EF; however, diagnosis can only be confirmed with histopathologic examination from a full-thickness skin-to-muscle biopsy, which characteristically reveals deep dermal fibrosis and fascial thickening with inflammatory infiltration of lymphocytes, plasma cells, and eosinophils. Magnetic resonance imaging (MRI), ultrasound and positron emission tomography/computed tomography (PET/CT) are useful noninvasive tools for establishing the diagnosis, choosing the optimal biopsy site,

and monitoring the effectiveness of treatment. On MRI, findings typically show high signal intensity of the deep and superficial fasciae on T₁, T₂, and short tau inversion recovery (STIR) imaging with enhancement after intravenous contrast administration.

Although spontaneous remission of EF has been reported, treatment can help prevent the progression of flexion contractures and limited mobility. Clinical response is usually defined as marked improvement in skin thickening, as fibrosed tissue becomes softer and looser, allowing for increased range of motion. Serum aldolase levels have been proposed as a useful indicator of disease activity.

There is substantial agreement among published reports that moderate- to high-dose corticosteroids serve as the first-line treatment for EF with *prednisone* as the standard agent, initially at 40 to 60 mg daily. A clinical response usually is noted within the first few weeks, and the dosage is then tapered slowly over several months to an alternate-day regimen. In steroid-refractory patients, the addition of *hydroxychloroquine* at 200 to 400 mg daily has also been effective both in combination and as monotherapy.

In patients with partial or no response to corticosteroids, immunosuppressive drugs are frequently introduced as a second-line treatment. *Ciclosporin* at 3.7 mg/kg daily tapered to 2.5 mg/kg daily has been successful within 1 month at improving clinical symptoms with no relapse after a year. *Methotrexate* at 15 to 20 mg/week in conjunction with prednisone has also been commonly used with a favorable response.

Cimetidine at 400 mg every 6 to 12 hours has shown reported success in some cases. *Pulsed methylprednisolone* 1 g daily for 5 days combined with ciclosporin 150 mg twice daily is another regimen that has led to remission for patients in need of more aggressive therapy. *Infliximab*, *D-penicillamine*, *ketotifen*, *chloroquine*, *psoralen* and *ultraviolet light (PUVA)*, *azathioprine*, *griseofulvin*, *dapsone*, and *sulfasalazine* have all been reported to have beneficial effects.

Specific Investigations

- Complete blood count
- Serum aldolase
- MRI
- Ultrasound

- Fludeoxyglucose (FDG) PET/CT
- History to exclude tryptophan, simvastatin, or trichloroethylene ingestion
- Infection

Eosinophilic fasciitis

Sibrack LA, Mazur EM, Hoffman R, Bollet AJ. Clin Rheum Dis 1982; 8: 443–54.

Peripheral eosinophilia is typically present during active disease, except in those patients who have an associated aplastic marrow. The eosinophilia is often transient and may precede the clinical diagnosis.

The use of an elevated aldolase in diagnosing and managing eosinophilic fasciitis

Nashel J, Steen V. Clin Rheumatol 2015; 34: 1481–4.

In this retrospective review of 15 patients, the aldolase level was the last parameter to normalize and the first to rise during a flare compared with eosinophilia and inflammatory markers.

Eosinophilic fasciitis: spectrum of MRI findings

Moulton SJ, Kransdorf MJ, Ginsburg WW, Abril A, Persellin S. AJR Am J Roentgenol 2005; 184: 975–8.

In this case series of six patients with histologically proven EF, MRI revealed characteristic findings, including thickening, signal abnormalities, and contrast enhancement of the superficial and, to a lesser extent, deep muscle fasciae.

Ultrasound assessment of subcutaneous compressibility: a potential adjunctive diagnostic tool in eosinophilic fasciitis

Kissin EY, Garg A, Grayson PC, Dubreuil M, Vradii D, York M, et al. J Clin Rheumatol 2013; 19: 382–5.

A cross-sectional study of 12 patients with EF revealed a significant reduction in subcutaneous compressibility quantified by ultrasound.

Usefulness of FDG PET/CT in the diagnosis of eosinophilic fasciitis

Kim HJ, Lee SW, Kim GJ, Lee JH. Clin Nucl Med 2014; 39: 801–2.

In one case report, increased uptake of FDG on PET/CT along the superficial and deep fasciae suggested FDG PET/CT may be a

noninvasive tool to illustrate more detailed anatomic involvement of the disease, especially if MRI is contraindicated.

Eosinophilic fasciitis associated with tryptophan ingestion: a manifestation of eosinophilia myalgia syndrome

Gordon ML, Lebwohl MG, Phelps RG, Cohen SR, Fleischmajer R. Arch Dermatol 1991; 127: 217–20.

Ingestion of contaminated tryptophan is associated with a very similar clinical entity called *eosinophilia–myalgia syndrome*.

Although the eosinophilia–myalgia syndrome is now mostly of historical significance, a new case was reported in 2011.

Eosinophilic fasciitis associated with *Mycoplasma arginini* infection

Silló P, Pintér D, Ostorházi E, Mazán M, Wikonkál N, Pónyai K, et al. J Clin Microbiol 2012; 50: 1113–7.

A 23-year-old male and former bodybuilder with a history of consuming anabolic steroids was diagnosed with EF in conjunction with *Mycoplasma arginini* infection, suggesting a potential pathogenic association.

Eosinophilic fasciitis. A pathologic study of twenty cases

Barnes L, Rodnan GP, Medsger TA, Short D. Am J Pathol 1979; 96: 493–517.

Deep fascia and subcutaneous tissue are infiltrated with lymphocytes, plasma cells, histiocytes, and eosinophils early in the course of the disease. Sclerosis of the dermis with increased collagen occurs later in the course of the disease.

Analysis of leukemia inhibitory factor, type 1 and type 2 cytokine production in patients with eosinophilic fasciitis

Viallard JF, Taupin JL, Leng B, Pellegrin JL, Moreau JF. J Rheumatol 2001; 28: 75–80.

Peripheral blood mononuclear cells in patients with EF have increased capacity to produce type 2 cytokines such as interleukin-5 (IL-5) and IL-10. Elevations in type 1 (interferon gamma [IFN- γ] and IL-2) and leukemia inhibitor factor cytokines in the same patients may suggest a compensatory response.

First-Line Therapies

• Systemic corticosteroids and methotrexate	B
• Systemic corticosteroids	B
• Pulsed methylprednisolone	D
• Prednisone and D-penicillamine	C

Epidemiology and treatment of eosinophilic fasciitis: an analysis of 63 patients from 3 tertiary care centers

Wright NA, Mazori DR, Patel M, Merola JF, Femia AN, Vleugels RA. JAMA Dermatol 2016; 152: 97–9.

A retrospective chart review of 63 EF patients revealed that complete response was more likely in those treated with a combination of corticosteroids and methotrexate (64%), compared with corticosteroid monotherapy (30%), other treatment combinations (29%), and without steroids (17%).

Eosinophilic fasciitis: clinical spectrum and therapeutic response in 52 cases

Lakhanpal S, Ginsburg WW, Michet CJ, Doyle JA, Moore SB. Semin Arthritis Rheum 1988; 17: 221–31.

Of the 52 patients, 34 were treated with prednisone (40–60 mg/daily). The remaining 18 were treated with hydroxychloroquine, colchicine, D-penicillamine, or no medication. Twenty of the 34 patients treated with prednisone had a partial response, and 5 had complete resolution. Eight of the 9 patients who had a poor response were treated with the addition of hydroxychloroquine (200–400 mg/daily). Two responded completely, 2 had an improvement of over 50%, and 3 were lost to follow-up. Eight patients also responded to treatment with hydroxychloroquine alone. Relapses occurred in some patients.

Eosinophilic fasciitis (Shulman disease): new insights into the therapeutic management from a series of 34 patients

Lebeaux D, Francés C, Barete S, Wechsler B, Dubourg O, Renoux J, et al. *Rheumatology* (Oxford) 2012; 51: 557–61.

Prednisone served as a first-line therapy for all patients. Before treatment initiation, 15 patients received methylprednisolone pulses (MPPs), which reduced the need for an immunosuppressive drug and increased the probability of complete remission. After treatment initiation, 12 patients received methotrexate as a second-line therapy. A poor outcome was present in 10 patients and was associated with a diagnosis time delay of more than 6 months and a lack of MPPs at treatment initiation. Overall, complete remission was achieved in 69% of patients.

Severe eosinophilic fasciitis: comparison of treatment with D-penicillamine plus corticosteroids vs. corticosteroids alone

Mendoza FA, Bai R, Kebede AG, Jimenez SA. *Scand J Rheumatol* 2015; 73: 1010.

A prospective, nonrandomized, open-label trial of 16 patients with a clinicohistopathologic diagnosis of severe EF revealed that the combination treatment of D-penicillamine plus corticosteroids was more efficacious than corticosteroids alone. Proteinuria was the most common adverse event reported in both groups.

Four prolonged cases of eosinophilic fasciitis in children

Hui-Yuen J, Lauren C, Garzon M, Starr AJ, Imundo LF. *Arthritis Rheumatol* 2014; 66: S85.

Four pediatric patients with EF confirmed the efficacy of corticosteroids as a first-line therapy. All patients required either methotrexate or mycophenolate mofetil, and three required both, suggesting a more severe course within the pediatric population.

Second-Line Therapies

• Hydroxychloroquine	C
• Ciclosporin	E
• Methotrexate	D
• Cimetidine	C

Eosinophilic rheumatic disorders

Clauw DJ, Crofford LJ. *Rheum Clin North Am* 1995; 21: 231–46.

Hydroxychloroquine at a dose of 200 to 400 mg daily can be used either alone or in combination with corticosteroids.

Eosinophilic fasciitis successfully treated with ciclosporin

Bukiej A, Dropiński J, Dyduch G, Szczeklik A. *Clin Rheumatol* 2005; 24: 634–6.

Case report of a 45-year-old female unresponsive to treatment with prednisolone followed by cimetidine, who experienced clinical remission after a regimen of ciclosporin at 5 mg/kg daily for 4 weeks tapered to 2.5 mg/kg daily.

Eosinophilic fasciitis: clinical characteristics and response to methotrexate

Berianu F, Cohen MD, Abril A, Ginsburg WW. *Rheum Dis* 2015; 18: 91–8.

Sixteen patients with biopsy-proven EF were treated with methotrexate after a course of either prednisone alone or in combination with azathioprine or hydroxychloroquine. Clinical response was noted within 6 months of therapy.

The fasciitis–panniculitis syndromes. Clinical and pathologic features

Naschitz JE, Boss JH, Misselevich I, Yeshurun D, Rosner I. *Medicine*

1996; 75: 6–16.

Complete and partial remission on cimetidine 400 mg twice daily occurred in nine and five patients, respectively. Only three did not respond to cimetidine monotherapy.

Third-Line Therapies

• PUVA	E
• Extracorporeal photochemotherapy	E
• D-penicillamine	E
• Azathioprine	E
• Chloroquine	E
• Sulfasalazine	E
• Surgery	E
• Infliximab	E
• Hydroxyzine	E
• Rituximab	E
• Dapsone	E
• Combination UVA1–retinoid–corticosteroid	E
• Mycophenolate mofetil	E
• Tocilizumab	E

Eosinophilic fasciitis treated with psoralen–ultraviolet A bath photochemotherapy

Schiener R, Behrens-Williams SC, Gottlober P, Pillekamp H, Peter RU, Kersch M. Br J Dermatol 2000; 142: 804–7.

PUVA had promising results within 6 months without side effects

in a 56-year-old patient.

Extracorporeal photochemotherapy in the treatment of eosinophilic fasciitis

Romano C, Rubegni P, De Aloe G, Stanghellini E, D'Ascenzo G, Andreassi L, et al. *J Eur Acad Dermatol Venereol* 2003; 17: 10–3.

Three patients were treated with extracorporeal photochemotherapy. After 1 year of therapy two patients showed a considerable improvement in clinical parameters.

D-penicillamine in the treatment of eosinophilic fasciitis: case reports and review of the literature

Manzini CU, Sebastiani M, Giuggioli D, Manfredi A, Colaci M, Cesinaro AM, et al. *Clin Rheumatol* 2012; 31: 183–7.

Three patients, two of them refractory to previous steroid therapy, were successfully treated with D-penicillamine.

Eosinophilic fasciitis with late onset arthritis responsive to sulfasalazine

Jones AC, Doherty M. *J Rheumatol* 1993; 20: 750–1.

In this patient there was a complete response to 2 g/day of sulfasalazine within 3 months.

Surgical management of eosinophilic fasciitis of the upper extremity

Suzuki G, Itoh Y, Horiuchi Y. *J Hand Surg* 1997; 22: 405–7.

All four patients experienced improved mobility a few weeks after fasciectomy with follow-up oral prednisolone.

Infliximab may be effective in the treatment of steroid-resistant eosinophilic fasciitis: report of three cases

Khanna D, Agrawal H, Clements PJ. *Rheumatology (Oxford)* 2010; 49: 1184–8.

Three patients refractory to initial treatment with prednisone (60 mg/daily), two of whom also received methotrexate (20 mg/week), noticed clinical improvement within 8 weeks of starting infliximab therapy (3 mg/kg every 8 weeks), leading ultimately to drug-free remission.

Eosinophilic fasciitis successfully treated with oral hydroxyzine:

a new therapeutic use of an old drug?

Uckun A, Sipahi T, Akgun D, Oksal A. Eur J Pediatr 2002; 161: 118–9.

Case report of a 3-year-old boy with biopsy-proven EF successfully treated with oral hydroxyzine (2 mg/kg/day) for 15 days.

Severe aplastic anemia associated with eosinophilic fasciitis: report of 4 cases and review of the literature

de Masson A, Bouaziz JD, Peffault de Latour R, Benhamou Y, Moluçon-Chabrot C, Bay JO, et al. Medicine 2013; 92: 69–81.

In a case series of four EF patients with severe aplastic anemia refractory to standard treatment regimens, one patient had significant improvement in his cutaneous and hematologic symptoms with rituximab infusion.

Dapsone treatment for eosinophilic fasciitis

Smith LC, Cox NH. Arch Dermatol 2008; 144: 845–7.

Report of a 38-year-old woman with minimal improvement from oral steroids and intolerance to ciclosporin who was started on dapsone, with marked clinical improvement.

Eosinophilic fasciitis and combined UVA1-retinoid-corticosteroid treatment: two case reports

Weber HO, Schaller M, Metzler G, Rocken M, Berneburg M. Acta Derm Venereol 2008; 88: 304–6.

Two patients treated with UVA1 phototherapy (60 J/cm²) three to five times per week, isotretinoin 20 mg daily, and prednisone showed marked improvement within 2 to 3 weeks.

Eosinophilic fasciitis in a pediatric patient

Loupasakis K, Derk CT. J Clin Rheumatol 2010; 16: 129–31.

A 9-year-old boy was successfully treated with early high-dose corticosteroids followed by mycophenolate mofetil (900 mg twice daily) with nearly complete resolution after 2 years.

Efficacy of tocilizumab in the treatment of eosinophilic fasciitis: report of one case

Espinoza F, Jorgensen C, Pers YM. Joint Bone Spine 2015; 82: 460–1.

Report of one case of biopsy-proven EF, refractory to high-dose corticosteroids and methotrexate, found to have an excellent response to a humanized monoclonal antibody targeting the IL-6 receptor,

tocilizumab.

Epidermal nevi

Jeffrey M. Weinberg

Epidermal nevi are congenital hamartomas of embryonal ectodermal origin classified on the basis of their major component. The components may be sebaceous, apocrine, eccrine, follicular, or keratinocytic. An estimated one third of individuals with epidermal nevi have involvement of other organ systems. In these cases, the condition is termed *epidermal nevus syndrome*.

The most common epidermal nevi are verrucous epidermal nevi, which are best treated with an ablative procedure using either surgical or laser technology. Inflammatory epidermal nevi may

respond to topical or systemic therapy.

The pluripotential stem cell in the embryonic ectoderm can develop into any of the cell types found within the epidermis and skin adnexae. Therefore many potential nevi may develop from these cell types. Epidermal nevi may be classified according to the predominant cell type. However, there may be different cell populations or overlap between different areas within the same nevus.

The focus of this chapter will be on nevi derived from keratinocytes. Of these, the verrucous epidermal nevus (VEN) is the most common. Other forms include an inflammatory linear verrucous epidermal nevus (ILVEN), an acantholytic or Darier-like nevus, an epidermolytic form, and linear porokeratosis. Very rarely an epidermal nevus may be associated with other birth defects, and a number of epidermal nevus syndromes have been described.

VEN may be localized, segmental, and rarely systematized. The individual lesions are verrucous papules, which may be pink, brown, or gray. These may develop as a result of mosaicism, and, if there is gonadal mosaicism, epidermal nevi may be transmitted to future offspring.

There are very rare case reports of malignant change within epidermal nevi, including squamous cell carcinoma and basal cell carcinoma.

Management Strategy

The major focus of therapy is improved cosmesis. A possible role for the dermis in the development of epidermal nevi is suggested by the difficulty experienced in ablating these lesions surgically without destroying the underlying dermis. *Surgical management* of these lesions presents challenges. Superficial treatments, which remove only the epidermis, have a high recurrence rate, whereas excision or more aggressive ablative procedures may produce unacceptable scarring. *Laser* technology provides the surgeon with more precise tools to maximize efficacy while minimizing scarring. Alternatively, for very widespread lesions, a variety of *topical regimens*, as well as *systemic retinoids*, have been reported to produce some benefit.

ILVEN presents in early childhood as a pruritic, erythematous, linear plaque. It shares many features with psoriasis, and certain cases respond to antipsoriatic therapies such as *topical vitamin D analogs*, *corticosteroids*, and *dithranol*. This has led some authors to suggest that

this condition is a nevoid form of psoriasis. Epidermolytic and acantholytic nevi are more likely to respond to treatment with *retinoids*.

Specific Investigations

- Skin biopsy
- X-ray, imaging studies (magnetic resonance imaging [MRI], computed tomography [CT] scans), and ophthalmologic examinations

An epidermal nevus can most often be diagnosed solely on the clinical presentation and distribution of the lesion. A skin biopsy can be used both to confirm the diagnosis if necessary and to determine the predominant cell type and the presence of inflammatory changes, acantholysis, or dysplasia. This can be helpful in determining which therapeutic modality is most likely to succeed. If histopathology demonstrates an epidermolytic nevus, the individual should be counseled that there is a possibility that the mutation could be transmitted to offspring, with the risk that their children may have generalized cutaneous involvement. Biopsy can also indicate the rare occurrence of squamous or basal cell carcinoma, which can develop in epidermal nevi.

Epidermal nevus syndromes refer to the association of epidermal nevi with extracutaneous manifestations involving the central nervous system, eyes, or bones. The evaluation for systemic involvement should be based on the clinical extent of the epidermal nevi and the presence of any extracutaneous signs and symptoms.

Generalized epidermolytic hyperkeratosis in two unrelated children from parents with localized linear form, and prenatal diagnosis

Chassaing N, Kanitakis J, Sportich S, Cordier-Alex MP, Titeux M, Calvas P, et al. *J Invest Dermatol* 2006; 126: 2715–7.

The authors report two unrelated children with epidermolytic hyperkeratosis, both born to a parent affected with epidermolytic epidermal nevi (EEN); prenatal diagnosis in two successive pregnancies of one of the patients with EEN is described.

Squamous cell carcinoma arising in a verrucous epidermal

naevus

Ichikawa T, Saiki M, Kaneko M, Saida T. *Dermatology* 1996; 193: 135–8.

A case report of a squamous cell carcinoma arising in a 74-year-old man with an epidermal nevus, plus a review of the literature, which revealed 18 previous reports of malignant change in epidermal nevi.

Basal cell carcinoma developing in verrucous epidermal nevus

De D, Kanwar AJ, Radotra BD. *Indian J Dermatol Venereol Leprol* 2007; 73: 127–8.

A 58-year-old farmer with a hyperpigmented, soft verrucous plaque on the right temporoparietal region since birth presented with an ulcer of 8 months' duration. A diagnosis of basal cell carcinoma (BCC) arising in a verrucous epidermal nevus was made. Biopsy was consistent with BCC.

Epidermal nevus syndromes

Sugarman JL. *Semin Cutan Med Surg* 2007; 26: 221–30.

Several subsets with characteristic features have been delineated, including the nevus sebaceous syndrome, Proteus syndrome, CHILD syndrome, Becker nevus syndrome, nevus comedonicus syndrome, and phakomatosis pigmentokeratotica.

Epidermal nevus syndromes: clinical findings in 35 patients

Vidaurri-de la Cruz H, Tamayo-Sanchez L, Duran-McKinster C, de la Luz Orozco-Covarrubias M, Ruiz-Maldonado R. *Pediatr Dermatol* 2004; 21: 432–9.

Of patients with epidermal nevi, 10% to 18% may have disorders of the eye, skeletal, and nervous systems.

Does inflammatory linear verrucous epidermal nevus represent a segmental type 1/type 2 mosaic of psoriasis?

Hofer T. *Dermatology* 2006; 212: 103–7.

The author hypothesizes that inflammatory linear verrucous eruption besides nevoid psoriasis/linear psoriasis represents a further segmental type 1/type 2 mosaic of psoriasis, which, if a (verrucous) epidermal nevus exists, shows a high affinity of occurrence in close context to such a nevus. Heritability is thought to be possible.

Papular epidermal nevus with skyline basal cell layer (PENS):

three new cases and review of the literature

Luna PC, Pannizardi AA, Martin CI, Vigovich F, Casas JG, Larralde M. *Pediatr Dermatol* 2016; 33: 296–300.

Papular epidermal nevus with skyline basal cell layer (PENS) is a recently described type of epidermal nevus with characteristic histopathologic findings. The authors note that cases of Blaschkoid distribution, associated extracutaneous manifestations, and familial cases have been reported. The probability of having extracutaneous manifestations is 6.3 times greater in those with more than four lesions. Therefore these patients require closer follow-up.

Verrucous epidermal nevi

First-Line Therapies

• Excision under local anesthetic	D
• Shave or curettage under local anesthetic	D
• Cryotherapy	C

Comparison of treatment modalities for epidermal nevus: a case report and review

Fox BJ, Lapins NA. *J Dermatol Surg Oncol* 1983; 9: 879–85.

A case report of treatment for a VEN. Review of the treatment modalities then available indicated that surgical excision was only suitable for small lesions; superficial dermabrasion often led to recurrence, and, if performed more deeply, could result in hypertrophic scarring. Similar considerations applied to cryosurgery.

Epidermal nevus: surgical treatment by partial-thickness skin excision

Dellon AL, Luethke R, Wong L, Barnett N. *Ann Plast Surg* 1992; 28: 292–6.

A case report of treatment of a systematized epidermal nevus by partial-thickness skin excision. This cleared the nevus but led to

extensive hypertrophic and keloidal scarring.

For small VEN, excision can be performed with an acceptable cosmetic result. In these cases, this approach is the treatment of choice. However, for larger lesions, or for those in cosmetically sensitive sites, excision may not be appropriate. For larger lesions, shave excision can be performed but often leads to recurrence. Cryotherapy can be used as a destructive method for these lesions, but recurrence is frequent. All these procedures have the benefit of being cost effective and easily performed.

Treatment of verrucous epidermal nevus: experience with 71 cases

Lapidoth M, Israeli H, Ben Amitai D, Halachmi S. *Dermatology*. 2013; 226: 342–6.

Of the 71 cases reviewed, 62 responded well to cryotherapy alone, and 9 facial VEN required CO₂ laser treatment. Small VEN required relatively few treatments (mean 3.4). Larger lesions required more treatments (mean 7.4) and did not respond as well.

Assessment of cryotherapy for the treatment of verrucous epidermal nevi

Panagiotopoulos A, Chasapi V, Nikolaou V, Stavropoulos PG, Kafouros K, Petridis A, et al. *Acta Derm Venereol* 2009; 89: 292–4.

Nine patients with VEN and two with extensive unilateral epidermal nevus were treated with cryosurgery. Ten patients had their nevi treated successfully in two to five sessions, in which two cycles of open spray technique were used, 10 to 15 seconds each, depending on the size and extent of the nevus. The authors reported that the cosmetic result was excellent, with no scarring. One patient showed a relapse within 8 months after the treatment. The authors noted postoperative healing times from 10 to 20 days.

Second-Line Therapies

• Laser ablation	B
• Dermabrasion	E
• Ruby laser	E
• Erbium:YAG laser	C

Epidermal nevi treated by carbon dioxide laser vaporization: a series of 25 patients

Paradela S, Del Pozo J, Fernández-Jorge B, Lozano J, Martínez-González C, Fonseca E. J Dermatol Treat 2007; 18: 169–74.

A total of 25 patients were treated with the CO₂ laser in the superpulsed mode. Good results were achieved in 92% of patients with soft, flattened nevi but in only 33% of patients with keratotic nevi. The authors concluded that the CO₂ laser in the superpulsed mode is an effective and safe treatment for VEN and provides fewer recurrences than other laser therapies. They noted that the main determining factor for the cosmetic result is thickness of the nevus.

Laser therapy of verrucous epidermal naevi

Hohenleutner U, Landthaler M. Clin Exp Dermatol 1993; 18: 124–7.

A series of 43 patients (41 with VEN and two with ILVEN) were treated with either the argon laser or the CO₂ laser. Soft, papillomatous lesions responded well to the argon laser, whereas hard keratotic nevi did not. A better response was seen with the CO₂ laser, but there was a tendency to hypertrophic scarring.

Er:YAG laser treatment of verrucous epidermal nevi

Park JH, Hwang ES, Kim SN, Kye YC. Dermatol Surg 2004; 30: 378–81.

Twenty patients with VEN were treated with the erbium:YAG

laser. After a single treatment, successful elimination of the VEN was observed in 15 patients. Five patients (25%) showed a relapse within the first year after treatment.

Successful treatment of dark-colored epidermal nevus with ruby laser

Baba T, Narumi H, Hanada K, Hashimoto I. J Dermatol 1995; 22: 567–70.

Five darkly pigmented epidermal nevi were successfully cleared after one to four treatments with a ruby laser in the normal mode. Two patients subsequently had hypopigmentation at the treatment site.

A resurfacing procedure, either mechanically by dermabrasion or with laser technology using either the erbium:YAG or the CO₂ laser, can produce very acceptable results. However, both these techniques are operator dependent, and in the case of laser therapy, access to expensive equipment is necessary. Darkly pigmented nevi may be treated using pigmented lesion lasers such as the ruby laser.

Third-Line Therapies

• Systemic retinoids	D
• Topical retinoids plus 5-fluorouracil	E
• Photodynamic therapy	E

A case of verrucous epidermal naevus successfully treated with acitretin

Taskapan O, Dogan B, Baloglu H, Harmanyeri Y. Acta Derm Venereol 1998; 78: 475–6.

Report of a case of VEN in a 20-year-old patient who responded to acitretin 75 mg daily. The nevus started to recur 6 weeks after cessation of therapy.

Topical tretinoin and 5-fluorouracil in the treatment of linear

verrucous epidermal nevus

Kim JJ, Chang MW, Shwayder T. J Am Acad Dermatol 2000; 43: 129–32.

In a 7-year-old boy with an extensive facial epidermal nevus there was significant improvement using a combination of topical tretinoin 0.1% cream and 5-fluorouracil.

Verrucous epidermal nevus successfully treated with photodynamic therapy

Sim JH, Kang Y, Kim YC. Eur J Dermatol 2010; 20: 814–5.

A 9-year-old girl presented with asymptomatic linear papillomatous and hyperkeratotic papules on the right thigh that developed at birth. She had no history of previous therapy. Treatment with methyl-aminolevulinate–photodynamic therapy (MAL-PDT) was performed. After four treatment sessions, the lesion was almost completely resolved, with mild residual hyperpigmentation. After 3 months of follow-up, the authors reported that the cosmetic and clinical response was excellent and the patient was very satisfied. After 5 months of follow-up, no recurrence had been observed.

Systemic retinoids have been shown to reduce hyperkeratosis in very extensive and cosmetically troublesome lesions. However, long-term use is required if the benefit is to be maintained. The topical combination of tretinoin and 5-fluorouracil has also been reported to achieve a significant improvement. Photodynamic therapy has been recently reported in the treatment of VEN.

Inflammatory/dysplastic epidermal nevi

First-Line Therapy

• Topical corticosteroids

D

Successful treatment of inflammatory linear verrucous epidermal nevus with tacrolimus and fluocinonide

Mutasim DF. J Cutan Med Surg 2006; 10: 45–7.

Successful treatment of ILVEN with potent topical steroid and tacrolimus ointments.

Nevi that have inflammatory, epidermolytic, acantholytic, or dysplastic features may respond more effectively to medical therapy than to surgical treatment. ILVEN is a relatively rare entity that presents during childhood and can be difficult to treat. Topical corticosteroids are often used as first-line therapy, but the response is variable. There is little clinical data on the use of topical corticosteroids, and their use appears to be empirical rather than evidence based; nevertheless, they are relatively cheap and safe.

Second-Line Therapy

• Topical calcipotriol/tacalcitol	D
• Topical retinoids	E
• Systemic retinoids	E
• Topical dithranol	E

Topical calcipotriol for the treatment of inflammatory linear verrucous epidermal nevus

Zvulunov A, Grunwald MH, Halvy S. Arch Dermatol 1997; 133: 567–8.

A report on the use of calcipotriol in the treatment of an ILVEN.

Successful therapy of an ILVEN in a 7-year-old girl with calcipotriol

Bohm I, Bieber T, Bauer R. Hautarzt 1999; 50: 812–4.

A report on the successful use of calcipotriol 0.005% ointment in the treatment of an ILVEN. After 8 weeks of therapy the ILVEN had almost cleared. There was no relapse 25 weeks after treatment was discontinued.

Acitretin treatment of a systematized inflammatory linear verrucous epidermal naevus

Renner R, Rytter M, Sticherling M. Acta Derm Venereol 2005; 85: 348–50.

In this case treatment with oral acitretin was initiated at a dose of 25 mg daily but had to be reduced to 20 mg daily because of increasing erythema on the face and left leg after 3 days of therapy. The dose was slowly increased to 30 mg daily. After 2 weeks at this level, the erythema had almost entirely resolved, and the hyperkeratosis was distinctly reduced. After 8 weeks on this dose the inflammatory and hyperkeratotic lesions had almost disappeared.

Dithranol in the treatment of inflammatory linear verrucous epidermal nevus

De Mare S, van de Kerkhof PC, Happle R. Acta Derm Venereol 1989; 69: 77–80.

Treatment with dithranol resulted in complete relief from pruritus and clearing of all linear lesions, except for a small verrucous band on the shin.

Third-Line Therapies

• Pulsed-dye laser	E
• CO ₂ laser	E
• Surgical excision	D
• Etanercept	E
• Photodynamic therapy	E

Pulsed dye laser for inflammatory linear verrucous epidermal nevus

Sidwell RU, Syed S, Harper JJ. Br J Dermatol 2001; 144: 1267–9.

Three cases of ILVEN in children ranging in age from 2 to 8 years were treated successfully with the pulsed-dye laser. The authors surmise that the destruction of capillaries by the laser reduces the release of inflammatory mediators.

Carbon dioxide laser therapy for an inflammatory linear verrucous epidermal nevus: a case report

Ulkur E, Celikoz B, Yuksel F, Karagoz H. Aesthet Plast Surg 2004; 28: 428–30.

A case of ILVEN was treated with the CO₂ laser. All symptoms, including erythema, excoriation, granulation, and pruritus, disappeared, and a pale pigmentation remained.

Full-thickness surgical excision for the treatment of inflammatory linear verrucous epidermal nevus

Lee BJ, Mancini AJ, Renucci J, Paller AS, Bauer BS. Ann Plast Surg 2001; 47: 285–92.

The authors report four patients with extensive ILVEN treated successfully with full-thickness surgical excision.

Successful treatment of a widespread inflammatory verrucous epidermal nevus with etanercept

Bogle MA, Sobell JM, Dover JS. Arch Dermatol 2006; 142: 401–2.

A 55-year-old woman diagnosed with widespread inflammatory epidermal verrucous nevi was presented. She had a history of multiple therapies, including emollients, topical and intramuscular steroids, topical lactic acid, pimecrolimus cream, and isotretinoin.

The authors initiated subcutaneous etanercept therapy at a dose of 25 mg twice weekly. After 1 month, the patient experienced good initial improvement in pruritus and erythema. The etanercept was increased to 50 mg twice weekly, which provided nearly 50% improvement over 3 months. She continued treatment at this dose for a total of 6 months and achieved almost complete resolution of pruritus and a significant improvement in roughness and erythema. The dose was then reduced to 25 mg twice weekly, and disease activity remained quiescent at follow-up.

Inflammatory linear verrucous epidermal nevus successfully treated with methyl-aminolevulinate photodynamic therapy

Parera E, Gallardo F, Toll A, Gil I, Sánchez-Schmidt J, Pujol R.
Dermatol Surg 2010; 36: 253–6.

The authors report a 67-year-old man with ILVEN who had failed multiple modalities. Treatment with MAL-PDT was performed. Almost complete resolution of the lesions after three PDT sessions (once a week) was observed. Pruritus completely disappeared, although small prurigo-like papules remained at the periphery of the lesion. No recurrence was observed after a follow-up period of 15 months.

Epidermodysplasia verruciformis

Slawomir Majewski, and Stefania Jablonska

Epidermodysplasia verruciformis (EV) is a rare genetic disease characterized by an impaired immune response to human papillomavirus (HPV) and HPV-associated cutaneous oncogenesis. The disease is characterized by chronic infection with potentially oncogenic HPV types 5 and 8 as well as nononcogenic types. Flat warts and pityriasis versicolor-like lesions begin to appear in early childhood and become widespread. In the fourth and fifth decades 50% to 70% of patients begin to develop multiple cutaneous

malignancies, mainly squamous cell carcinomas. It has been established that EV is mostly associated with mutations of two genes located on chromosome 17: *EVER1/TCM6* and *EVER2/TCM8*, coding transmembrane proteins located in the endoplasmic reticulum and involved in zinc transportation. However, about 25% of EV cases are not associated with these gene mutations.

A new and important problem is the occurrence of the EV phenotype in immunosuppressed individuals, which has been called *acquired epidermodysplasia verruciformis*. This EV-like syndrome has been described in patients with HIV infection, organ transplantation, Hodgkin disease, common variable immunodeficiency, systemic lupus erythematosus, immunoglobulin M deficiency, adult T-cell leukemia, some cases of graft-versus-host reaction, and others. Two varieties of acquired EV are described: a generalized verrucosis associated with large common warts mainly of HPV-3 type (sometimes referred to as *benign EV*) and a variety associated with diverse HPVs of types not usually related to EV.

The high risk of malignant transformation in genetic EV seems to be reduced in the acquired variety.

Management Strategy

No compound acts directly on HPV, and no therapy produces a complete and sustained clearing of both benign wartlike and keratotic lesions associated with oncogenic EV HPVs. A most important aspect of the management of EV is protection from ultraviolet radiation, which is a cancer cofactor. Light-avoiding behavior and topical sunblock creams (sun protection factor >50) are indicated. Other cancer cofactors (radiotherapy, immunosuppressants) must be avoided. Premalignant and troublesome benign lesions can be treated by a variety of destructive techniques: surgical (cryotherapy, shave excision, curettage, laser, full excision) or chemical (trichloroacetic acid, 5% 5-fluorouracil).

For more widespread lesions, with signs of premalignancy or malignancy, agents that modify keratinization are indicated, such as oral or topical retinoids, vitamin D₃ analogs, interferons, and imiquimod. Photodynamic therapy (PDT) can be useful for early malignancy. Larger malignancies can necessitate skin autografts.

Specific Investigations

- Family history and examination of other family members
- Skin biopsy
- HPV typing to identify potentially oncogenic and nononcogenic HPV types
- Evaluation of immune status and the presence of factors producing or enhancing immunosuppression: HIV, congenital and acquired immunodeficiency syndromes, iatrogenic immunosuppression

Common variable immunodeficiency syndrome associated with epidermodysplasia verruciformis

Vu J, Wallace GR, Singh R, Diwan H, Prieto V, Rady P. *Am J Clin Dermatol* 2007; 8: 307–10.

Generalized verrucosis: a review of the associated diseases, evaluation, and treatments

Sri JC, Dubina MI, Kao GF, Rady PL, Tyring SK, Gaspari AA. *J Am Acad Dermatol* 2012; 66: 2292–311.

Generalized verrucosis and distinct diseases (including EV) associated with generalized warts are defined. The indications for histopathologic examination, HPV typing, and other laboratory tests, as well as potential treatment options, are discussed.

Acquired epidermodysplasia verruciformis: a comprehensive review and proposal for treatment

Zampetti A, Giurdanella F, Manco S, Linder D, Gnarr M, Guerriero G, et al. *Derm Surg* 2013; 39: 974–9.

The treatment of acquired EV is not standardized, and several approaches have been described in the literature. Better results have been reported with combination procedures (e.g., photodynamic therapy and retinoids).

Deleterious effect of radiation therapy on epidermodysplasia verruciformis patients

de Oliveira WR, da Cruz Silva LL, Neto CF, Tyring S. *J Cutan Med Surg* 2015; 19: 416–21. Radiotherapy might be associated with progression of squamous cell carcinomas in EV patients, and it is

recommended that this method of treatment be avoided in this patient population.

First-Line Therapies

• Sun avoidance/protection	E
• Cryotherapy with liquid nitrogen	E
• Topical retinoic acid 0.05% to 0.1% for benign, flat, cosmetically troublesome lesions	E
• Shave excision of flat lesions	E
• Surgical excision of malignant lesions	E

Second-Line Therapies

• Interferon- α with retinoids (acitretin)	E
• Systemic isotretinoin	E
• Imiquimod 5% cream	E
• Topical 15% glycolic acid lotion	C
• Topical ingenol mebutate 0.015% gel	E
• Topical squaric acid dibutylester 2% solution (SADBE)	E
• Oral zinc sulfate	E
• Highly active antiretroviral therapy (HAART) in HIV-positive patients	E

Treatment of epidermodysplasia verruciformis with a combination of acitretin and interferon alfa-2a

Anadolu R, Oskay T, Erdem C, Boyvat A, Terzi E. J Am Acad Dermatol 2001; 45: 296–9.

A patient treated with oral acitretin 50 mg daily and systemic interferon- α_{2a} 3 MU subcutaneously three times weekly for 6 months. Improvement was followed by relapse after discontinuation of treatment, and the same regimen was reintroduced. The interferon was then discontinued after 4 months and the acitretin reduced to 25 mg for 3 months, then stopped. Improvement was maintained during the subsequent 12-month follow-up. Used as monotherapy,

interferon- α has only a slight effect and is not recommended.

Systemic low-dose isotretinoin maintains remission status in epidermodysplasia verruciformis

Rallis E, Papatheodorou G, Bimpakis E, Buutanska D, Menounos P, Papadakis P. *J Eur Acad Dermatol Venereol* 2008; 22: 523–5.

In this case isotretinoin 0.8 mg/kg/day for 6 months produced complete clearance, with relapse 4 months after discontinuation of medication. Maintenance treatment with 20 mg/day resulted in sustained remission. EV in this case was associated with HPV-3—that is, a more benign variant responsive to therapy.

Treatment of a patient with epidermodysplasia verruciformis carrying novel EVER2 mutation with imiquimod

Berthelot C, Dickerson MC, Rady P, He Q, Niroomand F, Tyring SK, et al. *J Am Acad Dermatol* 2007; 56: 882–6.

Acquired epidermodysplasia verruciformis syndrome in HIV-infected pediatric patients: prospective treatment trial with topical glycolic acid and human papillomavirus genotype characterization

Moore RL, de Schaetzen V, Joseph M, Lee IA, Miller-Monthrope Y, Phelps BR, et al. *Arch Dermatol* 2012; 148: 128–30.

Topical 15% glycolic acid lotion had a good effect in HIV-infected children; the therapy was regarded as safe and efficacious.

Treatment of imiquimod resistant epidermodysplasia verruciformis with ingenol mebutate

Kim C, Hashemi P, Caglia M, Shulman K. *J Drugs Dermatol* 2016; 15: 350–2. A patient with EV failed to respond to a 6-week course of 5% imiquimod on the forehead and was subsequently successfully treated with a 3-day course of 0.015% ingenol mebutate gel.

Epidermodysplasia verruciformis: successful treatment with squaric acid dibutylester

Kehdy J, Erickson C, Rady P, Tyring S, Gaspari AA. *Cutis* 2015; 96: 114–8. A case of 25-year history of refractory EV that was successfully treated with topical SADBE contact sensitizer agent. SADBE is used over the years for the treatment of a variety skin diseases, including alopecia areata and refractory cutaneous warts.

Efficacy of oral zinc therapy in epidermodysplasia verruciformis with squamous cell carcinoma

Sharma S, Barman KD, Sarkar R, Manjhi M, Kumar Garg V. Ind Derm Online J 2014; 5: 55–8.

A 24-year-old patient with EV was treated with oral zinc sulfate (550 mg/kg/day) with a satisfactory result (clearance of wartlike lesions on the face and upper and lower extremities by 30%–40%). The squamous cell carcinoma of the right hand was removed surgically.

Epidermodysplasia verruciformis in human immunodeficiency virus-infected patients: a marker of human papillomavirus-related disorders not affected by antiretroviral therapy

Jacobelli S, Laude H, Carlotti A, Rozenberg F, Deleuze J, Morini JP, et al. Arch Dermatol 2011; 147: 590–6.

Although there is no evidence-based therapy for acquired EV in HIV-positive patients, symptomatic treatments for HPV-induced lesions combined with HAART therapy could be partially effective. In most cases this therapy failed, although there was some improvement due to diminished viral load and increased CD4 cell count.

Third-Line Therapies

• Photodynamic therapy	E
• CO ₂ laser for malignant and premalignant lesions	E
• Skin autografts	E

Photodynamic therapy for human papillomavirus-related diseases in dermatology

Szeimies RM. Med Laser Appl 2003; 18: 107–16.

Topical PDT using 20% 5-aminolevulinic acid was reported to yield excellent results in a case of EV associated with HPV-5, -8, -36, and other strains. Twelve months after PDT the lesions started to reappear but resolved after repeated treatments. The authors suggest annually repeated PDT is safe and will control EV lesions.

CO₂ laser treatment of warts in immunosuppressed patients

Lauchli S, Kempf W, Dragieva G, Burg G, Hafner J. *Dermatology* 2003; 206: 148–52.

Alternative therapies for recalcitrant HPV-induced cutaneous warts in EV may include CO₂ laser or neodymium laser. Laser therapy of recalcitrant warts proved to be efficacious in both immunosuppressed and immunocompetent individuals.

Skin autografts in epidermodysplasia verruciformis: human papillomavirus-associated cutaneous changes need over 20 years for malignant conversion

Majewski S, Jablonska S. *Cancer Res* 1997; 57: 4214–6.

For very widespread, constantly developing new lesions not responding to any therapy, the only effective method is removal of the most involved skin area (usually on the forehead) and its replacement with skin from nonexposed inner aspects of the arms.

Epidermolysis bullosa

Anna F. Falabella, Ysabel M. Bello, and Lawrence A. Schachner

Epidermolysis bullosa (EB) is a complex group of mechanobullous disorders characterized by painful blister formation as a result of minor trauma to the skin. With the exception of the acquisita type, EB is an inherited disorder. The classification system for hereditary EB was updated in June 2014 and includes four major types according to the level of blister formation: simplex or intraepidermal (“epidermolytic”), junctional or intralamina lucida (“lamina lucidolytic”), dystrophic or sublamina densa (“dermolytic”), and Kindler syndrome or mixed. The disease can involve the skin, mucosae, and internal organs. The severity of EB ranges from mild to

severe, and skin involvement can be localized or generalized.

In addition to the four major types of EB, there are several dozen subtypes, resulting from more than 1000 documented mutations on at least 18 structural genes. The genetic variability of EB results in a wide variety of clinical presentations, extracutaneous manifestations, degree of morbidity, and risk for early mortality.

Management Strategy

The management of inherited EB has classically been supportive: avoidance of trauma, blister management, wound management, treatment of infections, and nutritional support. More recent efforts have been directed at identifying and treating the underlying cause of disease with the goal of improving wound healing and preventing new wound formation.

Avoidance of trauma to intact skin is important but difficult. Sewing foam pads into the lining of clothing is helpful, especially over the elbows, knees, and other pressure points. Blister management involves *puncturing new blisters* with a sterile needle to avoid extension of the blister. The punctured area should be covered with a *topical antibiotic and a nonadherent dressing*.

Wound management comprises assessing the location and characteristics of the wound, *cleansing with low-toxicity solutions* (e.g., saline, water), *gentle debridement* of eschar/slough if present, and covering the wound with an appropriate nonadherent dressing. Wounds need to be evaluated and treated on a daily basis. In general, it is beneficial to soak wounds in a bathtub for 5 to 10 minutes. This facilitates cleansing and nontraumatic removal of dressings. Use of *low-concentration acetic acid or bleach* in the bath water may also help control bacterial load in wounds.

Minimizing trauma to wounds is vital. *Mepilex* is a nonadherent, absorbent polyurethane foam pad that can be applied, removed, and reapplied to wounds with little discomfort, no trauma to the wound bed or surrounding skin, and no disruption of wound healing. Other nonadherent dressings, such as *white petrolatum-impregnated gauzes, hydrogels, and foams*, can be used and held in place with soft, roller gauze bandages or elastic tube dressings.

A variety of *skin grafts* have been used to treat the wounds of EB, including split-thickness skin grafts, allogeneic and autogeneic cultured keratinocytes, and cryopreserved acellular human dermis. A

study using intradermal injections of allogeneic fibroblasts demonstrated therapeutic potential in patients with recessive dystrophic epidermolysis bullosa (RDEB). Several trials have reported impressive results with *Apligraf*, a bilayered, tissue-engineered skin derived from neonatal foreskin. An allogeneic composite cultured skin (*OrCel*) has been approved by the U.S. Food and Drug Administration to treat hands and donor sites in patients with RDEB. More recently, amniotic membranes have been used to treat patients with EB with chronic nonhealing wounds.

Avoidance of wound infection is also critical to promote more rapid healing and to avoid overwhelming infections and sepsis, which are associated with an increased mortality rate. *Topical antibiotics* are routinely used but should be rotated monthly to avoid the development of resistant organisms. Cutaneous infections unresponsive to topical measures need to be treated with *systemic antibiotics*, but the chronic use of systemic antibiotics is not recommended as a preventive measure.

Common nutritional problems in patients with EB include chewing and swallowing difficulties, malnutrition, constipation, and vitamin and mineral deficiencies. Avoidance of malnutrition depends on *active and continuous nutritional support*. Early nutritional supplementation can promote better childhood growth rates and promote healing of skin lesions. In patients who develop esophageal strictures, balloon dilation is sometimes needed. *Daily multivitamin trace elements and zinc supplementation* is recommended. Anemia may be profound in EB, and *oral iron replacement* is mandatory for patients with iron deficiency. *Erythropoietin* has been recommended if the iron level is <500 mU/mL. Some have recommended intravenous iron therapy for patients resistant to oral replacement. Albumin should be monitored to assess the patient's nutritional status. If necessary, *protein supplements* can be added to the diet. Severe malnutrition can be treated with enteral feeding via gastrostomy tube if necessary.

Systemic therapies, such as *psoralens in combination with UVA irradiation*, *corticosteroids*, *vitamin E*, *cyclosporine*, *antimalarials*, *retinoids*, *phenytoin*, *tetracycline*, *trimethoprim-sulfamethoxazole*, and *ciproheptadine*, have been used to treat EB, but their efficacy is unproven.

Current therapies are focused on gene-, protein-, and cell-based techniques. There have been improvements in genetic manipulation of keratinocytes ex vivo and of graft techniques in vivo. Gene transfer

of epidermal stem cells in combination with tissue engineering procedures is promising.

Specific Investigations

- Skin biopsy for transmission electron microscopy
- Skin biopsy for immunofluorescence antigenic mapping
- Mutational analysis

The classification of inherited epidermolysis bullosa (EB): report of the Third International Consensus Meeting on Diagnosis and Classification of EB

Fine J-D, Eady RAJ, Bauer EA, Bauer JW, Heagerty A, Bruckner-Tuderman L, et al. J Am Acad Dermatol 2008; 58: 931–50.

Both transmission electron microscopy (EM) and immunofluorescence have been successfully employed to diagnose EB. EM is likely to play a decreasing role in the diagnosis because there are only a few highly proficient EM laboratories, although it has an important place in research because it permits visualization and assessment of keratin filaments, hemidesmosomes, and anchoring fibrils. Immunofluorescence antigen mapping is relatively inexpensive and simple to perform, requiring immunofluorescence transport media. It can reveal the level of the split by defining its location relative to proteins expressed at various levels of the basement membrane zone. Mutational analysis remains a superb research tool that lets us determine the mode of inheritance, the precise site, and the type of molecular mutation. However, it is not considered the first-line diagnostic test.

First-Line Therapies

• Sterile dressing and topical antibiotics	B
• Nutritional support	C

Best practice guidelines for skin and wound care in

epidermolysis bullosa. International consensus

Denyer J, Pillay E. DEBRA, 2012.

www.woundsinternational.com/media/issues/623/files/content_10609.

Wound care is the cornerstone of treatment for patients with EB. This document was developed to help care for these patients. Skin and wound management must be tailored to suit both the type of EB and the specific characteristics of the wound. EB is a life-long disorder that requires specialist intervention and considerations to minimize complications and improve quality of life.

Management of epidermolysis bullosa in infants and children

Bello YM, Falabella AF, Schachner LA. Clin Dermatol 2003; 21: 278–82.

Open or only partially healed erosions are best covered with polymyxin, bacitracin, or silver sulfadiazine and then covered with either petrolatum-impregnated gauze or nonadherent synthetic dressing. Such dressings are usually changed daily. Mupirocin may be substituted for those infected sites unresponsive to milder antibiotics but is best avoided for routine use because of the potential for development of resistance.

The challenges of meeting nutritional requirements in children and adults with epidermolysis bullosa: proceedings of a multidisciplinary team study day

Hubbard L, Haynes L, Sklar M, Martinez AE, Mellerio JE. Clin Exp Dermatol 2011; 36: 579–83.

This is a report of a study day held in London on March 3, 2010, to discuss measures with which to meet the nutritional requirements of patients with EB. Members of national and international multidisciplinary teams (MDTs) caring for patients with EB attended this event. The study day focused on four challenging aspects of management intimately associated with nutritional status in EB necessitating close cooperation between MDT members: iron-deficiency anemia, gastrostomy placement and feeding, muscle mass and mobility, and dental health.

The study day provided a unique forum for dietitians, doctors, nurses, physiotherapists, psychologists, psychotherapists, dentists, dental hygienists, and occupational therapists to share knowledge and debate problems common to all who strive to promote best practice in this rare and complex group of conditions.

Second-Line Therapies

• Skin grafts	C
• Cultured keratinocytes	C
• Keratin gel	C
• Fibroblast cell therapy	D
• Amniotic cell membrane	D

Punch grafting of chronic ulcers in patients with laminin-332-deficient, non-Herlitz junctional epidermolysis bullosa

Yuen WY, Huizinga J, Jonkman MF. J Am Acad Dermatol 2012; 68: 93–7.

Four patients with laminin-332-deficient JEB-nH were treated with punch grafting. Over a 10-year period, 23 ulcers were treated using punch grafting without any complications or adverse effects. The ulcers had on average persisted 6 years before treatment. Healing rate after punch grafting was 70% ($n = 16$), with a mean healing time of 2 months. Thirty percent ($n = 7$) of the treated ulcers did not completely heal, but did show improvement. The recurrence rate after 3 months was 13% ($n = 2$) and was a result of renewed blistering. Punch grafting can be used as a first-line treatment in small persistent ulcers in patients with JEB-nH.

Tissue-engineered skin (Apligraf) in the healing of patients with epidermolysis bullosa wounds

Falabella AF, Valencia IC, Eaglstein WH, Schachner LA. Arch Dermatol 2000; 135: 1219–22.

An open-label uncontrolled study of 15 patients with 69 acute wounds and 9 chronic wounds who were treated with tissue-

engineered skin; a week later, 79% of the wounds were healed. The patients and their families considered that healing with the tissue-engineered skin was faster and less painful and that quality of life was improved, compared with healing with conventional dressings.

Apligraf in the treatment of severe mitten deformity associated with recessive dystrophic epidermolysis bullosa

Fivenson DP, Scherschum L, Cohen LV. *Plast Reconstruct Surg* 2003; 112: 584–8.

Five patients with RDEB were treated for mitten deformity with a bioengineered skin equivalent. These patients exhibited increased range of motion and have maintained web space separation for more than 12 months, improving the quality of their life.

Keratin gel in the management of epidermolysis bullosa

Denyer J, Marsh C, Kirsner RS. *J Wound Care* 2015; 24: 446–50.

In this pilot study, keratin gel (keratin-rich hydrogels extracted from sheep wool) was introduced into the management of different types of EB wounds, maintaining other aspects of their care. This treatment reported faster healing and was found to be effective in 6 of 10 patients and ineffective in 2 and caused itching leading to discontinuation in 2 other patients.

Amniotic membrane grafting in patients with epidermolysis bullosa with chronic wounds

Lo V, Lara-Corrales I, Stuparich A, Pope E. *J Am Acad Dermatol* 2010; 62: 1038–44.

A retrospective chart review of two patients with EB who were treated with amniotic membranes revealed the potential usefulness of amniotic membrane grafting in promoting healing of chronic wounds in patients with EB.

Third-Line Therapies

• Bone marrow transplantation	E
• Tetracycline	C
• Phenytoin (ineffective)	A
• Trimethoprim–sulfamethoxazole	D
• Cyproheptadine	C
• Isotretinoin	C
• Gene therapy	E
• Granulocyte colony-stimulating factor	C

Bone marrow transplantation for recessive dystrophic epidermolysis bullosa

Wagner JE, Ishida-Yamamoto A, McGrath JA, Hordinsky M, Keene DR, Woodley DT, et al. *N Engl J Med* 2010; 363: 629–39.

Seven children with RDEB were treated with immunomyeloablative chemotherapy and allogeneic stem-cell transplantation. One patient died of cardiomyopathy before transplantation. Of the remaining six patients, one had severe regimen-related cutaneous toxicity, with all having improved wound healing and a reduction in blister formation between 30 and 130 days after transplantation. Increased collagen type VII (C7) deposition was observed at the dermal–epidermal junction in five of the six recipients, albeit without normalization of anchoring fibrils. Five recipients were alive 130 to 799 days after transplantation; one died at 183 days as a consequence of graft rejection and infection. The six recipients had substantial proportions of donor cells in the skin, and none had detectable anti-C7 antibodies.

Allogeneic blood and bone marrow cells for the treatment of severe epidermolysis bullosa: repair of the extracellular matrix

Tolar J, Wagner JE. *Lancet* 2013 5; 382: 1214–23.

Several trials have demonstrated that protein replacement therapy

by allogeneic blood and marrow transplantation can attenuate the mucocutaneous manifestations of epidermolysis bullosa and improve patients' quality of life. Further studies are needed to explore these therapies.

Treatment of epidermolysis bullosa simplex with tetracycline

Veien NK, Buus SK. Arch Dermatol 2000; 136: 424–5.

A number of patients using tetracycline were observed over a 7-year period. The article reports an increase in bulla formation during the summer months, but healing was more rapid and less painful while patients took the tetracycline.

Tetracycline and epidermolysis bullosa simplex: a double-blind, placebo-controlled, crossover randomized clinical trial

Weiner M, Stein A, Cash S, de Leoz J, Fine JD. Br J Dermatol 2004; 150: 613–4.

Six of 12 patients completed at least the first arm: 4 experienced a reduction in the total number of EB lesions; 2 experienced an increased number of lesions after 4 months of active therapy (oral tetracycline administered 1000 mg every morning and 500 mg every evening). The risk of tetracycline-induced dental discoloration in children needs to be balanced against the severity and chronicity of the symptoms.

A systematic review of randomized controlled trials of treatment for inherited forms of epidermolysis bullosa

Langan SM, Williams HC. Clin Exp Dermatol 2009; 34: 20–5.

There are five randomized double-blind placebo-controlled trial crossover studies for inherited epidermolysis bullosa. Two studies reported the use of oral tetracycline, but the beneficial effect is unclear. Another two randomized controlled trials (RCTs) assessed the use of aluminum chloride hexahydrate solution 20% and bufexamac cream 5% in EB reporting no benefit over placebo. In an RCT of 36 patients, phenytoin failed to show any difference compared with placebo.

The efficacy of trimethoprim in wound healing of patients with epidermolysis bullosa: a feasibility trial

Lara-Corrales I, Parkin PC, Stephens D, Hamilton J, Koren G, Weinstein M, et al. J Am Acad Dermatol 2012; 66: 264–70.

Ten patients with RDEB were treated with trimethoprim (TMP). The study assessed lesion counts, quality of life, and emergence of antibiotic resistance. All patients showed improved wound healing on TMP, but primary and secondary outcome measures did not achieve statistical significance. This proof-of-concept study demonstrates the potential efficacy of TMP in improving wound healing in RDEB and provides useful information for further prospective studies.

Chemoprevention of squamous cell carcinoma in recessive dystrophic epidermolysis bullosa: results of a phase I trial of systemic isotretinoin

Fine JD, Johnson LB, Weiner M, Stein A, Suchindran C. J Am Acad Dermatol 2004; 50: 563–71.

Patients with RDEB are at high risk of developing squamous cell carcinoma (SCC). An initial study on 20 patients aged 15 years or older who were treated with isotretinoin 0.5 mg/kg/day for 8 months reported that isotretinoin may be safely used. However, a chemoprevention effect has yet to be proven.

Correction of junctional epidermolysis bullosa by transplantation of genetically modified epidermal stem cells

Mavillo F, Pellegrini G, Ferrari S, Di Nunzio F, Di Nunzio F, Di Iorio E, et al. Nature Med 2006; 12: 1397–402.

Ex vivo transduction of autologous epidermal stem cells with a normal copy of the defective gene, followed by reconstitution of the patient's skin with epithelial sheets that were grown from these genetically corrected cells, kept the epidermis firmly adherent and stable for the duration of follow-up (1 year).

Risk of squamous cell carcinoma in junctional epidermolysis bullosa, non-Herlitz type: report of 7 cases and a review of the literature

Yuen WY, Jonkman MF. J Am Acad Dermatol 2011; 65: 780–9.

SCC is the most severe complication and most common cause of death in patients with RDEB. The SCCs have a high recurrence rate and follow an aggressive course that results in death in one of five patients. It is recommended that annual checks of all JEB patients for SCC start at 25 years of age.

Systemic granulocyte colony-stimulating factor (G-CSF)

enhances wound healing in dystrophic epidermolysis bullosa (DEB): results of a pilot trial

Fine JD, Manes B, Frangoul H. J Am Acad Dermatol 2015; 73: 56–61.

Seven patients with DEB were treated daily with subcutaneous G-CSF daily (10 µg/kg/dose) for 6 days with reduction in lesional size and blister/erosion count. However, small patient number is a limitation of this pilot study but could be considered an option when conventional therapies fail; new prospective studies are needed.

Epidermolysis bullosa acquisita

Lawrence S. Chan

Epidermolysis bullosa acquisita is a relatively rare, chronic, autoimmune blistering disease affecting the skin and mucous membranes. The disorder predominantly affects elderly patients, and the skin lesions occur commonly at trauma-prone skin areas (in the

noninflammatory mechanobullous scarring subset) or widespread skin areas (in the generalized inflammatory nonscarring subset). Although IgG (or rarely IgA) class autoantibodies targeting the skin basement membrane component type VII collagen (anchoring fibrils) are major contributing factors, minor physical trauma also plays an important role in the blister development.

Management Strategy

Epidermolysis bullosa acquisita, particularly the noninflammatory mechanobullous subset, is characteristically very refractory to conventional medical therapies. For an immune-mediated blistering disease associated with autoantibodies that target skin components, the obviously logical approach is to suppress the immune responses, thereby reducing the production and effect of the autoantibodies to their target skin component type VII collagen. Unfortunately, currently there is no target-specific medication available. Thus the presently available non-target-specific immunosuppressive medications not only suppress the immune responses against type VII collagen but also reduce the patient's immune defense to pathogens, leading to a relative immunodeficiency. Therefore when treating patients with this disease, every effort should be made to use antiinflammatory instead of immunosuppressant agents, to use the lowest possible doses of immunosuppressant for the shortest time frame, and to replace immunosuppressants with antiinflammatory medications whenever feasible. A commonly used start-up regimen consists of *systemic corticosteroid combined with either mycophenolate mofetil or dapsone or both* as a corticosteroid-sparing agent. For adult patients without major medical problems, a combination of oral prednisone (1 mg/kg daily), mycophenolate mofetil (1–2 g daily), and dapsone (100–200 mg daily) can be initiated. Because of its rarity, well-controlled clinical trials have not been performed for epidermolysis bullosa acquisita. The following therapeutic guidelines are derived mainly from case reports of small groups or single patients.

Other medications have also been reported to be beneficial for this disease. *Colchicine* (1–2 mg daily) has shown significant improvement for the disease. *Ciclosporin* (5–9 mg/kg daily) has been reported to be beneficial in reducing blister formation and speeding up healing. *Intravenous immunoglobulin (IVIG)* treatment (400 mg/kg daily) has

also been determined to reduce new blister formation and facilitate healing. In addition, *extracorporeal photochemotherapy* has been used successfully in some patients. Most recently, a monoclonal antibody against B-cell-specific target CD20, *rituximab* (usual dose 375 mg/m² body surface area, multiple doses), has been reported to be effective in several cases. Due to its high cost the physician may encounter difficulty obtaining insurance company approval for the use of rituximab.

In addition, patients with this disease should be educated to *avoid physical trauma* as much as possible. Activities such as vigorous rubbing of their skin and the use of harsh soaps and hot water should also be eliminated. Patients should be informed to *care for open wounds promptly* and to recognize local skin infection and *seek medical attention when infection occurs*.

Specific Investigations

- Skin biopsy and serum for direct and indirect immunofluorescence, respectively, to detect in vivo bound and circulating IgG (or IgA, IgM) class skin basement membrane-specific autoantibodies
- Serum for enzyme-linked immunosorbent assay (ELISA) to detect IgG (or IgA, IgM) class type VII collagen-specific autoantibodies
- Gastrointestinal workup for possible inflammatory bowel disease

Epidermolysis bullosa acquisita: ultrastructural and immunologic studies

Yaoita H, Briggaman RA, Lawley TJ, Provost TT, Katz SI. J Invest Dermatol 1981; 76: 288–92.

Identification of the skin basement-membrane autoantigen in epidermolysis bullosa acquisita

Woodley DT, Briggaman RA, O’Keefe EJ, Inman AO, Queen LL, Gammon WR. N Engl J Med 1984; 310: 1007–13.

Direct immunofluorescence detects IgG deposits linearly at the dermoepidermal junction in all patients. Indirect immunofluorescence detects IgG circulating autoantibodies bound to the dermal side of salt-separated normal skin substrate in about 50% of patients with this disease.

Development of an ELISA for rapid detection of antitype VII collagen autoantibodies in epidermolysis bullosa acquisita

Chen M, Chan LS, Cai X, O'Toole EA, Sample JC, Woodley DT. *J Invest Dermatol* 1997; 108: 68–72.

ELISA using eukaryotically expressed recombinant protein of the noncollagenous (NC1) domain of type VII collagen is the most sensitive and specific method for detecting IgG class circulating autoantibodies in patients with this disease.

The use of biochip immunofluorescence microscopy for the serological diagnosis of epidermolysis bullosa acquisita

Marzano AV, Cozzani E, Biasin M, Russo I, Alaibac M. *Arch Dermatol Res* 2016; 308: 273–6.

A new biochip technology has been reported to be useful in the initial screening circulating autoantibodies to type VII collagen.

IgA-mediated epidermolysis bullosa acquisita: two cases and review of the literature

Vodegel RM, de Jong MC, Pas HH, Jonkman MF. *J Am Acad Dermatol* 2002; 47: 919–25.

In rare cases, IgA class rather than IgG class autoantibodies were found to target the type VII collagen, resulting in a clinical phenotype indistinguishable from the classic IgG-mediated disease. However, IgA-mediated disease has a lesser tendency to form scar and is more responsive to dapsone treatment.

IgM-type epidermolysis bullosa acquisita

Omland SH, Gniadecki R. *Br J Dermatol* 2015; 173: 1566–8.

This is a very rare case where the targeting autoantibodies appear to be the IgM class.

Epidermolysis bullosa acquisita and inflammatory bowel disease

Raab B, Fretzin DF, Bronson DM, Scott MJ, Roenigk Jr HH, Medenica M. *JAMA* 1983; 250: 1746–8.

Inflammatory bowel disease, particularly Crohn disease, is strongly associated with epidermolysis bullosa acquisita. All patients should be questioned for symptoms of inflammatory bowel disease. If symptoms are present, a comprehensive gastrointestinal workup is indicated.

The epidermolysis bullosa acquisita antigen (type VII collagen) is present in human colon and patients with Crohn's disease have autoantibodies to type VII collagen

Chen M, O'Toole EA, Sanghavi J, Mahmud N, Kelleher D, Weir D, et al. *J Invest Dermatol* 2002; 118: 1059–64.

The presence of type VII collagen in the gut and autoantibodies to type VII collagen in patients with inflammatory bowel disease without skin manifestations supports a link between the gut and the skin.

Black patients of African descent and HLA-DRB1*15:03 frequency overrepresented in epidermolysis bullosa acquisita

Zumelzu C, Le Roux-Villet C, Loiseau P, Busson M, Heller M, Aucouturier F, et al. *J Invest Dermatol* 2011; 131: 2386–93.

This study reported that a higher percentage of patients affected by epidermolysis bullosa acquisita are black patients of African descent and that the human leukocyte antigen HLA-DRB1*15:03 allele seems to contribute to this disease development.

Congenital epidermolysis bullosa acquisita: vertical transfer of maternal autoantibody from mother to infant

Abrams ML, Smidt A, Benjamin L, Chen M, Woodley D, Mancini AJ. *Arch Dermatol* 2011; 147: 337–41.

Although epidermolysis bullosa acquisita rarely occurs in children, it has never been reported in an infant until now. This case, which occurred in an infant, should raise the awareness of maternally transferred epidermolysis bullosa acquisita by physicians when they encounter blistering disease in a neonate.

Physicians need to recognize the possibility of maternal transfer of autoantibodies and the transient nature of the blisters (with no need for systemic treatment). This case of passive transfer of disease further demonstrates the pathogenic role of the autoantibodies, as was illustrated in an animal model of epidermolysis bullosa acquisita.

First-Line Therapies

• Systemic corticosteroids	D
• Mycophenolate mofetil	E
• Dapsone	D

Epidermolysis bullosa acquisita – a pemphigoid-like disease

Gammon WR, Briggaman RA, Woodley DT, Heald PW, Wheeler Jr CE. J Am Acad Dermatol 1984; 11: 820–32.

Five patients with the generalized inflammatory subset of disease responded at least partially to prednisone (40–120 mg daily), with or without the addition of azathioprine 100 mg daily.

Childhood IgA-mediated epidermolysis bullosa acquisita responding to mycophenolate mofetil as a corticosteroid-sparing agent

Tran MM, Anhalt GJ, Barrett T, Cohen BA. J Am Acad Dermatol 2006; 54: 734–6.

Mycophenolate mofetil (700 mg/day) was added to the regimen of prednisolone (25 mg/day) and dapsone (25 mg/day) when the disease flared upon reduction of prednisolone dose in this 2-year-old patient affected by an IgA-mediated epidermolysis bullosa acquisita. With the addition of mycophenolate mofetil, the systemic corticosteroid was totally tapered off over a 9-month period. This case illustrates the usefulness of mycophenolate mofetil in childhood-onset disease.

Mycophenolate mofetil in epidermolysis bullosa acquisita

Kowalzick L, Suckow S, Zuiegler H, Waldmann T, Pönnighaus JM, Gläser V. Dermatology 2003; 207: 332–4.

Mycophenolate mofetil (1 g twice daily) was used successfully in conjunction with plasmapheresis as a corticosteroid-sparing agent in one patient with epidermolysis bullosa acquisita not controlled by azathioprine (150 mg daily) and prednisolone (60 mg daily). The clinical improvement was associated with a reduction in autoantibody titers.

Bullous pemphigoid and epidermolysis bullosa acquisita: presentation, prognosis, and immunotherapy in 11 children

Edwards S, Wakelin SH, Wojnarowska F, Marsden RA, Kirtschig G, Bhogal B, et al. *Pediatr Dermatol* 1998; 15: 184–90.

A survey of five childhood-onset cases showed good clinical responses to combined corticosteroids and dapsone, as well as a good long-term prognosis.

Epidermolysis bullosa acquisita responsive to dapsone therapy

Hughes AP, Callen JP. *J Cutan Med Surg* 2001; 5: 397–9.

One patient who failed to respond to prednisone (40 mg daily) plus tetracycline and niacinamide achieved complete control of blistering activities after 2 months on dapsone 150 mg daily.

Second-Line Therapies

• Intravenous immunoglobulin	D
• Colchicine	D
• Ciclosporin	D

Severe, refractory epidermolysis bullosa acquisita complicated by an oesophageal stricture responding to intravenous immune globulin

Harman KE, Whittam LR, Wakelin SH, Black MM. *Br J Dermatol* 1998; 139: 1126–7.

The patient had the noninflammatory mechanobullous subset of disease and esophageal stricture and was refractory to prednisone (up to 80 mg daily), dapsone (100 mg daily), cyclophosphamide (150 mg daily), and azathioprine (3 mg/kg daily). The patient was treated with courses of IVIG (0.4 g/kg daily) on 5 consecutive days at 4- to 6-week intervals as a monotherapy, resulting in a dramatic fall in the circulating titers of anti-basement membrane IgG autoantibodies, reduction of new blister formation, and disappearance of dysphagia.

However, not all patients reported in the literature responded to this treatment. The major disadvantage of this regimen is the high cost.

Treatment of epidermolysis bullosa acquisita with intravenous immunoglobulin in patients non-responsive to conventional therapy: clinical outcome and post-treatment long-term follow-up

Ahmed AR, Gürcan HM. J Eur Acad Dermatol Venereol 2012; 26: 1074–83.

In this report the authors examined 10 epidermolysis bullosa acquisita patients (mean age 57.4 years), who received 16 to 31 cycles (2 g/kg/cycle) of IVIG (mean 23.1 cycles) for 30 to 52 months (mean 38.8 months), with all other medications tapered off in 5 to 9 months (mean 7.2 months) and IVIG as monotherapy thereafter. All treated patients had satisfactory improvement. At the time of follow-up occurring 29 to 123 months post treatment (mean 53.9 months) they revealed no disease recurrence. No serious side effects were noted.

Colchicine for epidermolysis bullosa acquisita

Cunningham BB, Kirchmann TT, Woodley DT. J Am Acad Dermatol 1996; 34: 781–4.

Four patients with the noninflammatory mechanobullous subset of disease, some refractory to prednisone treatment, were treated with oral colchicine (1–2 mg daily), with or without the addition of cyclophosphamide (50 mg daily). In all patients there was substantial clinical improvement in the reduction of skin fragility and spontaneous blister formation. An initial dose of 0.4 to 0.6 mg daily is recommended, with an increase by 0.6 mg daily each week until diarrhea develops. The patients are instructed to take the highest tolerable doses. Other than diarrhea, the long-term administration of colchicine (up to 4 years) was well tolerated. The side effect of diarrhea, however, makes it questionably suitable for those patients who have associated inflammatory bowel disease.

Oral cyclosporine in the treatment of inflammatory and noninflammatory cases. A clinical and immunopathologic analysis

Gupta AK, Ellis CN, Nickoloff BJ, Goldfarb MT, Ho VC, Rocher LL, et al. Arch Dermatol 1990; 126: 339–50.

Two patients with epidermolysis bullosa acquisita (subset not defined) were treated with oral ciclosporin (6 mg/kg daily) for a total

of 8 weeks. These patients experienced a gradual reduction in the frequency of new blister and erosion formation. The known renal toxicity of ciclosporin makes it questionable as a suitable long-term regimen and warranted only as a last-resort measure.

Third-Line Therapies

• Rituximab	D
• Minocycline	E

Successful adjuvant treatment of recalcitrant epidermolysis bullosa acquisita with anti-CD20 antibody rituximab

Schmidt E, Benoit S, Brocker E-B, Zillikens D, Goebeler M. Arch Dermatol 2006; 142: 147–50.

The patient, who had both skin and oral mucosal involvement, was not controlled with prednisolone (up to 250 mg/day), dapsone (150 mg/day), and subsequently azathioprine (up to 175 mg/day) and colchicine (2.5 mg/day). The regimen was changed to rituximab weekly infusion (375 mg/m² body surface area) for 4 consecutive weeks, with continuous use of azathioprine (175 mg/day) and colchicine (2.5 mg/day) and reducing doses of prednisolone. The patient's lesions completely healed in 11 weeks post-rituximab infusion, allowing the tapering of systemic steroid, colchicine, and azathioprine. Fourteen weeks after the discontinuation of colchicine and prednisolone, the patient remained in clinical remission. No complication was reported except an event of deep vein thrombosis.

A successful therapeutic trial of rituximab in the treatment of a patient with recalcitrant, high-titer epidermolysis bullosa acquisita

Crichlow SM, Mortimer NJ, Harman KE. Br J Dermatol 2006; 156: 194–

6.

A patient with both oral mucosal and skin lesions and a high titer of IgG autoantibodies to skin basement membrane zone (indirect immunofluorescence titer up to 1:3200) was treated with conventional therapeutic agents (prednisolone up to 60 mg/day, mycophenolate mofetil 2 g/day, and subsequently IVIG infusions (2 g/kg body weight/month)) without much success. Moreover, the patient could not tolerate azathioprine (due to liver toxicity) or ciclosporin (due to nephrotoxicity and hypertension). In the meantime, the patient's conditions were worsening, with increasing autoantibody titer and involvement of the esophagus. Therefore weekly rituximab infusions (375 mg/m² body surface area) were then given to the patient along with mycophenolate mofetil (2 g/day) and prednisolone (30 mg/day). The patient had slow but progressive improvement of the lesions, and all were healed 5 months after starting rituximab. One year after the rituximab treatment the patient was still in partial remission, suffering only occasional trauma-induced blisters, and the autoantibody titer fell to 1:10.

Epidermolysis bullosa acquisita following bullous pemphigoid, successfully treated with anti-CD20 monoclonal antibody rituximab

Wallet-Faber N, Franck N, Matteux F, Mateus C, Gilbert D, Carlotti A, et al. *Dermatology* 2007; 215: 252–5.

An interesting patient who initially developed bullous pemphigoid but who upon subsequent flare manifested a generalized skin and mucosal (oral and genital) blistering disease that was confirmed as epidermolysis bullosa acquisita by target antigen identification. The initial success of treatment (combined prednisone 1.5 mg/kg/day and azathioprine 100 mg/day) did not last long, as the reduction of prednisone resulted in rapid worsening of the condition, further complicated by a life-threatening *Legionella pneumophila* infection. Furthermore, the patient could not tolerate mycophenolate mofetil. Therefore rituximab (375 mg/m² body surface area) was initiated on a weekly interval for 4 consecutive weeks, resulting in dramatic improvement of the patient's condition. At 10 months' follow-up post rituximab initiation the patient had only a few visible blisters.

Treatment-resistant classical epidermolysis bullosa acquisita responding to rituximab

Sadler E, Schafleitner B, Lanschuetzer C, Laimer M, Pohla-Gubo G, Hametner R, et al. *Br J Dermatol* 2007; 157: 417–9.

A patient with both skin and multiple mucosal (oral, esophageal, and laryngeal) lesions who failed to respond to multiple conventional immunosuppressive medications subsequently responded to rituximab. Over a 6-year period the patient failed to show complete clinical response to methylprednisolone (up to 5 mg/kg/day), azathioprine (up to 2.5 mg/kg body weight), ciclosporin (up to 9 mg/kg/day), mycophenolate mofetil (up to 30 mg/kg/day), cyclophosphamide (500 mg/m² body surface area IV, followed by 1 mg/kg/day orally), colchicine (up to 1.5 mg/day), IVIG (up to 2.5 g/kg body weight/cycle), gold (1 mg/kg/week IV, followed by IM and oral preparations), and daclizumab (1 mg/kg body weight, six infusions over 3 weeks). Therefore a regimen of a reduced dose of rituximab (144 mg/m² infusion per week for 5 weeks) along with azathioprine (2 mg/kg/day) was given; the patient tolerated the treatment without any side effects or infections. A remarkable improvement was noticed 4 weeks after the initiation of rituximab treatment, and all medications were subsequently discontinued. Two years after all medications were tapered, the patient's disease activity remained at a very low level.

Clinical response of severe mechanobullous epidermolysis bullosa acquisita to combined treatment with immunoadsorption and rituximab (anti-CD20 monoclonal antibodies)

Niedermeier A, Eming R, Pfütze M, Neumann CR, Happel C, Reich K, et al. *Arch Dermatol* 2007; 143: 192–8.

Two patients affected by the mechanobullous type of epidermolysis bullosa acquisita were treated with combined immunoadsorption (daily treatment for 8 consecutive days) and rituximab (375 mg/m² body surface area/week for a total of 4 weeks). Mycophenolate mofetil (1–3 g/day) was given continuously during this period. In both patients treatment with multiple medications, including ciclosporin, azathioprine, dapsone, dexamethasone pulse, and cyclophosphamide pulse, was unsuccessful. One patient achieved near-complete clinical resolution, but the other could only obtain stable disease status. This report illustrates the treatment-resistant nature of this disease.

Inflammatory epidermolysis bullosa acquisita effectively treated with minocycline

Kawase K, Oshitani Y, Mizutani Y, Shu E, Fujine E, Selshima M. *Acta Derm Venereol* 2014; 94: 615–6.

In this report, a patient with generalized inflammatory subtype of the disease was effectively controlled with an antibiotic that has antiinflammatory function.

Erosive pustular dermatosis

Bhavnit K. Bhatia, and Jenny E. Murase

Erosive pustular dermatosis (EPD) is a rare condition characterized by pustular, erosive, and crusted lesions in areas of alopecia that tend to be atrophic, actinically damaged, or subject to local iatrogenic or external trauma. The condition primarily affects the elderly and is located on the scalp but has also been rarely documented to occur on the legs. EPD lesions tend to be chronic, progressive, and difficult to treat. Laboratory and histopathologic findings are not diagnostic.

Management Strategy

Traditionally, *potent topical corticosteroids* have been used in EPD with a generally positive but variable response within a few months of use. Due to steroid-related cutaneous atrophy and residual scarring, *tacrolimus 0.1% ointment*, *calcipotriol cream*, *oral zinc*, and *photodynamic therapy* (PDT) have been introduced as alternative therapies. A series has shown *dapsone 5% gel* to be effective in resolving EPD, and *oral dapsone* was shown to be successful in one case report. *Retinoids* and *oral corticosteroids* have also shown some promise when used in conjunction with topical antibiotics, topical corticosteroids, topical tacrolimus, oral dapsone, and oral zinc therapy. Topical and systemic antibiotics and antifungals are essentially ineffective.

First-Line Therapy

• High-potency topical corticosteroids	D
--	----------

Chronic atrophic erosive dermatosis of the scalp and extremities: a recharacterization of erosive pustular dermatosis

Patton D, Lynch PJ, Fung MA, Fazel N. J Am Acad Dermatol 2007; 57: 421–7.

Topical steroids, predominantly in the form of clobetasol, successfully treated 10 of 11 patients, with the last patient responding to topical tacrolimus. Nine of the 11 had scalp EPD, and all but 1 patient were elderly.

Erosive pustular dermatosis of the scalp

Pye RJ, Peachey RD, Burton JL. Br J Dermatol 1979; 100: 559–66.

Six case reports are presented in the first description of erosive pustular dermatosis of the scalp (EPDS) in the literature. Five of the six cases were resolved after use of potent topical steroids, specifically 0.025% triamcinolone with 0.75% halquinol, 0.01% betamethasone valerate with neomycin, and 0.05% clobetasol propionate, often used with neomycin or nystatin.

Three series and 23 case reports exist for high-potency topical

corticosteroids in the literature.

Second-Line Therapies

• Photodynamic therapy	D
• Topical 5% dapsone gel	E
• Topical 0.1% tacrolimus ointment	E

Aminolevulinic acid photodynamic therapy in the treatment of erosive pustular dermatosis of the scalp: a case series

Yang CS, Kuhn H, Cohen LM, Kroumpouzou G. JAMA Dermatol 2016; 152: 694–7.

Eight patients with EPDS underwent curettage followed by aminolevulinic acid photodynamic therapy 1 to 2 weeks later, with complete resolution of lesions in six patients. The remaining two patients had complete resolution after a second cycle of curettage and PDT.

One case series and two case reports for PDT exist in the literature. Although this case series shows good results after PDT, the literature also notes that PDT is a risk factor for developing EPD.

Erosive pustular dermatosis of the scalp: a review with a focus on dapsone therapy

Broussard KC, Berger TG, Rosenblum M, Murase JE. J Am Acad Dermatol 2012; 66: 680–6.

In the first of four cases, a patient had previously failed clobetasol foam, fluocinonide solution, topical salicylic acid, and ultraviolet (UV) phototherapy. Seventeen weeks of up to 200 mg topical dapsone therapy achieved resolution. In the second patient, 3 months of fluocinolone solution yielded no results, but switching to dapsone 5% gel for 3 months achieved full resolution. In the third patient, topical dapsone applied twice daily resolved crusting within 3 months. The last patient had failed courses of oral prednisone, cephalexin, minocycline, doxycycline, silver sulfadiazine cream, topical

tacrolimus, topical betamethasone dipropionate, intralesional triamcinolone, and wound care with silver-impregnated dressings. A side-by-side trial of clobetasol ointment and topical 5% dapsona gel determined dapsona to be more efficacious, resolving all lesions in just over 4 weeks.

Erosive pustular dermatosis of the scalp: treatment with topical tacrolimus

Laffitte E, Kaya G, Piguet V, Saurat JH. Arch Dermatol 2003; 139: 712–4.

In two patients, topical 0.1% tacrolimus ointment resulted in marked improvement within 2 weeks, with complete resolution and recovery of skin atrophy within 6 to 8 months. In the second patient, 0.05% retinaldehyde cream was added but was stopped after 1 week of use due to lesion relapse.

Thirteen case reports exist for topical tacrolimus ointment in the literature, two in conjunction with oral steroids and two as maintenance therapy after successful short-term treatment with topical steroids.

Erosive pustular dermatosis of the scalp after photodynamic therapy

López V, López I, Ramos V, Ricart JM. Dermatol Online J 2012; 18: 13.

A patient was treated with mometasone furoate cream twice daily for 1 week, followed by tacrolimus ointment twice daily for 1 month, with scarring alopecia, but no signs of recurrence at 4-month follow-up.

Third-Line Therapies

• Oral dapsone	E
• Oral steroids	E
• Oral zinc	E
• Retinoids	E
• Topical calcipotriol cream	E

Disseminated erosive pustular dermatosis also involving the mucosa: successful treatment with oral dapsone

Feramisco JD, George T, Schulz SE, Ma HL, Metze D, Steinhoff M. *Acta Derm Venereol* 2012; 92: 91–2.

A patient presented after failing antifungal creams, antiseptic solutions, and oral antibiotics and experiencing only mild improvement with a combination of antiseptic solution, potent glucocorticoids, oral zinc replacement, and oral fluconazole. She was started on oral dapsone 50 mg twice a day for 1 week, then 50 mg three times a day, along with vitamin C 1000 mg daily. Significant improvement was observed in a few days and complete pustule resolution in 6 weeks.

Erosive pustular dermatosis of the scalp successfully treated with oral prednisone and topical tacrolimus

Zahdi MR, Seidel GB, Soares VC, Freitas CF, Mulinari-Brenner FA. *An Bras Dermatol* 2013; 88: 796–8.

The patient initially experienced significant improvement with prednisone 40 mg daily; however, the patient had increased purulent discharge when tapered. When prednisone was restarted with 0.1% topical tacrolimus, lesions healed completely after 10 weeks, and prednisone was successfully tapered.

Erosive pustular dermatosis of the scalp: an uncommon condition typical of elderly patients

Vaccaro M, Guarneri C, Barbuzza O, Guarneri B. J Am Geriatr Soc 2008; 56: 761–2.

An EPDS patient was treated with 16 mg/day (with progressive tapering) oral methylprednisolone, 200 mg/day oral zinc sulfate, and 0.05% clobetasol propionate foam, achieving complete resolution after 2 months.

Nine cases for oral steroids have been reported, three in combination with zinc and topical steroids and two in combination with topical tacrolimus.

Erosive pustular dermatosis of the scalp successfully treated with oral zinc sulfate

Ikeda M, Arata J, Isaka H. Br J Dermatol 1982; 106: 742–3.

A patient's pustules disappeared after 90 mg zinc sulfate daily for 5 days. The dose was increased to 180 mg daily thereafter, and the patient remained pustule free.

Six cases for oral zinc exist, five in combination with topical steroids, and two in combination with both oral and topical steroids.

Erosive pustular dermatosis of the scalp responding to acitretin

Darwich E, Muñoz-Santos C, Mascaró JM Jr. Arch Dermatol 2011; 147: 252–3.

After failing minocycline, betamethasone 17-valerate, and fusidic acid cream, a patient was started on acitretin 50 mg daily and topical 0.1% tacrolimus ointment. Tacrolimus was discontinued after 10 days due to burning. The lesions were completely healed after 3 months.

Four cases for retinoids are in the literature, one with worsening of erosions and three with good results when combined with combinations of the following: zinc, topical steroids, tacrolimus, antibiotics, topical antiseptics, oral dapsone.

Erosive pustular dermatosis of the scalp successfully treated with calcipotriol cream

Boffa MJ. Br J Dermatol 2003; 148: 593–5.

In a patient with significant skin atrophy, topical steroids were avoided and EPDS was treated with calcipotriol, first once daily and then twice daily. Calcipotriol was discontinued 2 months later after complete resolution, and some hair regrowth was seen at visits 3 and 9 months post treatment.

Erythema annulare centrifugum

Christie G. Regula, and Bryan E. Anderson

Erythema annulare centrifugum (EAC) is a gyrate erythema characterized by minimally pruritic, polycyclic, erythematous patches or plaques that may expand up to 2 to 3 mm/day and clear centrally. There are two forms: the far more common superficial form has

trailing scale at the inner borders of the erythema, whereas the deep form has erythematous induration with minimal to no scale. EAC has a mean duration of 2.8 years, and treatment is often difficult. EAC has been seen to persist for decades.

Management Strategy

EAC represents a hypersensitivity reaction to a myriad of conditions; therefore a search for and treatment of an underlying disease is the primary management strategy. Most often an underlying cause is not found.

A concurrent skin infection is the most common underlying association. Fungal, bacterial, viral, mycobacterial, and parasitic pathogens have been reported. Typically, the infection is cutaneous and is at a distant location from the EAC eruption. Dermatophytosis is implicated in up to 48%. Thus the skin, especially the feet, groin, and nails, should be carefully examined for tinea. Anecdotal reports of other associated skin infections include molluscum contagiosum, herpesvirus infection, and *Phthirus pubis* infestation. Less commonly the infection is internal and intestinal *Giardia* or *Candida*. Latent Epstein–Barr virus infection, human immunodeficiency virus (HIV) infection, chronic viral hepatitis, appendicitis, tonsillitis, secondary syphilis, urinary tract *Escherichia coli*, and nematode infestations have been anecdotally reported. Although EAC is typically associated with an active infection, it has also been reported to occur after reactivation of herpes zoster virus in corresponding dermatomes.

Rarely, EAC may be associated with either benign or malignant hematologic and solid neoplasms. This paraneoplastic erythema annulare centrifugum eruption (PEACE) is thought to result from hypersensitivity to tumor proteins released by these neoplasms. However, in the absence of strong clinical suspicion, an extensive search for malignancy is not recommended. Should neoplasia be identified, EAC activity correlates with tumor response to treatment.

Medications may be associated with EAC—anecdotal reports include acetazolamide, amitriptyline, ampicillin, chloroquine, cimetidine, cyclopenthiazide, cotrimoxazole, etizolam, finasteride, gold, hydrochlorothiazide, hydroxychloroquine, ibuprofen, iron, neutraddon (aluminum silicate and belladonna), oxprenolol, pegylated interferon- α -2a plus ribavirin, piroxicam, rituximab, salicylates, spironolactone, thiacetazone, and ustekinumab. Early

reports of antimalarials as a cause of EAC may be debated: what was considered EAC in these reports may actually have been unrecognized forms of subacute cutaneous lupus erythematosus. EAC may also be caused by hypersensitivity to other ingested agents, such as blue cheese *Penicillium*.

Other conditions associated with EAC include thyroid disease, liver disease, hypereosinophilic syndrome, sarcoidosis, surgical trauma, linear IgA dermatosis, and autoimmune disease such as relapsing polychondritis, rheumatoid arthritis, pemphigus vulgaris, hemolytic anemia, polyglandular autoimmune disease, autoimmune hepatitis, and pregnancy. One form of EAC, described as *autoimmune progesterone dermatitis* (see [Chapter 20](#)), can be reproduced by intradermal and patch testing to progesterone and may involve Th1-type cytokines. Another form of EAC may occur annually and seasonally over 2 to 40 years and may be associated with hereditary lactate dehydrogenase deficiency. EAC may even be familial: there has been one report involving identical twins. Rarely, EAC may be a form of contact dermatitis: there is a single report of contact-induced EAC attributed to a hypersensitivity reaction from topical nickel and cobalt exposure.

Once the underlying condition is treated, EAC usually resolves spontaneously. Frequently, however, the cause is elusive, and treatment becomes empiric and temporizing. Spontaneous remission is also possible, making assessments of therapy difficult. *Topical steroids* may provide symptomatic relief and may improve its appearance. In one report of EAC with unknown etiology, all lesions cleared with *topical calcipotriol* treatment. *Topical tacrolimus* can be helpful as well. In another case, EAC remitted after the patient was treated with *oral metronidazole* given for rosacea. A trial of empiric antimicrobials may be helpful to eradicate an underlying, clinically undetected infection—a case series has shown significant improvement with *oral erythromycin* treatment. If these more conservative treatments fail, the patient's perceived need for treatment should be reassessed. Stronger treatments may be more harmful than the condition itself. Systemic glucocorticoids can usually suppress EAC, but it commonly recurs after the course is completed, and they cannot be routinely recommended. If EAC is very disabling to the patient, other *systemic immunomodulators* may need to be considered. One patient responded very well to *etanercept* therapy.

EAC should be distinguished from the following clinical

mimickers: tinea corporis, granuloma annulare, sarcoidosis, mycosis fungoides, psoriasis, pityriasis rosea, tinea versicolor, cutaneous lupus, annular erythema of Sjögren syndrome, granuloma faciale, necrolytic migratory erythema, bullous pemphigoid, secondary syphilis, Hansen disease, annular urticarial and fixed drug reactions, hypereosinophilic dermatitis, annular erythema of infancy, and other reactive erythemas such as erythema multiforme, erythema gyratum repens, erythema migrans, and erythema marginatum. Such clinical possibilities are ruled out by routine histologic examination.

Specific Investigations

- Biopsy for histologic examination
 - Superficial type: focal spongiosis, superficial perivascular lymphocytic infiltrate
 - Deep type: superficial and deep perivascular lymphohistiocytic infiltrate
- Full skin examination for potential skin infections
- Potassium hydroxide (KOH) test or culture of suspected EAC lesion and any sites of potential dermatophyte infection
- Wood light examination
- Consider intradermal trichophyton or candidal skin injection and tuberculin test to test for underlying infection
- Review medication list
- Systemic workup: complete blood count (CBC), liver function tests (LFTs), urinalysis (UA), chest x-ray (CXR) initial screen; if warranted, antinuclear antibodies (ANAs), thyroid-stimulating hormone (TSH), HIV, syphilis serology, malignancy workup including serum protein electrophoresis/urine protein electrophoresis (SPEP/UPEP) with immunofixation

Shelley WB. *Arch Dermatol* 1964; 90: 54–8.

Erythema annulare centrifugum and Hodgkin's disease: association with disease activity

Leimert JT, Corder MP, Skibba CA, Gingrich RD. *Arch Intern Med* 1979; 139: 486–7.

Erythema annulare centrifugum responding to natural ultraviolet light

Coronel-Perez IM, Morillo-Andújar M. *Actas Dermosifiliogr* 2010; 101: 177–8.

Two patients, ages 22 and 27 years, each with more than 8 years of EAC, failed treatment with topical corticosteroids. After years of sunlight avoidance, one patient cleared, and the other had significant improvement with summer sunlight exposure.

Second-Line Therapies

• Empiric antimicrobials	E
• Topical or systemic antipruritics	E
• Topical tacrolimus	E

Annular erythema responding to tacrolimus ointment

Rao NG, Pariser RJ. J Drugs Dermatol 2003; 2: 421–4.

Two patients with annular erythema of unclear etiology treated selected lesions with topical tacrolimus 0.1% ointment twice daily. Those lesions that were treated resolved within 2 to 6 weeks, whereas other untreated lesions did not respond until they, too, were treated with tacrolimus.

This suggests that tacrolimus, and not spontaneous remission, was responsible for the improvement.

Third-Line Therapies

• Systemic corticosteroids	E
• Immunomodulatory agents	E
• Topical calcipotriol	E
• Metronidazole	E

Erythema annulare centrifugum

Seidel DR, Burgdorf WHC. In: Demis DJ, et al., eds. Clinical Dermatology. Lippincott Williams & Wilkins, Philadelphia, 1999; Ch 7–5: 1–4.

Calcipotriol for erythema annulare centrifugum

Gnaiadecki R. Br J Dermatol 2002; 146: 317–9.

A 73-year-old woman had EAC of unknown cause that was resistant to topical and systemic steroids, antifungals, and psoralen and ultraviolet light (PUVA) treatment. It cleared completely after 3 months of topical, once-daily calcipotriol.

Erythema annulare centrifugum successfully treated with

metronidazole

De Aloe G, Rubegni P, Risulo M, Sbrano P, Poggiali S, Fimiani M. Clin Exp Dermatol 2005; 30: 583–4.

A 38-year-old man with EAC failed oral antibiotics and antifungals, as well as topical calcipotriol. Only systemic steroids provided temporary improvement of his skin lesions. Because the patient had rosacea, oral metronidazole 400 mg daily was prescribed for 6 weeks, with resolution of EAC.

A novel therapeutic approach to erythema annulare centrifugum

Minni J, Sarro R. J Am Acad Dermatol 2006; 54: S134–5.

In a personal communication, one patient with extensive EAC was reported to clear with etanercept 25 mg twice-weekly injections. After 4 weeks of treatment the patient was 95% clear, and complete remission was achieved after continued therapy. After 6 months the treatment was discontinued and EAC recurred. The lesions responded again to a repeat treatment regimen.

Erythema dyschromicum perstans

Christine Soon, and John Berth-Jones

Erythema dyschromicum perstans (EDP) is an acquired, generalized dermal hypermelanosis of unknown etiology. Clinically it presents as asymptomatic, ashen-gray-blue macules of varying sizes, most commonly on the trunk and proximal extremities. Variable

components include erythema and papulation. It has been reported most frequently in dark-skinned Latin American people, although all racial groups can be affected. EDP has similarities to lichen planus pigmentosus and the “ashy dermatosis” of Ramirez, although the precise relationship of these conditions remains uncertain.

Management Strategy

Histology reveals vacuolar degeneration of the basal layer associated with pigmentary incontinence. Dermal vessels are surrounded with an infiltrate of lymphocytes and histiocytes, and many melanophages are present.

EDP may need to be differentiated from the late stage of pinta. Dark-field examination and serologic tests for syphilis should be carried out to exclude this treponematoses in suspected cases.

Idiopathic eruptive macular pigmentation is a similar condition. Histology demonstrates that the pigment is located in the basal layer of the epidermis, and the lichenoid inflammation characteristic of EDP is not present.

Although EDP may persist for many years, there have been reports of spontaneous resolution. *Camouflage creams* can be helpful. Treatment is otherwise based on anecdotal evidence. Treatments that are reportedly ineffective include sun protection, peeling lotions, antibiotics, topical hydroquinone, topical corticosteroid therapy, antimalarials, and griseofulvin.

Specific Investigation

- Biopsy

Therapy

• No therapy	D
• Topical corticosteroid	E
• Antihistamines	E
• Topical tacrolimus	E
• Isotretinoin	E
• Dapsone 100 mg/day for 3 months	D
• Oral corticosteroid therapy	E
• Clofazimine 100 mg/day for 3 months	E

Erythema dyschromicum perstans in children: a report of 14 cases

Torrelo A, Zaballos P, Colmenero I, Mediero IG, de Prada I, Zambrano A. J Eur Acad Dermatol Venereol 2005; 19: 422–6.

No treatment was used. In six of these cases the eruption cleared or improved during follow-up ranging from 1 to 5 years.

Erythema dyschromicum perstans: identical to ashy dermatosis or not?

Numata T, Harada K, Tsuboi R, Mitsuhashi Y. Case Rep Dermatol 2015; 7: 146–50.

In this case the erythema responded to a topical steroid and the pruritus responded to an antihistamine.

Erythema dyschromicum perstans: response to topical tacrolimus

Mahajan VK, Chauhan PS, Mehta KS, Sharma AL. Indian J Dermatol 2015; 60: 525.

Two cases cleared within 2 to 3 months using 0.1% tacrolimus ointment twice daily.

Erythema dyschromicum perstans response to isotretinoin

Wang F, Zhao YK, Wang Z, Liu JH, Luo DQ. JAMA Dermatol 2016; 152: 841–2.

A 41-year-old man with EDP demonstrated 90% improvement within 4 months of isotretinoin (20 mg daily). Periodic recurrences responded to doses as low as 10 mg daily during 7 years of follow-up.

Erythema dyschromicum perstans in phototype II women: three unusual clinical cases studied with electron microscopy

Persechino S, Caperchi C, Cortesi G, Persechino F, Raffa S, Pulcini F, et al. *Eur J Dermatol* 2011; 21: 261–2.

Three cases demonstrated marked decrease in pigmentation on treatment with dapsone 100 mg daily for 3 months.

Erythema dyschromicum perstans: a case report and review

Osswald SS, Proffer LH, Sartori CR. *Cutis* 2001; 68: 25–8.

One case of EDP with active inflammatory areas responded to 3 weeks of oral corticosteroid therapy. The authors do not state the dose.

Involvement of cell adhesion and activation molecules in the pathogenesis of erythema dyschromicum perstans (ashy dermatitis). The effect of clofazimine therapy

Baranda L, Torres-Alvarez B, Cortes-Franco R, Moncada B, Potaless-Perez DP, Gonzalez-Amaro R. *Arch Dermatol* 1997; 133: 325–9.

A prospective clinical and immunohistochemical study indicating that clofazimine reduces the inflammatory response in EDP. Four out of six patients treated with clofazimine 100 mg/day showed marked improvement after 3 months of treatment.

Erythema elevatum diutinum

Tashmeeta Ahad, Emma Benton, and Ian Coulson

Erythema elevatum diutinum (EED) is a rare neutrophilic dermatosis consisting of violaceous, brown or red papules, plaques, nodules, and occasionally vesicobullous lesions over the extensor surfaces of the joints and buttocks, genitalia, trunk, and face. Early

lesions tend to be soft and erythematous, whereas advanced lesions tend to be nodular and firm, secondary to fibrosis. EED is thought to be a form of immune complex–mediated leukocytoclastic vasculitis, although its etiology remains unclear. Infections (including HIV and streptococcal), hematologic abnormalities, autoimmune diseases, and other conditions have been associated.

Management Strategy

EED is a chronic disease; there are only a few well-documented instances of spontaneous long-term resolution.

EED has been reported in association with diseases such as HIV, hematologic disorders, inflammatory bowel disease, celiac disease, verrucous carcinoma, systemic lupus erythematosus, primary Sjögren syndrome, ophthalmic disorders (peripheral keratitis), and pulmonary lymphoepithelioma-like carcinoma (possibly as part of a paraneoplastic syndrome), and evidence of these should be sought. Drug-induced EED may result from interferon- β , erythropoietin, antituberculosis chemotherapy, and cisplatin exposure.

After management of any underlying disease, *dapsone* 100 mg daily remains the initial treatment of choice. The response may be partial and dose dependent. In other patients both intralesional and systemic corticosteroids (prednisolone 30–40 mg daily) have produced favorable responses.

Sulfonamides (sulfamethoxypyridazine 500 mg once daily and sulfapyridine 0.5–1 g three times daily), *nicotinamide/niacinamide* 100 mg three times daily, *colchicine* 0.5 mg twice daily with 0.5 mg three times daily for 3 to 4 days to abate minor disease flares, and *chloroquine* 300 mg daily have produced resolution of lesions.

Differential diagnoses of early lesions of EED include extrafacial granuloma faciale, Sweet syndrome, rheumatoid neutrophilic dermatitis or palisaded neutrophilic, and granulomatous dermatitis, and advanced lesions include rheumatoid nodules and multicentric reticulohistiocytosis.

Specific Investigations

- Full blood count
- Full metabolic panel

- Immunoglobulins and serum electrophoresis/immunofixation electrophoresis
- Antinuclear antibody (ANA)
- Antineutrophil cytoplasmic antibodies (ANCA)
- Anti-nDNA antibody
- Antiphospholipid antibodies
- Celiac disease screen
- Hepatitis B and C serology
- HIV test
- Chest radiograph
- Urinalysis
- Histology
- Skin biopsy

Erythema elevatum diutinum: clinical, histopathologic, and immunohistochemical characteristics of six patients

Wahl CE, Bouldin MB, Gibson LE. Am J Dermatopathol 2005; 27: 397–400.

The vascular endothelium of EED stains positive for CD31, CD34, VEGF, and factor VIII, and negative for factor XIIIa, TGF β , and LANA. This pattern does not distinguish it from similar-appearing lesions. Therefore the chronic and recurrent nature of EED is the primary means of distinguishing it from entities that are clinically and histologically similar.

Erythema elevatum diutinum and IgA paraproteinaemia: ‘a preclinical iceberg’

Chowdhury MMU, Inaloz HS, Motley RJ, Knight AG. Int J Dermatol 2002; 41: 368–70.

The technique of immunofixation electrophoresis is more sensitive than immunoelectrophoresis. This uses a combination of zone electrophoresis and immunoprecipitation with specific antisera to detect monoclonal immunoglobulins or light chains at very low concentrations in serum and urine. This is useful in EED because patients may have associated paraproteinemias which, in some cases, may undergo malignant transformation.

The authors note that in monoclonal disorders there is extensive asymptomatic tumor proliferation and possible malignant transformation in 20% of patients during long-term follow-up. It was recommended that there

should be lengthy follow-up and monitoring for patients with both EED and IgA paraproteinemia because of the risk of progression to IgA myeloma.

Is IgA antineutrophil cytoplasmic antibody a marker for patients with erythema elevatum diutinum? A further three cases demonstrating this association

Crichlow SM, Alexandroff AB, Simpson RC, Saldanha G, Walker S, Harman KE. Br J Dermatol 2011; 164: 675–7.

Two studies evaluating the prevalence of ANCAs in EED. IgA ANCAs were present in all patients with EED.

Erythema elevatum diutinum and HIV infection: a report of five cases

Muratori S, Carrera C, Gorani A, Alessi E. Br J Dermatol 1999; 141: 335–8.

The largest case series of patients with EED and HIV infection. Streptococcal infection seemed to trigger exacerbations in four of five patients. EED can stimulate Kaposi sarcoma and bacillary angiomatosis, which may be particularly confusing in the context of an HIV-seropositive patient. Histopathologic confirmation of the diagnosis is therefore advocated.

Erythema elevatum diutinum associated with peripheral ulcerative keratitis

Erythema elevatum diutinum in systemic lupus erythematosus

Chan Y, Mok CC, Tang WYM. Rheumatol Int 2011; 31: 259–62.

These citations indicate the range of pathologies associated with EED.

First-Line Therapies

• Dapsone	D
• Dapsone plus antiretrovirals in HIV-associated disease	E
• Dapsone plus another agent (e.g., corticosteroids, antibiotics)	D

Erythema elevatum diutinum: a review of presentation and treatment

Momen SE, Jorizzo J, Al-Niaimi F. J Eur Acad Dermatol Venereol 2014; 28: 1594–602.

Dapsone is considered to be the main mode of treatment for EED as per multiple case series and case reports. No randomized controlled trials have evaluated treatment. This review of the literature between 1977 and 2012 identified 66 reported cases of EED treated with dapsone, including 59 treated with dapsone monotherapy. Eighty percent ($n = 47$) of patients on dapsone monotherapy showed a reduction in lesion size or complete resolution. Dapsone was also found to improve extracutaneous manifestations of EED, such as arthralgia ($n = 10$).

Eleven out of 13 HIV-positive patients treated with dapsone

showed a good clinical response.

Dapsone is often ineffective for fibrotic nodular advanced EED, in which case other agents such as corticosteroids, colchicine, or sulfonamide may be added.

Effective dapsone treatment doses ranged from 50 to 300 mg daily. It has been suggested that effectiveness may be dose dependent. A usual dose of 100 mg daily is used, and a lower dose (25–50 mg) may be administered at the start of treatment and titrated up depending on patient tolerance and response to therapy.

Other treatments have shown variable results. Oral glucocorticoids used alone or in conjunction with dapsone may improve EED. Sulfonamide antibiotics were used in nine cases, and clinical improvement was observed in three cases. Antibiotics such as clarithromycin, erythromycin, and penicillin were used in three patients in combination with excision ($n = 2$) and dapsone ($n = 1$) with variable results.

Dapsone may be ineffective once nodules appear; treatment of associated concomitant conditions is often beneficial to EED outcome.

Alternative procedure to allow continuation of dapsone therapy despite serious adverse reaction in a case of dapsone-sensitive erythema elevatum diutinum

Seneschal J, Guillet S, Ezzedine K, Taïeb A, Milpied B. *Dermatology* (Basel) 2012; 224: 115–9.

This patient responded well to dapsone but developed hypersensitivity reaction with DRESS, confirmed in vitro by the presence of circulating dapsone-specific T cells. As treatment alternatives to dapsone are limited, it is recommended that dapsone hypersensitivity syndrome is confirmed using interferon assay and modified lymphocyte transformation tests. After confirmation, a dapsone tolerance induction protocol may be administered over a period of days in order to obtain tolerance, thus allowing continuation of dapsone.

Nodular lesions of erythema elevatum diutinum in patients infected with the human immunodeficiency virus

LeBoit PE, Cockerell CJ. *J Am Acad Dermatol* 1993; 28: 919–22.

A clinicopathologic study of four patients with HIV infection who had unusual nodular lesions of EED. None of the patients responded to treatment with oral dapsone, and the authors commented that this

observed lack of response may reflect the preponderance of fibrosis rather than neutrophils in these advanced lesions.

Second-Line Therapies

• Sulfonamides	D
• Colchicine	D
• Oral steroids	D
• Niacinamide and tetracycline	E
• Chloroquine	E
• Methotrexate	E
• Dapsone with ciclosporin	E

Erythema elevatum diutinum: a case successfully treated with colchicine

Henriksson R, Hofer PA, Hörnqvist R. Clin Exp Dermatol 1989; 14: 451–3.

A case report of a 68-year-old man with EED refractory to treatment with oral dapsone who responded well to treatment with colchicine 0.5 mg twice daily over 6 weeks. Minor flares were abated temporarily, increasing colchicine to 0.5 mg three times a day for 3 to 4 days, without provoking diarrhea.

Erythema elevatum diutinum treated with niacinamide and tetracycline

Kohler IK, Lorincz AL. Arch Dermatol 1980; 116: 693–5.

A 60-year-old woman with EED that cleared completely after 4 weeks of treatment with oral niacinamide 100 mg three times daily

and oral tetracycline hydrochloride 250 mg four times daily. After this, oral niacinamide alone was sufficient for disease suppression.

Successful combination therapy with dapsone and cyclosporine for erythema elevatum diutinum with unusual appearance

Takahashi H, Fukami Y, Honma M, Ishida-Yamamoto A, Iizuka H. J Dermatol 2012; 39: 486–7.

In this case of EED with an unusual distribution on the soles, fingers, trunk, and feet accompanied with ulcerations, the patient initially failed to respond to oral dapsone 75 mg daily but improved with the addition of ciclosporin 4 mg/kg/day.

Third-Line Therapies

• Topical dapsone 5%	E
• Localized surgical excision (nodular EED)	E
• Cyclophosphamide	E
• Plasma exchange ± thalidomide	E
• Reduction in ciclosporin dose	E
• Transdermal nicotine patches	E
• Methylprednisolone	E
• Colectomy	E
• Gluten-free diet	E
• Phenformin	E

Novel use of topical dapsone 5% gel for erythema elevatum diutinum: safer and effective

Frieling GW, William NL, Lim SJ. J Drugs Dermatol 2013; 12: 481–4.

This case report showed some improvement in erythema and

flattening of lesions of EED using dapsone 5% gel for 1 week before start of oral dapsone therapy.

Other topical treatments, including topical corticosteroids and intralesional steroid injections, have shown variable results in a few case reports.

Successful surgical treatment of advanced erythema elevatum diutinum

Rinard JR, Mahabir RC, Greene JF, Grothaus P. *Can J Plast Surg* 2010; 18: 28–30.

In this case report, a patient with late-stage nodular EED in whom medical treatment was contraindicated was treated with continued surgical excisions of recurrent nodules with symptomatic relief.

Fibrotic nodules often respond poorly to dapsone; surgical excision may help.

Erythema elevatum diutinum in a patient with relapsing polychondritis

Bernard P, Bedane C, Delrous JL, Catanzano G, Bonnetblanc JM. *J Am Acad Dermatol* 1992; 26: 312–5.

A 69-year-old man with a history of relapsing polychondritis developed EED, which responded to treatment with oral cyclophosphamide 100 mg daily and prednisolone 20 mg daily. Cyclophosphamide was discontinued after 2 months, and the prednisolone was subsequently tapered to 15 mg daily.

Erythema elevatum diutinum associated with IgA paraproteinemia successfully controlled with intermittent plasma exchange

Chow RK, Benny WB, Coupe RL, Dodd WA, Ongley RC. *Arch Dermatol* 1996; 132: 1360–4.

Intermittent plasma exchange has been reported to successfully control EED associated with IgA paraproteinemia.

Case of erythema elevatum diutinum associated with IgA paraproteinemia successfully controlled with thalidomide and plasma exchange

Manni E, Cervadoro E, Papineschi F. *Ther Apher Dial* 2015; 19: 195.

An 83-year-old woman with EED treated with dapsone for a year was found to have an IgA kappa paraproteinemia consistent with

monoclonal gammopathy of undetermined significance and commenced on treatment with plasma exchange, three-weekly sessions down to one-weekly sessions. Commenced thalidomide on week 13, with 200mg/day and 100mg/day alternatively and plasma exchange reduced to one exchange every 2 weeks. Thalidomide was then continued as monotherapy followed by treatment regimen with periods of plasma exchange $\pm$ thalidomide, which led to improvement of skin lesions and stabilization of raised IgA values.

Erythema elevatum diutinum after liver transplantation: disappearance of the lesions associated with a reduction in cyclosporine dosage

Hernández-Cano N, De Lucas R, Lázaro TE, Mayor M, Burón I, Casado M. *Pediatr Dermatol* 1998; 15: 411–2.

Lesions of EED resolved after a reduction in ciclosporin dosage in a 10-year-old patient who had previously received a cadaveric hepatic allograft because of Alagille disease.

Erythema elevatum diutinum manifesting as a penile ulcer

Yoshii N, Kanekura T, Higashi Y, Oyama K, Azagami K, Kanzaki T. *Clin Exp Dermatol* 2007; 32: 211–3.

A 74-year-old man developed EED. The lesions on his limbs responded well to the nicotine patches that released 6.25 mg nicotine applied every 24 hours. The penile lesions remained recalcitrant to the nicotine patches as well as dapsone, requiring treatment with methylprednisolone (40 mg/day).

Erythema elevatum diutinum: an unusual association with ulcerative colitis

Buahene K, Hudson M, Mowat A, Smart L, Ormerod AD. *Clin Exp Dermatol* 1991; 16: 204–6.

A 58-year-old woman developed EED during severe acute exacerbation of ulcerative colitis, which resolved after a colectomy.

Erythema elevatum diutinum in association with coeliac disease

Tasanen K, Raudasoja R, Kallioinen M, Ranki A. *Br J Dermatol* 1997; 136: 624–7.

A 47-year-old woman who presented with typical EED in whom previously undiagnosed celiac disease was found. Treatment with dapsone was partially effective, but complete healing of the EED

lesions was achieved only after the introduction of a strict gluten-free diet. Maintenance treatment with a gluten-free diet only was required.

Erythema elevatum diutinum: cutaneous vasculitis, impaired clot lysis, and response to phenformin

Schumacher HR, Carroll E, Taylor F, Shelley WB, Wood MG. J Rheumatol 1977; 4: 103–12.

A variety of treatments were tried with no success in this case report, but phenformin 50 mg three times daily produced marked improvement for periods of 11 and 16 months on two occasions.

Phenformin is a biguanide antidiabetic drug that has been withdrawn in many countries due to high risk of lactic acidosis.

Erythema multiforme

Jean Revuz

Erythema multiforme (EM) is a distinct cutaneous reaction pattern to a variety of stimuli, predominantly herpes simplex virus (HSV) infection, occurring predominantly in young adults. It usually runs a self-limiting course but has a tendency to recur. It is defined by the presence of “typical” three-zone target lesions, with a predominantly acral distribution. The presence of mucosal involvement at more than one site distinguishes EM major from EM minor. A specific variant has mucosal lesions only, without skin involvement. EM major can be distinguished from Stevens–Johnson syndrome, which lacks typical targetlike lesions and acral location but, instead, irregular macule or atypical targets and a truncal location. EM is frequently misdiagnosed

in cases of urticarial and common rashes and more rarely in cases of cutaneous lupus, vasculitis, erythema annulare, and drug eruption.

Management Strategy

In 30% to 50% of cases the etiology of EM is unknown. The most commonly recognized precipitant is HSV infection, both types I and II. HSV-specific DNA has been isolated from lesional tissue in 60% to 70% of cases. HSV particles are found in the circulating precursors of epidermal Langerhans cells. A variety of other viral infections (orf, zoster varicella virus [VZV], Epstein–Barr virus [EBV], cytomegalovirus [CMV], HIV, hepatitis B vaccination), bacterial infections (mainly *Mycoplasma pneumoniae*), and fungal infections (mainly histoplasmosis) have been implicated. An extensive list of drugs has been reported to trigger EM, but most cases, if not all, are the result of confusion with Stevens–Johnson syndrome. Rare cases are attributed to contact allergy.

Acute episodes of EM need only *symptomatic treatment* in most cases. Recurrent EM, which may severely affect quality of life, has a well-recognized *preventive treatment* in case of HSV infection but may be highly recalcitrant when no cause is identified. A persistent continuous variety of EM has been reported; several patients had antidesmoplakin antibodies, the significance of which is debated: epiphenomena or defining a variety of pemphigus?

There are no double-blind or open trials of treatments for acute episodes of EM. Most cases, particularly EM minor, run a self-limiting course. Symptomatic measures include *oral antihistamines* and *mild- to moderate-potency topical corticosteroids* to reduce pruritus. Underlying conditions, mainly *Mycoplasma pneumoniae* infection, should be treated. Recurrent EM (>6 attacks per year) may respond to long-term *aciclovir*. In aciclovir resistant cases a variety of other therapies can be helpful (see later).

Mucosal manifestations of EM are a source of morbidity and occur in up to 70% of cases. The most common sites affected are the buccal mucosa and lips. Symptomatic measures include *mouthwashes*, a *soft diet*, *topical anesthetics* (lidocaine gel, benzocaine lozenges, or 0.15% benzydamine hydrochloride), and *topical corticosteroids* (e.g., 0.1% triamcinolone acetonide paste). Budesonide or beclomethasone inhalers (one puff three to four times daily) provide an alternative method of delivering local corticosteroid to the inflamed mucosal

surfaces. Short courses of high-dose *oral prednisolone* may be needed for severe oral disease. Strict eye care to reduce secondary infection and scarring includes *saline washes* for removal of crusts, *local antibiotics*, and frequent *debridement of tarsal and bulbar conjunctival adherences*.

Specific Investigation

- Histology/immunofluorescence

EM is a clinical diagnosis. Histology, with direct immunofluorescence, can be useful in atypical cases to exclude other bullous diseases that present with oral manifestations, such as pemphigus vulgaris or cicatricial pemphigoid.

Investigations directed at determining the underlying trigger factors include culture or serologic testing for HSV or other infections, especially *M. pneumoniae*, as indicated by clinical findings.

First-Line Therapy

- | | |
|---|---|
| • Antivirals (aciclovir, valaciclovir, ganciclovir) | A |
|---|---|

Recurrent erythema multiforme: clinical features and treatment in a large series of patients

Schofield JK, Tatnall FM, Leigh IM. Br J Dermatol 1993; 128: 542–5.

A review of 65 patients with recurrent EM: 71% had episodes triggered by HSV infection. Treatment with standard doses of aciclovir for HSV was relatively disappointing; continuous aciclovir 400 mg twice daily for 6 months was more effective, with remission in some responders. Some patients responded to dapsone, antimalarials, azathioprine (10 of 11), and human immunoglobulin.

A double-blind, placebo-controlled trial of continuous aciclovir therapy in recurrent erythema multiforme

Tatnall FM, Schofield JK, Leigh IM. Br J Dermatol 1995; 132: 267–70.

Aciclovir 400 mg twice daily for 6 months suppressed EM in 7 of 11

patients (including 1 with apparently idiopathic EM). Two patients went into complete remission.

A therapeutic trial of aciclovir is justified even when clinical evidence of HSV is lacking. aciclovir 400 mg twice daily can be administered for 6 months to 2 years because it has a good long-term safety profile. It is ineffective in an acute episode once the herpetic lesion or EM eruption has developed. Recurrence is usual after stopping the drug.

Recurrent erythema multiforme unresponsive to aciclovir prophylaxis and responsive to valaciclovir continuous therapy

Kerob D, Assier-Bonnet H, Esnault-Gelly P, Blanc F, Saiag P. Arch Dermatol 1998; 134: 876–7.

A reduced response to aciclovir may be due to the low oral bioavailability of the drug, and one of the second-generation antivirals, such as valaciclovir (500 mg daily) or famciclovir (250 mg twice daily), may need to be substituted.

Recurrent erythema multiforme: clinical characteristics, etiologic associations, and treatment in a series of 48 patients at Mayo Clinic, 2000 to 2007

Wetter DA, Davis MD. J Am Acad Dermatol 2010; 62: 45–53.

Of 48 patients HSV was responsible in 11 (23%); the cause remained unknown in 28 (58%). Systemic corticosteroids were used in most patients. Sixteen of 33 patients receiving continuous antiviral treatment had either partial or complete disease suppression. Mycophenolate mofetil provided partial or complete response in 6 of 8 patients.

Erythema multiforme major associated with CMV infection in an immunocompetent patient

Vitiello M, Echeverria B, Elgart G, Kerdel F. J Cutan Med Surg 2011; 15: 115–7.

Ganciclovir was used successfully.

Second-Line Therapies

• Dapsone	C
• Azathioprine	C
• Thalidomide	B
• Potassium iodide	C

Oral EM

• Topical corticosteroid	B
• Levamisole	B
• Systemic corticosteroid	D

Dapsone-responsive persistent erythema multiforme

Mahendran R, Grant JW, Norris PG. *Dermatology* 2000; 200: 281–2.

Dapsone 100 mg daily was effective in controlling EM in a patient with ovarian malignancy.

Characteristics of the oral lesions in patients with cutaneous recurrent erythema multiforme

Farthing PM, Maragou P, Coates M, Tatnall F, Leigh IM, Williams DM. *J Oral Pathol Med* 1995; 24: 9–13.

In this series of 82 patients with typical cutaneous EM, 70% had oral mucosal involvement. Five patients with resistant disease were controlled with azathioprine 100 to 150 mg daily.

Azathioprine therapy in the management of persistent erythema multiforme

Jones RR. Br J Dermatol 1981; 105: 465–7.

Azathioprine 100 to 150 mg daily was effective in two patients and permitted reduction of the corticosteroid dosage.

Treatment by thalidomide of chronic multiforme erythema: its recurrent and continuous variants. A retrospective study of 26 patients

Cherouati K, Claudy A, Souteyrand P, Cambazard F, Vaillant L, Moulin G, et al. Ann Dermatol Venereol 1996; 123: 375–7 (in French).

Thalidomide reduces the duration of episodes of recurrent EM by 11 days on average; it is dramatically effective in the exceptional continuous variant. Remission can be maintained with low-dose (25–50 mg daily) thalidomide.

Potassium iodide in erythema nodosum and other erythematous dermatoses

Horio T, Danno K, Okamoto H, Miyachi Y, Imamura S. J Am Acad Dermatol 1983; 9: 77–81.

Fourteen of 16 subjects with EM (6 related to HSV infection) responded within 1 week to 300 mg potassium iodide three times daily. Gastrointestinal and cutaneous side effects can occur with this treatment.

Erythema multiforme – response to corticosteroid

Ting HC, Adam BA. Dermatologica 1984; 169: 175–8.

Thirteen patients with EM minor treated with systemic corticosteroids were compared with 12 treated without. Apart from a shorter duration of fever, the corticosteroid-treated group did not respond better than the noncorticosteroid-treated group.

There is no reason to treat EM minor with steroids. This drug may still be useful in EM major.

Open preliminary clinical trial of clobetasol propionate ointment in adhesive paste for treatment of chronic oral vesiculoerosive diseases

Lozada-Nur F, Huang MZ, Zhou GA. Oral Surg Oral Med Oral Pathol 1991; 71: 283–7.

Clobetasol propionate 0.05% ointment mixed 1:1 with Orabase

paste two to three times daily was helpful in four patients with chronic oral EM.

Erythema multiforme: diagnosis, clinical manifestations and treatment in a retrospective study of 22 patients

Sanchis JM, Bagán JV, Gavalda C, Murillo J, Diaz JM. J Oral Pathol Med 2010; 39: 747–52.

Systemic corticosteroids are effective in controlling the outbreaks; their use as maintenance therapy is not clearly indicated.

Prednisone and azathioprine in the treatment of patients with vesiculoerosive oral diseases

Lozada F. Oral Surg Oral Med Oral Pathol 1981; 52: 257–63.

In this open trial, two patients with oral EM required lower doses of prednisolone (15–20 mg on alternate days) when treated simultaneously with azathioprine (50 mg daily).

Recurrent oral erythema multiforme. Clinical experience with 11 patients

Bean SF, Quezada RK. JAMA 1983; 249: 2810–2.

In this retrospective study, patients with severe recurrent oral EM involvement were treated with prednisolone 40 to 60 mg daily, subsequently tapered over 2 to 3 weeks. This reduced the time taken for oral erosions to heal but did not influence recurrences.

Some authorities, however, believe that use of corticosteroids in EM increases the frequency and chronicity of attacks.

Third-Line Therapies

• Antimalarials	D
• Human immunoglobulin	D
• Interferon- α	E
• Rituximab	D
• Tamoxifen	E
• Zinc sulfate	E
• Cimetidine	E
• Ciclosporin	E
• Pulsed methylprednisolone	E

Recurrent erythema multiforme: clinical features and treatment in a large series of patients

Schofield JK, Tatnall FM, Leigh IM. Br J Dermatol 1993; 128: 542–5.

The use of normal human immunoglobulins and antimalarials was reported in a few patients in this study. Intramuscular human immunoglobulin 750 g once a month caused suppression of EM in 11 of 13 patients. One responder remained in remission after therapy was discontinued. There was a 50% success rate with antimalarials (both hydroxychloroquine and mepacrine) used in four patients.

Recurrent erythema multiforme and chronic hepatitis C: efficacy of interferon alpha

Dumas V, Thieulent N, Souillet AL, Jullien D, Faure M, Claudy A. Br J Dermatol 2000; 142: 1248–9.

One patient with recurrent EM and hepatitis C virus infection

responded to two courses of interferon-alpha (IFN- α) (9 MU weekly for 6 and 8 months, respectively).

Severe erythema multiforme responding to interferon alfa

Geraminejad P, Walling HW, Voigt MD, Stone MS. J Am Acad Dermatol 2006; 54: S18–21.

A patient with recurrent EM associated with hepatitis C had been in complete remission for 6 years after treatment with IFN- α . A new recurrence was successfully treated with IFN- α in the absence of recurring hepatitis C virus infection.

Interferon may be a first-line treatment for patients with hepatitis C.

Rituximab, a new treatment for difficult to treat chronic erythema multiforme major. Five cases

Hirsch G, Ingen-Housz-Oro S, Fite C, Valeyrie-Allanore L, Ortonne N, Buffard V, et al. J Eur Acad Dermatol Venereol 2016; 30:1140–3.

Chronic continuous or relapsing EM resistant to several drugs, including aciclovir corticosteroids, and thalidomide; four patients had antidesmoplakin antibodies; four had complete remission.

Progesterone-induced erythema multiforme

Wojnarowska F, Greaves MW, Peachey RD, Drury PL, Besser GM. J Roy Soc Med 1985; 78: 407–8.

EM linked to the luteal phase of the menstrual cycle was controlled with tamoxifen.

Topical treatment of recurrent herpes simplex and postherpetic erythema multiforme with low concentrations of zinc sulphate solution

Brody I. Br J Dermatol 1981; 104: 191–4.

Treatment of the skin at the site of the herpetic infection with zinc sulfate solution prevented relapse of postherpetic EM over a 2-year period of observation in one patient. For the skin, 0.025% to 0.05% and for the oral mucous membrane 0.01% to 0.025% zinc sulfate solution was used.

Cimetidine prevents recurrent erythema multiforme major resulting from herpes simplex virus infection

Kurkcuoglu N, Alli N. J Am Acad Dermatol 1989; 21: 814–5.

EM resistant to aciclovir responded to cimetidine 400 mg three

times daily in one patient.

Ciclosporin therapy for bullous erythema multiforme

Wilkel CS, McDonald CJ. Arch Dermatol 1990; 126: 397–8.

High-dose ciclosporin (5–10 mg/kg daily) suppressed an atypical bullous eruption with histologic features of EM. The use of ciclosporin permitted tapering of the corticosteroid dosage.

Erythema nodosum

Amy Forrestel, and Misha Rosenbach

Erythema nodosum (EN) is a septal panniculitis that presents as tender, erythematous nodules and plaques classically located on the extensor surfaces of the lower extremities. EN is generally viewed as a cutaneous reactive process that can be seen as an isolated, idiopathic condition or, more commonly, as a secondary sign of another systemic disease (listed later). Individual lesions frequently resolve within 2 to 6 weeks, but persistent lesions and intermittent recurrent

disease are not uncommon. EN is often accompanied by systemic symptoms such as fever, fatigue, arthritis, cough, and gastrointestinal complaints.

Management Strategies

Management of EN first requires investigation for an underlying etiology, which should include detailed history and review of systems and a targeted evaluation. Numerous etiologies have been implicated, including chronic inflammatory states, infections, reactions to medications or hormones, and malignancies. Even after extensive evaluation, many cases are classified as idiopathic.

Many infectious agents have been associated with erythema nodosum. Bacterial and protozoan causes include *Streptococcus* (most common), *Mycoplasma pneumonia*, *Chlamydia pneumonia*, *Chlamydia trachomatis*, *Yersinia enterocolitica*, *Salmonella enteritidis*, *Giardia lamblia*, *Shigella*, *Klebsiella* spp., tuberculosis, brucellosis, psittacosis, cat scratch disease, chancroid, tularemia, rickettsiosis, leptospirosis, and *Campylobacter*. Viral causes include hepatitis B, hepatitis C, Human immunodeficiency virus (HIV), and herpes simplex virus (HSV). Fungal infections include blastomycosis, sporotrichosis, coccidioidomycosis, histoplasmosis, nocardiosis, and fungal kerions.

Chronic inflammatory conditions associated with EN include sarcoidosis (most common), inflammatory bowel disease (IBD), Behçet disease, Sweet syndrome, pyoderma faciale, and diverticulitis.

Associated medications include oral contraceptives (most common) and other female hormone therapies, antibiotics (in particular the penicillins and sulfonamides), iodides, bromides, quinolones, lidocaine injections, aromatase inhibitors, all-trans retinoic acid, propylthiouracil, granulocyte colony-stimulating factor, echinacea supplements, glatiramer acetate, valproate, nonsteroidal antiinflammatory drugs (NSAIDs), thalidomide, and dapsone. Targeted chemotherapeutic agents such as BRAF and MEK inhibitors have been recently described to cause an EN-like panniculitis. Multiple vaccines have been suggested as well, albeit in very small numbers—and the health benefits of vaccines outweigh the rare potential for this type of reaction.

Malignancies such as leukemias, lymphomas, myelodysplastic syndrome, and parathyroid carcinoma have been implicated.

Skin biopsy is generally not necessary if the history and physical

signs are suggestive of EN. Biopsies are typically performed in atypical cases, persistent or treatment-refractory cases, or cases where there is a broad differential diagnosis and a biopsy may help exclude alternative etiologies. If a biopsy is done, the pathology classically demonstrates inflammation in the septae between fat lobules of the subcutis. The type of inflammation may vary between acute and chronic inflammation, including multinucleated giant cells (“Meischer granulomas”). Other findings can include fibrosis, increased thickness of the intralobular septae, and radial arrays of macrophages around blood vessels. A biopsy is usually helpful in ruling out other forms of panniculitis, and if an infectious cause is in the differential diagnosis, tissue may be sent for culture and stains.

If identified, treatment or elimination of an underlying trigger will often lead to spontaneous remission of EN. This is the primary treatment strategy and should be emphasized in all cases; if there is an EN-triggering disease, it should be treated, and if there is an EN-associated medication, it should be discontinued. Direct EN treatment consists primarily of bed rest, leg elevation, compression, NSAIDs, and potassium iodide. Of the NSAIDs, naproxen and indomethacin have the most evidence and experience. A reasonable starting dose of indomethacin is 50 mg three times daily. Note that NSAIDs have also been reported as potential EN-inducing drugs, and in such cases treatment with NSAIDs is not advised. Potassium iodide is generally well tolerated, effective, and nonimmunosuppressive but may not be widely available. Typical dosing is with a supersaturated solution of potassium iodide (SSKI) starting at 1 to 2 drops three times daily and gradually titrating up to 5 drops (often dissolved in orange juice to increase tolerability of taste) taken three times per day. Side effects include hypothyroidism and hyperkalemia; rarely, concentrated iodide can induce a neutrophilic eruption (iododerma). Thyroid-stimulating hormone (TSH) should be monitored monthly while on treatment.

In patients who fail these treatments, alternative treatments can be considered. Prednisone is very effective and may be used in particularly refractory, widespread, or very symptomatic patients to gain rapid control. Infection and malignancy should be ruled out before initiation. Colchicine, hydroxychloroquine, dapsone, and some immunomodulatory and immunosuppressive agents have anecdotal reports of efficacy, as described later.

Specific Investigations

- Complete blood count (with differential), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP)
- Antistreptolysin O (ASO) titer or Anti-Deoxyribonuclease B (Anti-DNase B) titre, throat culture
- Urinalysis and urine pregnancy test
- Chest radiograph
- Purified protein derivative (PPD) standard tuberculosis skin test or interferon gamma release assay
- Skin biopsy

Erythema nodosum: a review

Soderstrom RM, Krull EA. Cutis 1978; 21: 806–10.

Streptococcal infection was the most common etiology, and sarcoidosis is the most common disease associated with EN.

All patients should have a chest radiograph, ASO titer, throat culture, and PPD/testing for latent tuberculosis.

Erythema nodosum: an evaluation of 100 cases

Mert A, Kumbasar H, Ozaras R, Erten S, Tasli L, Tabak F, et al. Clin Exp Rheumatol 2007; 25: 563–70.

The results showed a 6:1 female predominance; 53% idiopathic and 11% streptococcal infections, 10% tuberculosis, 10% sarcoidosis, 6% Behçet, 5% drug reactions, 3% IBD, and 2% pregnancy.

First-Line Therapies

• NSAIDs	E
• Potassium iodide	B

Suppression of erythema nodosum by indomethacin

Ubogay Z, Persellin RH. *Acta Derm Venereol* 1982; 62: 265–7.

Three patients with EN secondary to streptococcal pharyngitis refractory to erythromycin, penicillin, and aspirin improved with indomethacin 100 to 150 mg for 2 weeks.

Chronic erythema nodosum treated with indomethacin

Barr WG, Robinson JA. *Ann Intern Med* 1981; 95: 659.

Idiopathic EN in a 32-year-old woman refractory to aspirin resolved with indomethacin 25 mg three times daily for 1 month.

Control of chronic erythema nodosum with naproxen

Lehman CW. *Cutis* 1980; 26: 66–7.

A 28-year-old woman with recurrent EN refractory to phenylbutazone and aspirin was treated with naproxen 250 mg orally twice daily for 1 month, with cessation of symptoms within 96 hours and clearing in 14 days. Relapsed with therapy cessation but recleared when naproxen restarted.

Potassium iodide in erythema nodosum and other erythematous dermatoses

Horio T, Danno K, Okamoto H, Miyachi Y, Imamura S. *J Am Acad Dermatol* 1983; 9: 77–81.

Twelve of 16 patients treated with potassium iodide improved within a few days, with complete resolution in 10 to 14 days. Six had recurrent attacks, with resolution upon repeat dosing with potassium iodide. Better outcomes were obtained with earlier treatment initiation.

Potassium iodide may be a reasonable choice for those patients who cannot tolerate NSAIDs or corticosteroids.

Treatment of erythema nodosum and nodular vasculitis with potassium iodide

Schultz EJ, Whiting DA. *Br J Dermatol* 1976; 94: 75–8.

Twenty-four of 28 patients with EN improved within 48 hours and resolved within 2 weeks with 300 to 900 mg daily of potassium iodide.

Potassium iodide in dermatology. A 19th century drug for the 21st century: uses, pharmacology, adverse effects, and contraindications

Sterling JB, Heymann WR. J Am Acad Dermatol 2000; 43: 691–7.
An excellent review article.

Second-Line Therapies

• Colchicine	D
• Hydroxychloroquine	E
• Prednisone	E

Traitement de l'erythème noueux par la colchicine

De Coninck P, Baclet JL, Di Bernardo C, Büschges B, Plouvier B.
Presse Med 1984; 13: 680.

Five women were treated with colchicine (2 mg daily for 3 days, then 1 mg daily for 2–4 weeks) and improved within 72 hours. None recurred after treatment cessation.

Erythema nodosum treated with colchicine

Wallace S. JAMA 1967; 202: 144.

One patient with EN was successfully treated with colchicine.

Hydroxychloroquine in the treatment of chronic erythema nodosum

Alloway JA, Franks LK. Br J Dermatol 1995; 132: 661–70.

A 38-year-old woman with a 24-year history of EN with almost monthly flares refractory to aspirin and indomethacin was treated with hydroxychloroquine 200 mg orally twice daily. Within 3 months she had a dramatic reduction in lesions and remained stable for at least 6 months.

Hydroxychloroquine and chronic erythema nodosum

Jarrett P, Goodfield MJD. Br J Dermatol 1996; 134: 373.

A 52-year-old with idiopathic EN refractory to NSAIDs and prednisone improved with hydroxychloroquine 200 mg orally twice a day and prednisone 15 mg four times a day for 8 weeks. Prednisone was stopped, and 8 weeks later the hydroxychloroquine dose was cut by half, but the patient experienced a flare, and the original dose was restarted. After 3 more months the hydroxychloroquine was stopped, although intermittent dosing was required.

Third-Line Therapies

• Dapsone	E
• Extracorporeal monocyte granulocytapheresis	E
• Erythromycin	E
• Mycophenolate mofetil	E
• Etanercept	E
• Adalimumab	E
• Infliximab	E
• Prophylactic penicillin	E
• Vitamin B ₁₂ (if levels low)	E
• Tetracycline	E

Acne fulminans and erythema nodosum during isotretinoin therapy responding to dapsone

Tan B, Lear J, Smith A. Clin Exp Dermatol 1997; 22: 26–7.

Acne fulminans and EN that occurred in a patient 3 weeks after starting isotretinoin responded to dapsone without oral prednisone.

Extracorporeal monocyte granulocytapheresis was effective for a patient of erythema nodosum concomitant with ulcerative colitis

Fukunaga K, Sawada K, Fukuda Y, Matoba Y, Natsuaki M, Ohnishi K,

et al. *Ther Apher Dial* 2003; 7: 122–6.

A patient with ulcerative colitis and EN refractory to high-dose corticosteroids improved after monocyte granulocytapheresis once a week for 5 weeks. He was also on 5-aminosalicylic acid.

Severe erythema nodosum due to Behçet's disease responsive to erythromycin

Kaya TI, Tursen U, Baz K, Ikizoglu G, Dusmez D. *J Dermatol Treat* 2003; 14: 124–7.

A patient with refractory Behçet disease and EN responded to coincidental treatment with erythromycin for erythrasma.

Use of mycophenolate mofetil in erythema nodosum

Boyd AS. *J Am Acad Dermatol* 2002; 47: 968–9.

A patient taking estrogen replacement with EN refractory to discontinuing hormone therapy and azathioprine cleared with mycophenolate mofetil 750 mg twice a day and remained clear after a slow taper.

Dermatologic manifestations of Crohn disease in children: response to infliximab

Kugathasan S, Miranda A, Nocton J, Drolet BA, Raasch C, Binion DG. *J Pediatr Gastroenterol Nutr* 2003; 37: 150–4.

One child with Crohn disease and resistant EN cleared with infliximab 5 mg/kg and was maintained on 6-mercaptopurine.

Treatment of chronic erythema nodosum with infliximab

Clayton TH, Walker BP, Stables GI. *Clin Exp Dermatol* 2006; 31: 823–4.

A 26-year-old woman with IBD and EN improved with infliximab.

Etanercept treatment of erythema nodosum

Boyd AS. *Skinmed* 2007; 6: 197–9.

One patient with a 5-year history of recalcitrant EN was treated with etanercept 25 mg subcutaneously twice. She was clear after 4 months. After 6 months the etanercept dose was reduced to 25 mg subcutaneously weekly.

Prophylaxis of recurrent erythema nodosum with penicillin

Bhalla M, Thami GP. *Dermatology* 2007; 215: 363–4.

Three patients with recurrent EN were cleared with monthly doses of intramuscular benzathine penicillin 2.4 million units. One patient had high ASO titers, and the other two had idiopathic biopsy-proven EN. All patients remained clear at 6 months.

Refractory chronic erythema nodosum successfully treated with adalimumab

Ortego-Centeno N, Callejas-Rubio JL, Sanchez-Cano D, Caballero-Morales T. J Eur Acad Dermatol Venereol 2007; 21: 408–10.

A 79-year-old patient with chronic recalcitrant EN cleared with adalimumab 40 mg subcutaneously every 2 weeks and was clear after 7 months of follow-up.

Adalimumab for the treatment of Japanese patients with intestinal Behçet's disease

Tanida S, Inoue N, Kobayashi K, Naganuma M, Hirai F, Iizuka B, et al. Clin Gastroenterol Hepatol 2015; 13: 940–8.e3.

Twenty patients with active intestinal Behçet's disease refractory to corticosteroids and/or immunomodulator therapies were given 160 mg adalimumab, 80 mg 2 weeks later, then 40 mg every other week for 52 weeks. Eighty-eight percent of the patients with EN cleared.

Successful treatment of chronic erythema nodosum with vitamin B₁₂

Volkov I, Rudoy I, Press Y. J Am Board Fam Pract 2005; 18: 567–9.

One patient had EN resolve after being treated for a low serum B₁₂ level with twice-weekly injections of 1000 µg of B₁₂.

Response of recalcitrant erythema nodosum to tetracyclines

Davis MD. J Am Acad Dermatol 2011; 64: 1211–2.

One patient with a renal transplant and recalcitrant EN resolved after 1 month of minocycline 100 mg twice daily. Minocycline was discontinued because of hyperpigmentation. EN recurred within a week and resolved again with tetracycline 500 mg twice a day.

Role of tetracycline in recalcitrant erythema nodosum

Rohatgi S, Basavaraj KH, Ashwini PK, Kanthraj GR. Indian Dermatol Online J 2014; 5: 314–5.

A 40-year-old male with chronic recurrent EN cleared after 2 weeks

of tetracycline 500 mg four times daily. The patient was switched to doxycycline and the EN recurred, so tetracycline was restarted with sustained complete regression for 6 months.

Erythrasma

Melissa C. Barkham

In its most typical form, erythrasma is characterized by well-defined, reddish-brown, flexural plaques that show fine scaling and no tendency to central clearing. It may also present with maceration of the toe webs.

The responsible organism, *Corynebacterium minutissimum*, is an inhabitant of normal human skin. Factors that predispose to clinically apparent infection include diabetes mellitus, obesity, Human Immunodeficiency Virus (HIV), old age, and a humid environment.

Management Strategy

Erythrasma is often a trivial infection, but therapy may be requested because of the cosmetic appearance or because of pruritus.

Coinfection with dermatophyte fungi or *Candida albicans* is common and may influence the choice of treatment.

Fusidic acid cream is the topical treatment of choice where no concomitant yeast or fungal infection is found. It is both effective and well tolerated.

Topical imidazoles (miconazole, clotrimazole, bifonazole) are well tolerated and also effective against concomitant fungal or yeast infection.

When the disease is extensive or when compliance with topical therapy is unlikely, oral antibiotics such as *single-dose clarithromycin* or *oral erythromycin* should be considered.

A combination of oral and topical treatment may be required for stubborn infections, particularly of the toe webs.

Specific Investigations

- Examination under Wood light
- Potassium hydroxide (KOH) preparation of skin scrapings

Rapid confirmation of the diagnosis is achieved by examination of the skin under Wood (long-wave ultraviolet) light. The characteristic coral-red fluorescence observed is due to the production of coproporphyrin III by the organism. Fluorescence may not be seen if the patient has bathed immediately before examination. Culture is unreliable because the organism does not always grow satisfactorily. Microscopy of skin scrapings is performed to seek evidence of concomitant infection, such as the presence of fungal hyphae or yeasts.

First-Line Therapies

• Fusidic acid cream	A
• Miconazole cream	B
• Clotrimazole cream	D
• Clindamycin lotion or solution	E
• Bifonazole cream	E

A comparison between the effectiveness of erythromycin, single dose clarithromycin and topical fusidic acid in the treatment of erythrasma

Avci O, Tanyildizi T, Kuskü E. J Dermatolog Treatment 2013; 24: 70–4.

One hundred fifty-one patients were included in this study. Around two thirds of them had toe web infections. A complete response (defined as no fluorescence) was observed in 30/31 patients treated with 2% fusidic acid cream twice daily for 14 days in this double-blind, placebo-controlled trial. The response was superior to oral clarithromycin (20/30), oral erythromycin (16/30), placebo cream (4/30), and placebo tablets (1/30). The authors acknowledged the limitations of the grading system of fluorescence used to assess response. They mention that the higher efficacy of fusidic acid cream over oral antibiotics might well be due to the removal of coproporphyrin III from the stratum corneum during topical applications. Despite the apparent efficacy of fusidic acid cream alone, they supported the opinion of previous authors who have recommended a combination of oral and topical treatment for extensive or stubborn toe web infections.

A clinical double-blind trial of topical miconazole and clotrimazole against superficial fungal infections and erythrasma

Clayton YM, Knight AG. Clin Exp Dermatol 1976; 1: 225–32.

This was a comparison of the two preparations in dermatophyte infection, but 11 patients with erythrasma were also studied: 6 treated with miconazole, 5 with clotrimazole, both twice daily. All patients in

both groups were free of infection at 4 weeks.

Topical treatment for erythrasma

Cochran RJ, Rosen T, Landers T. Int J Dermatol 1981; 20: 562–4.

Two cases cleared with two or three times daily application of 2% aqueous clindamycin solution for 1 week. No recurrence was noted 6 weeks later.

Bifonazole – an antifungal and antibacterial agent with excellent in vitro activity against *Corynebacterium minutissimum* – an in vitro study of erythrasma

Nenoff P, Herrmann J, Kruger C, Tchernev G, Becker N. Mycoses 2012; 55: 338.

Bifonazole exhibits very good in vitro activity against *Corynebacterium* spp. This cream is available over the counter for the treatment of dermatophyte infection of the toe webs. Because coinfections are common, it may be efficient at treating both.

Second-Line Therapies

• Single-dose clarithromycin	B
• Erythromycin	C

Erythrasma treated with single-dose clarithromycin

Wharton JR, Wilson PL, Kincannon JM. Arch Dermatol 1998; 134: 671–2.

Three patients treated with a single 1-g dose of clarithromycin showed no sign of residual disease at 2 weeks. Compliance is likely to be good with this regimen.

Systemic or local treatment of erythrasma? A comparison between erythromycin tablets and Fucidin cream in general practice

Hamann K, Thorn P. Scand J Prim Health Care 1991; 9: 35–9.

This double-blind trial compared 14 days' treatment with erythromycin 500 mg twice daily, 2% fusidic acid cream twice daily, and placebo. Four weeks after treatment 18 of 21 patients with erythromycin and 23 of 25 with fusidic acid cream were cured. Both were better than placebo.

Antibiotic susceptibility of *Corynebacterium minutissimum* isolated from lesions of Turkish patients with erythrasma

Turk BG, Turkmen M, Aytimur D. J Am Acad Dermatol 2011; 65: 1230–1.

This laboratory-based study examined antibiotic susceptibility in *C. minutissimum* isolates. Interestingly, it demonstrated high levels of antibiotic resistance to erythromycin and high levels of susceptibility to fusidic acid and amoxicillin clavulanate.

Erythroderma

Tang Ngee Shim, and John Berth-Jones

Erythroderma (exfoliative dermatitis) is defined as inflammation of at least 90% of the body surface, characterized by generalized

erythema and a variable degree of scaling or desquamation. Erythroderma is commonly the result of generalization of a preexisting chronic dermatosis or a systemic disease (see [Table 77.1](#)). These include genodermatoses and congenital disorders such as severe ichthyoses and ichthyosiform erythrodermas; severe cases of dermatoses such as psoriasis and atopic, seborrheic, or contact allergic dermatitis; cutaneous T-cell lymphoma (CTCL); allergic reactions to drugs (see [Table 77.2](#)); and internal malignancies (especially lymphoma and other lymphoreticular malignancies). Some cases develop without any apparent trigger, and erythroderma remains “idiopathic” in up to 25% of the cases.

Management Strategy

Erythroderma, especially when fulminant, is a life-threatening state of skin failure that demonstrates vividly that the skin is as vital to life as any internal organ. The dangers arise from the loss of an effective barrier to entry of bacteria, from the loss of thermoregulation, from increased fluid loss through evaporation or exudation, from loss of protein due to the increased proliferative and metabolic activity that accompanies uncontrolled desquamation, and from the risk of high-output cardiac failure. All these hazards are greatest in the very young and the elderly. Many patients who are otherwise healthy can tolerate a chronic or permanently erythrodermic state. By contrast, very young and elderly patients with fulminant disease may develop septicemia and die within a matter of hours.

Many aspects of the management of a patient with erythroderma are similar, regardless of the etiology, and it is often necessary to treat a case without knowing the cause. However, for optimal longer term management it is vital to establish a more precise diagnosis whenever possible. In many cases there has been preexisting skin disease and the diagnosis may be quite clear from the history, but when erythroderma arises *de novo*, establishing the cause can be difficult or impossible. A comprehensive drug history should include all over-the-counter and herbal remedies such as St. John wort. Severe pruritus may suggest atopic eczema or lymphoma. Although physical examination may be entirely nonspecific, there may be clues such as bullae, indicating the presence of bullous pemphigoid or pemphigus foliaceus. Severe scaling is suggestive of psoriasis. Pityriasis rubra pilaris shows islands of uninvolved skin within erythrodermic

regions with “orange” palmoplantar keratoderma and follicular keratotic plugs on the knees, elbows, and dorsal aspects of the hands and toes. Sparing of the flexures (“deck-chair sign”) may suggest papuloerythroderma of Ofuji. Lymphadenopathy is often present but is more often reactive than malignant.

Histology of the skin is often nonspecific and rarely pathognomonic. Occasionally, however, the presence of atypical large lymphocytes will point to a diagnosis of CTCL, or there may be features suggestive of psoriasis, a lichenoid reaction, or pityriasis rubra pilaris. Repeated or multiple biopsies are sometimes helpful. Immunofluorescence for immunoglobulin deposition should be performed if an immunobullous disease is suspected.

Patients with acute onset of erythroderma are usually best managed in a hospital because frequent observations and intensive supportive care are required, and bed rest may be highly therapeutic. All unnecessary medications should be discontinued. Good skin care is essential. Frequent applications of abundant quantities of bland emollients such as petrolatum are required to soothe the skin, and these help to partially restore the barrier. Oatmeal baths and wet dressings to weeping or crusted sites should be followed by application of bland emollients and low-potency topical corticosteroids. Careful attention must be paid to body temperature, hydration, and nutrition.

The use of more active pharmaceutical intervention requires careful consideration. Some patients with erythroderma have multiple drug allergies. Immunosuppressive drugs may be considered to be contraindicated if malignancy is suspected (particularly cutaneous lymphoma). Topical treatments may be far more irritating than expected, and systemic absorption will be greater than usual. *Prophylactic antibiotics* such as *erythromycin* are often given orally. *Corticosteroids* are often applied topically. *Antihistamines* are often prescribed but act largely as sedatives.

If a diagnosis can be established, withdrawal of a causal drug or specific treatment for an underlying dermatosis, combined with the supportive measures described earlier, will usually produce a rapid improvement in the erythroderma. When a firm diagnosis cannot be made, treatment may have to be directed at the most likely cause, based on the clinical and histologic features.

Specific Investigations

- Hematology
- Urea and electrolytes
- Liver function tests
- Blood cultures
- Monitoring of temperature and vital signs
- Nasal and skin swabs
- Skin biopsy
- T-cell receptor analysis
- Lymph node biopsy
- Screening for connective tissue disease
- Immunodeficiency screen
- Potassium hydroxide preparation and fungal culture

Diagnosing erythrodermic cutaneous T-cell lymphoma

Russell-Jones R. Br J Dermatol 2005; 153: 1–5.

A very useful review with an algorithm to help differentiate between erythroderma due to CTCL and “reactive” causes of erythroderma. The author proposed three key procedures to determine the correct diagnosis for patients with chronic erythroderma of unknown etiology: biopsy of lesional skin, analysis of peripheral blood, and lymph node biopsy. Each sample should be analyzed for morphology, immunophenotype, and the presence of a T-cell clone.

Survival outcomes and prognostic factors in mycosis fungoides/Sézary syndrome: validation of the revised International Society for Cutaneous Lymphomas/European Organisation for Research and Treatment of Cancer staging proposal

Agar NS, Wedgeworth E, Crichton S, Mitchell TJ, Cox M, Ferreira S, et al. J Clin Oncol 2010; 28: 4730–9.

A significant difference in survival and progression was noted for patients with early-stage disease having patches alone (T1a/T2a) compared with those having patches and plaques (T1b/T2b).

Erythrodermic bullous pemphigoid

Amato L, Gallerani I, Mei S, Pestelli E, Caproni M, Fabbri P. Int J Derm 2001; 40: 343–6.

Two cases of bullous pemphigoid presented with exfoliative erythroderma. Both were treated with oral prednisolone with complete clinical resolution.

A case of erythrodermic dermatomyositis associated with gastric cancer

Kim SW, Kang YS, Park SH, Lee UH, Park HS, Jang SJ. Ann Dermatol 2009; 21: 435–9.

Subacute cutaneous lupus erythematosus presenting as erythroderma

Kalavala M, Shah V, Blackford S. Clin Exp Dermatol 2007; 32: 388–90.

Erythroderma is occasionally a presentation of dermatomyositis or lupus.

Idiopathic erythroderma: a follow-up study of 28 patients

Sigurdsson V, Toonstra J, van Vloten WA. Dermatology 1997; 194: 98–101.

During the median follow-up of 33 months, 35% of the patients went into remission and 52% improved. Three patients, all females, had persistent erythroderma. Two of these progressed to CTCL (one to Sézary syndrome and one to mycosis fungoides).

Interleukin-36γ (IL-1F9) identifies psoriasis among patients with erythroderma

Braegelmann J, D’Erme AM, Akmal S, Maier J, Braegelmann C, Wenzel J. Acta Derm Venereol 2016; 96: 386–7.

A retrospective review of histologic features seen in a series of 46 cases of erythroderma and a relatively specific stain to identify psoriasis.

Inherited ichthyoses: a review of the histology of the skin

Scheimberg I, Harper JI, Malone M, Lake BD. Pediatr Pathol Laboratory Med 1996; 16: 359–78.

A review of the histologic features in 46 cases of congenital ichthyosis. Features of bullous ichthyosiform erythroderma, Netherton syndrome, and neutral lipid storage disease can be recognized on routine hematoxylin and eosin staining. Electron microscopy, frozen sections, and other diagnostic techniques may also be required.

Early skin biopsy is helpful for the diagnosis and management of neonatal and infantile erythrodermas

Leclerc-Mercier S, Bodemer C, Bourdon-Lanoy E, Larousserie F, Hovnanian A, Brousse N, et al. J Cutan Pathol 2010; 37: 249–55.

Skin biopsy can be helpful to investigate early erythroderma of infancy, particularly in immunodeficiency and Netherton syndrome.

Use of the frozen section “jelly roll” technique to aid in the

diagnosis of bullous congenital ichthyosiform erythroderma (epidermolytic hyperkeratosis)

Galler B, Bowen C, Arnold J, Kobayashi T, Dalton SR. J Cutan Pathol 2016; 43: 434–7.

A neonate was initially diagnosed by histologic examination of detached skin (blister roof).

Congenital erythrodermic psoriasis: case report and literature review

Salleras M, Sanchez-Regana M, Umberto P. Pediatr Dermatol 1995; 12: 231–4.

A girl suffered from erythroderma, palmoplantar hyperkeratosis, and scalp desquamation since birth. A skin biopsy at 1 year of age showed features of psoriasis. She was successfully treated with acitretin at the age of 4 years. Plaque psoriasis developed at the age of 7 years.

Erythroderma due to dermatophyte

Gupta R, Khera V. Acta Dermatol Venereol 2001; 81: 70.

Dermatophytosis rarely presents as erythroderma. In this case the presence of multiple mycelia without spores in KOH preparation confirmed the clinical suspicion of dermatophytosis. The scaling and erythema completely cleared with oral fluconazole 150 mg daily and miconazole nitrate cream 2% topically.

Erythroderma as the initial presentation of the acquired immunodeficiency syndrome

Janniger CK, Gascon PM, Schwartz RA, Hennessey NP, Lambert WC. Dermatologica 1999; 183: 143–5.

Erythroderma can be the presenting feature of HIV infection.

First-Line Therapies

• Bed rest in a hospital	C
• Emollients	C

Second-Line Therapies

• Topical corticosteroids	C
• Psoralen and UVA (PUVA)	C
• Systemic corticosteroids	C
• PUVA with retinoid	E

Cushing's syndrome caused by short-term topical glucocorticoid use for erythrodermic psoriasis and development of adrenocortical insufficiency after glucocorticoid withdrawal

Durmazlar SP, Oktay B, Eren C, Eskioglu F. Eur J Dermatol 2009; 19: 169–70.

Salicylism from topical salicylates: review of the literature

Brubacher JR, Hoffman RS. J Toxicol Clin Toxicol 1996; 34: 431–6.

Hypercalcemia caused by vitamin D3 analogs in psoriasis treatment

Braun GS, Witt M, Mayer V, Schmid H. Int J Dermatol 2007; 46: 1315–7.

Low but detectable serum levels of tacrolimus seen with the use of very dilute, extemporaneously compounded formulations of tacrolimus ointment in the treatment of patients with Netherton syndrome

Shah KN, Yan AC. Arch Dermatol 2006; 142: 1362–3.

These reports illustrate the potential for unexpected toxicity due to systemic absorption of topical medications through erythrodermic skin. Care should be exercised with the use and quantities of topical medication.

Ofuji's papuloerythroderma: a study of 17 cases

Bech-Thomson N, Thomsen K. Clin Exp Dermatol 1998; 23: 79–83.

This retrospective study reviewed the clinical, laboratory, and histologic features; treatment methods; and disease course in 17 patients with papuloerythroderma. Psoralen photochemotherapy (PUVA) and oral prednisolone 10 to 20 mg daily given in combination or alone were effective, and a combination of UVB phototherapy and topical steroids was also successful.

Treatment of papuloerythroderma of Ofuji with Re-PUVA: a case report and review of the therapy

Mutluer S, Yerebakan O, Alpsoy E, Ciftcioglu MA, Yilmaz E. J Eur Acad Dermatol Venereol 2004; 18: 480–3.

A 60-year-old man with papuloerythroderma of Ofuji responded to retinoid plus PUVA (Re-PUVA).

A dermatitis–eosinophilia syndrome. Treatment with methylprednisolone pulse therapy

Dahl MV, Swanson DL, Jacob HS. Arch Dermatol 1984; 120: 1595–7.

A case of persistent erythroderma after a wasp sting despite intensive topical therapy and oral corticosteroids. Pulsed methylprednisolone, 2 g intravenously, repeated after a week, cleared the erythroderma.

Toxic shock syndrome responsive to steroids

Vergis N, Gorard DA. J Med Case Rep 2007; 1: 5.

Toxic shock syndrome should be considered in the differential diagnosis of unexplained fever, erythroderma, and features of septic shock. Systemic steroids can be lifesaving.

Third-Line Therapies

• Ciclosporin	B
• Cytotoxic drugs/antimetabolites	C
• Systemic retinoids	C
• Extracorporeal photochemotherapy	C
• UVA1 phototherapy	C
• Topical calcipotriol	E
• Topical tacrolimus	D
• Erythromycin	E
• Photopheresis and interferon	C
• Ustekinumab	E
• Brodalumab	D
• Infliximab	C
• Etanercept	C
• Alemtuzumab	E
• Daclizumab	E
• Bexarotene	D

Management of erythrodermic psoriasis with low-dose ciclosporin

Studio Italiano Multicentrico nella Psoriasi (SIMPSO). 1993; 187: 30–7.
In this open-label, multicenter study of 33 patients with

erythrodermic psoriasis, ciclosporin (initial mean dose 4.2 mg/kg/day) was slowly tapered after remission by 0.5 mg/kg every 2 weeks. Sixty-seven percent achieved complete remission, and 27% had significant improvement at 2 to 4 months.

Papuloerythroderma of Ofuji responding to treatment with ciclosporin

Sommer S, Henderson CA. Clin Exp Dermatol 2000; 25: 293–5.

A patient with papuloerythroderma of Ofuji responded to systemic steroids, but remission was not maintained on reduction of the dose. Ciclosporin was added, which led to rapid clearing of the skin, and remission was maintained after discontinuation of treatment.

Psoriatic erythroderma and bullous pemphigoid treated successfully with acitretin and azathioprine

Roeder C, Driesch PV. Eur J Dermatol 1999; 9: 537–9.

A 59-year-old man with severe psoriasis who developed bullous pemphigoid was successfully treated with acitretin and azathioprine, avoiding the use of systemic corticosteroids.

Methotrexate in psoriasis: 26 years' experience with low-dose long-term treatment

Haustein UF, Rytter M. J Eur Acad Dermatol Venereol 2000; 14: 382–8.

A retrospective review of 36 patients with erythrodermic psoriasis treated with methotrexate at varying dosages (initial dose 7.5–40 mg/week, maintenance dose 7.5–15 mg/week). Response to therapy noted within 1 to 4 weeks of onset.

Systemic methotrexate treatment in childhood psoriasis: further experience in 24 children from India

Kaur I, Dogra S, De D, Kanwar AJ. Pediatr Dermatol 2008; 25: 184–8.

Twenty-two children showed >75% reduction in Psoriasis Area and Severity Index (PASI). This retrospective study supports the use of methotrexate in severe childhood psoriasis under expert supervision and laboratory monitoring.

An appraisal of acitretin therapy in children with inherited disorders of keratinization

Lacour M, Mehta-Nikhar B, Atherton DJ, Harper JI. Br J Dermatol 1996; 134: 1023–9.

A review of the use of acitretin and etretinate in 46 children with severe ichthyoses and erythrodermas. Acitretin therapy is safe and effective, provided the minimal effective dose is maintained and that side effects are carefully monitored.

Treatment of classic pityriasis rubra pilaris

Dicken CH. *J Am Acad Dermatol* 1994; 31: 997–9.

A retrospective review of 75 cases. Retinoids offer the best chance of complete clearing. Methotrexate should be considered if retinoids fail or are contraindicated.

Treatment of refractory adult-onset pityriasis rubra pilaris with TNF-alpha antagonists: a case series

Garcovich S, Di Giampetruzzi AR, Antonelli G, Garcovich A, Didona B. *J Eur Acad Dermatol Venereol* 2010; 24: 881–4.

Pityriasis rubra pilaris is a rare inflammatory dermatosis with frequent clinical presentation as erythroderma. Seven patients with resistance or contraindication to conventional systemic treatment (six were erythrodermic) received a single course of infliximab or etanercept therapy, alone or in combination with low-dose acitretin (>0.25 mg/kg/daily). Six patients achieved complete remission after a single course of anti-TNF- α therapy.

Evidence-based practice of photopheresis 1987 to 2001: a report of a workshop of the British Photodermatology Group and the UK Skin Lymphoma Group

McKeena KE, Whittaker S, Rhodes LE, Taylor P, Lloyd J, Ibbotson S, et al. *Br J Dermatol* 2006; 154: 7–20.

Extracorporeal photopheresis in Sézary syndrome: hematologic parameters as predictors of response

Evans AV, Wood BP, Scarisbrick JJ, Fraser-Andrews EA, Chinn S, Dean A, et al. *Blood* 2001; 98: 1298–301.

Twenty-three patients with Sézary syndrome who received monthly (up to 1 year) extracorporeal photopheresis (ECP) as the sole therapy showed that 57% achieved a reduction in erythema of more than 25% from baseline.

U.K. consensus statement on the use of extracorporeal photopheresis for treatment of cutaneous T-cell lymphoma and

chronic graft-versus-host disease

Scarisbrick JJ, Taylor P, Hiltick U, Makar Y, Douglas K, Berlin G, et al. Br J Dermatol 2008; 158: 659–78.

The literature supports ECP as an effective therapy in CTCL and chronic graft-versus-host disease (GVHD).

Treatment of severe erythrodermic acute graft-versus-host disease with photochemotherapy

Kunz M, Wilhelm S, Freund M, Zimmermann R, Gross G. Br J Dermatol 2001; 144: 901–22.

A 34-year-old man with grade IV GVHD who failed three different high-dose immunosuppressive agents responded to photochemotherapy.

The benefit of PUVA treatment for acute GVHD is well known, but successful treatment of severe GVHD is less common.

“High-dose” UVA1 therapy of widespread plaque-type, nodular, and erythrodermic mycosis fungoides

Zane C, Leali C, Airó P, De Panfilis G, Pinton PC. J Am Acad Dermatol 2001; 44: 629–33.

In a series of 13 patients, 11 showed complete clinical and histologic response to 100 J/cm² UVA1 daily until remission. Nonirradiated control lesions did not improve. Serious short-term side effects were not recorded. “High-dose” UVA1 seems at least as effective as PUVA in the treatment of cutaneous mycosis fungoides.

Bullous congenital ichthyosiform erythroderma: safe and effective topical treatment with calcipotriol ointment in a child

Bogenrieder T, Landthaler M, Stolz W. Acta Venereol 2002; 83: 52–5.

A report of the safe and long-term (over 3 years) use of topical calcipotriol ointment in a 9-year-old boy with a keratinization disorder.

Successful treatment of Netherton’s syndrome with topical calcipotriol

Godic A, Dragos V. Eur J Dermatol 2004; 14: 115–7.

Efficacy and safety of tacrolimus 0.03% ointment in a 1-month-old “red baby”: a case report

Leonardi S, Rotolo N, Marchese G, La Rosa M. Allergy Asthma Proc

2006; 27: 523–6.

Erythrodermic chronic actinic dermatitis responding to topical tacrolimus

Evans AV, Palmer RA, Hawk JL. Photodermatol Photoimmunol Photomed 2004; 20: 59–61.

A 55-year-old man with erythrodermic chronic actinic dermatitis failed standard topical and systemic treatments but responded to topical tacrolimus ointment 0.1%.

Successful treatment of bullous congenital ichthyosiform erythroderma with erythromycin

Freyhaus K, Kaiser HW, Proelss J, Tüting T, Bieber T, Wenzel J. Dermatol 2007; 215: 81–3.

This patient failed to respond to acitretin 30 mg daily. Erythromycin 500 mg twice daily was instituted, and marked clinical improvement was observed within 1 month.

Combination therapy with extracorporeal photopheresis, interferon-alpha, PUVA and topical corticosteroids in the management of Sézary syndrome

Brooken N, Weiss C, Utikal J, Felcht M, Goerdts S, Klemke CD. J Dtsch Dermatol Ges 2010; 428–38.

Twelve Sézary patients were retrospectively analyzed to evaluate the combination therapy of ECP, interferon- α , PUVA, and topical corticosteroids. All Sézary patients had erythroderma, generalized lymphadenopathy, and circulating Sézary cells ($>1000/\mu\text{L}$) in the peripheral blood at the time of diagnosis. Four patients achieved a partial remission and one a stable disease.

Efficacy and safety of biologics in erythrodermic psoriasis: a multicenter, retrospective study

Viguier M, Pagés C, Aubin F, Delaporte E, Descamps V, Lok C, et al. Br J Dermatol 2012; 167: 417–23.

This study addresses the efficacy and safety of biologics (infliximab, adalimumab, etanercept, ustekinumab, and efalizumab) in 28 patients. Overall 42% of patients with erythrodermic psoriasis reached a 75% improvement of skin severity 10 to 14 weeks after starting biologics. Safety is mostly affected by infectious complications with skin origin.

Erythrodermic psoriasis improved by ustekinumab: a report of two cases

Kim YS, Kim HJ, Lee S, Park YL. *Ann Dermatol* 2016; 28: 121–2.

Sustained responses are reported in two refractory cases.

Efficacy and safety of brodalumab in patients with generalized pustular psoriasis and psoriatic erythroderma: results from a 52-week, open-label study

Yamasaki K, Nakagawa H, Kubo Y, Ootaki K. *Br J Dermatol* 2017; 176: 741–51.

Improvement or remission was observed in 18 cases of psoriatic erythroderma over the course of this 52-week study.

Infliximab as sole or combined therapy, induces rapid clearing of erythrodermic psoriasis

Takahashi MDF, Castro LG, Romiti R. *Br J Dermatol* 2007; 157: 828–31.

This is an open-label, single-center study of seven patients with erythrodermic psoriasis. One patient was treated with infliximab 5 mg/kg at week 0, 4, and 6 and methotrexate 15 mg/week. Four patients were treated with infliximab (same regimen as before) and acitretin 0.3 to 0.6 mg/kg. All five patients reported excellent outcome at week 6 after the third infusion.

Treatment of erythrodermic psoriasis with etanercept

Esposito M, Mazzotta A. *Br J Dermatol* 2006; 155: 156–9.

An open-label study of 10 patients with erythrodermic psoriasis. Etanercept was administered as a 25-mg subcutaneous injection twice weekly; 6 achieved PASI 75 and 2 achieved PASI 50 at week 24. These improvements were noted as early as week 12 of the study.

Alemtuzumab for relapsed and refractory erythrodermic cutaneous T-cell lymphoma: a single institution experience from the Robert H Lurie Comprehensive Cancer Center

Querfeld C, Mehta N, Rosen ST, Guitart J, Rademaker A, Gerami P, et al. *Leuk Lymphoma* 2009; 50: 1969–76.

This is an open-label clinical trial on the use of alemtuzumab in 19 advanced and heavily pretreated erythrodermic cutaneous T-cell lymphomas.

Novel treatment of Sézary-like syndrome due to adult T-cell

leukemia/lymphoma with daclizumab (humanized antiinterleukin-2 receptor alpha antibody)

Osborne GE, Pagliuca A, Ho A, du Vivier AW. *Br J Dermatol* 2006; 15: 617–20.

A patient with erythrodermic T-cell leukemia/lymphoma resistant to multiple therapies developed a rapid and sustained complete response to daclizumab, which suggests significant activity of anti-IL-2 receptor- α antibody in this disease process.

The treatment of cutaneous T-cell lymphoma with a novel retinoid

Heald P. *Clin Lymphoma* 2000; 1: S45–9.

Four patients with erythrodermic CTCL were treated with high-dose oral bexarotene, and all showed rapid (within 2 weeks) improvement of erythroderma.

Bexarotene therapy for mycosis fungoides and Sézary syndrome

Abbott RA, Whittaker SJ, Morris SL, Russell-Jones R, Hung T, Bashir SJ, et al. *Br J Dermatol* 2009; 160: 1299–307.

This retrospective study of 66 patients demonstrates that bexarotene is well tolerated in most patients and responses are well seen in almost half of patients with all disease stages. Two patients with erythroderma achieved complete response with bexarotene (one subsequently received reduced-intensity stem cell transplant and the other remains on bexarotene).

Erythrokeratodermas

Gabriele Richard

Erythrokeratodermas are a clinically and genetically heterogeneous group of rare inherited disorders of cornification characterized by two distinct morphologic features: localized hyperkeratosis and erythema. The hallmark of erythrokeratoderma variabilis (EKV) is the seemingly independent occurrence of transient, figurate erythema and hyperkeratosis, which can be localized or generalized. Progressive symmetric erythrokeratoderma (PSEK) is characterized

by fixed, slowly progressive, symmetric, and well-defined hyperkeratotic plaques with underlying erythema, predominantly on the extensor surface of the extremities, on the trunk, and on the face. EKV and PSEK have been observed within the same family, and the same disease-causing *GJB4* (connexin 30.3) mutation has been reported in patients with EKV and PSEK. These findings indicate that a subset of PSEK cases belong to the clinical spectrum of EKV, and the name *erythrokeratoderma variabilis et progressiva* (EKVP) has been suggested. However, many other PSEK cases do not have identifiable connexin gene mutations and likely represent a heterogeneous group of other disorders that remain to be better defined on a clinical and molecular level.

Management Strategy

Erythrokeratodermas are heritable, chronic disorders that often require lifelong treatment. Management depends on the severity and extent of hyperkeratosis, which may vary over time and from patient to patient. The spectrum may range from fixed hyperkeratotic plaques over the knees and elbows to generalized hyperkeratosis with accentuated skin markings and peeling, or thickened plates with a spiny, hystrix-like appearance.

The *topical management* of erythrokeratodermas remains a therapeutic cornerstone, although it can be disappointing in some cases. Topical treatment of patients with mild, localized hyperkeratosis is symptomatic and focuses on hydration, lubrication, and keratolysis. Whereas in some patients *emollients* such as petrolatum twice daily may suffice, most patients require topical treatment with *keratolytic agents*. Lactic acid (6%–12%) and urea applied once or twice daily in combination with emollients are effective, although their use may be limited, especially in children, because of irritation. Other α -hydroxy acids, salicylic acid (3%–6%), propylene glycol, glycolic acid (11%), topical vitamin D analogs (calcipotriol), or combinations of these are alternative treatment options. Topical treatment with *retinoids* and derivatives has been successful in some patients (especially with EKV) but ineffective in others. Regimens with newer synthetic retinoids, such as short-contact topical tazarotene therapy combined with moisturizers, seem promising in EKV. In addition, avoidance of trauma to the skin, such as sudden temperature changes, friction, and mechanical irritation,

may be beneficial.

Systemic retinoids are the treatment of choice in erythrokeratodermas with extensive or generalized skin involvement. Although they are highly effective in EKV, the therapeutic response in PSEK is less satisfactory. As is the case for other disorders of cornification, the effects of acitretin or etretinate are superior to those of systemic isotretinoin. It seems advantageous to start at low doses of acitretin for 3 to 6 weeks and then to gradually increase the dose until the desired therapeutic effect is achieved. The minimal effective maintenance dose for patients with EKV is usually lower than for patients with PSEK. Both morphologic components respond well to retinoid treatment, resulting in rapid and dramatic improvement or clearing of the hyperkeratosis and significant moderation of the erythema. In some patients with EKV the erythematous component may be completely suppressed. Nevertheless, the use of retinoids should always be considered carefully, as chronic therapy is required to achieve continuing results, and long-term side effects, especially in children, may ensue. In some cases, intermittent cycles of systemic retinoid treatment may be considered to balance between beneficial therapeutic and adverse effects. Anecdotally, *PUVA therapy* alone or combined with acitretin (Re-PUVA) has been beneficial in the treatment of PSEK. Few patients have been reported with clearing of skin lesions under oral treatment with low-dose vitamin A or a polyaromatic retinoid (arotinoid ethylester).

The variable erythema in EKV often results in cosmetic concerns, which can be limited by masking uncovered skin with makeup and camouflage. Serious discomfort due to burning and pruritus, which may accompany the variable erythema in some patients, can be therapeutically challenging. If systemic aromatic retinoid therapy alone fails to reduce or suppress erythema and the associated burning and itching sensations, symptomatic relief has been achieved in anecdotal cases with systemic therapy using sedating H_1 -antihistamines.

Specific Investigations

- Histopathology

Connexin disorders of the skin

Richard G. Clin Dermatol 2005; 23: 23–32.

Summary of the clinical features and molecular genetics of EKV and other connexin disorders. The review discusses the spectrum and mechanism of disease-causing missense mutations in the connexin genes *GJB3* and *GJB4*, which encode the gap junction proteins β -3 (connexin-31, Cx31) and β -4 (connexin-30.3, Cx30.3) associated with EKV. It also describes the mutation spectrum in other epidermal connexin genes, including *GJB2* (Cx26), *GJB6* (Cx30), and *GJA1* (Cx43).

The missense mutation G12D in connexin 30.3 can cause both erythrokeratoderma variabilis of Mendes da Costa and progressive symmetric erythrokeratoderma of Gottron

Van Steensel MAM, Oranje AP, van der Schroeff JG, Wagner A, van Geel M. Am J Med Genet Part A 2008; 149A: 657–61.

Mutation analysis in two patients with PSEK and three patients with EKV revealed the same G12D mutation in *GJB4* (Cx30.3). All five Dutch patients shared the same haplotype over 2 Mb across the disease locus, indicating that G12D might be a Dutch founder mutation, which may manifest with features of either EKV or PSEK. Systemic treatment of an adult male patient with features of PSEK with 20 to 40 mg etretinate during the wintertime reportedly resulted in satisfactory symptomatic relief. The name *erythrokeratoderma variabilis et progressiva* was proposed to indicate the clinical variability of this disorder.

Dominant de novo mutations in GJA1 cause erythrokeratoderma variabilis et progressiva, without features of oculodentodigital dysplasia

Boyden LM, Craiglow BG, Zhou J, Hu R, Loring EC, Morel KD, et al. J Invest Dermatol 2015; 135: 1540–7.

Three unrelated patients with features of EKVP as well as enlarged, porcelain-white lunulae were reported to have a pathogenic missense variant in the *GJA1* gene encoding connexin 43 (Cx43), the most widely expressed gap junction protein, which is coexpressed with *GJB3* and *GJB4* in human epidermis. In contrast, the vast majority of pathogenic sequence variants in *GJA1* cause the multisystem disorder oculodentodigital dysplasia (ODDD), which very rarely may include palmoplantar keratoderma.

Evidence for the absence of mutations at GJB3, GJB4 and LOR in progressive symmetric erythrokeratoderma

Wei S, Zhou Y, Zhang TD, Huang ZM, Zhang XB, Zhu HL, et al. Clin Exp Dermatol 2011; 36: 399–405.

None of 25 patients with PSEK was found to have a pathogenic mutation in the connexin genes *GJB3* (Cx31) and *GJB4* (Cx30.3) and the *loricrin* gene, suggesting that in the majority of cases PSEK is a disorder distinct from EKV and of currently unknown molecular cause.

First-Line Therapies

• Emollients	E
• Topical keratolytics	E
• Topical retinoids	E
• Topical calcipotriol	E

Erythrokeratoderma variabilis successfully treated with topical tazarotene

Yoo S, Simzar S, Han K, Takahashi S, Cotliar R. Pediatr Dermatol 2006; 23: 382–5.

Topical short-contact (15 minutes) treatment with tazarotene (0.05% gel) once a day followed by the application of a topical corticosteroid (fluocinolone oil) on moist skin and hydrophilic ointments resulted in complete remission of hyperkeratotic plaques and erythematous patches in a 16-month-old child with EKV within 1 month. Emollients were continued during quiescent periods, and the aforementioned regimen during flares.

Tazarotene is a topical, receptor-selective retinoid.

Erythrokeratoderma variabilis. Report of 3 clinical cases and evaluation of the topical retinoic acid treatment

Lacerda E, Costa MH, de Brito Caldeira J. Med Cutan Ibero Lat Am 1975; 3: 281–7.

Topical retinoic acid (0.1% cream) treatment of three patients with EKV substantially reduced hyperkeratosis. Discontinuation resulted in prompt relapse.

Progressive symmetrische erythrokeratodermie Darier-Gottron

Ott H, Lehmann S, Poblete-Guitierrez P, Frank J. Hautarzt 2004; 10: 994–6.

A 5-year-old boy with PSEK and severe palmoplantar keratoderma leading to flexural contractures on both hands was treated with topical steroids of various strength and urea without lasting improvement. Topical tretinoin 0.03% cream combined with hydrophilic ointments as well as physical therapy resulted in significant and lasting skin improvement and regression of contractures after a few weeks.

Erythrokeratoderma variabilis. Case report and review of the literature

Knipe RC, Flowers FP, Johnson FR Jr, DeBusk FL, Ramos-Caro FA. Pediatr Dermatol 1995; 12: 21–3.

Topical treatment with 0.025% triamcinolone cream and retinoic acid 0.05% cream, each for 4 to 6 weeks, was ineffective in a 5-month-old boy with EKV.

Progressive symmetric erythrokeratoderma: report of an Indian family

Gupta LK, Saini P, Khare AK, Mittal A. Int J Dermatol 2014; 53: e317–9.

The proband of a multigenerational family with a clinical diagnosis of PSEK showed no appreciable improvement when treated with topical emollients, urea, and salicylic acid ointment, nor with acitretin 25 mg/d for 3 months.

Progressive symmetric erythrokeratoderma – response to topical calcipotriol

Bilgin I, Bozdağ KE, Uysal S, Ermete M. J Dermatol Case Rep. 2011; 5: 50–2.

A female with symmetrically distributed, reddish-brown, hyperkeratotic plaques in flexural regions and palmoplantar keratoderma was diagnosed with PSEK and treated with 0.5 mg/kg/day isotretinoin for 2 months without improvement. Topical calcipotriol ointment applied twice daily yielded marked improvement of hyperkeratosis within 2 weeks.

Second-Line Therapies

• Acitretin	C
• Isotretinoin	E

Clinical and genetic heterogeneity of erythrokeratoderma variabilis

Common JEA, O'Toole EA, Leigh IM, Thomas A, Griffiths WAD, Venning V, et al. J Invest Dermatol 2005; 125: 920–7.

Four of six EKV patients had a reportedly good to excellent response to oral acitretin when treated with 0.125 to 0.25 mg/kg/day. Two of these patients cleared completely, one on 20 mg acitretin daily. The remaining patients had residual hyperkeratosis, especially on the legs.

Erythrokeratoderma variabilis caused by a recessive mutation in GJB3

Fuchs-Telem D, Pessach Y, Mevorah B, Shirazi I, Sarig O, Sprecher E. Clin Exp Dermatol 2011; 36: 406–11.

Third report of a consanguineous family with EKV due to an autosomal-recessive mutation in *GJB3* (Cx31). A 14-year-old boy with EKV showed dramatic improvement followed by complete resolution of hyperkeratosis with low-dose treatment (25 mg four times a week) with acitretin. The migratory erythematous patches, however,

remained.

Erythrokeratoderma variabilis

Hunzeker CM, Soldano AC, Levis WR. *Dermatol Online J* 2008; 14: 13.

A 51-year-old woman with EKV was treated with acitretin 25 mg/day. After 4 months, near complete clearance of hyperkeratotic plaques and erythematous patches was achieved except for hyperpigmentation, and no appreciable side effects were observed.

Erythrokeratoderma variabilis responding to low-dose isotretinoin

Singh N. *Pediatr Dermatol* 2010; 27: 111–3.

Low-dose treatment with oral isotretinoin at a dose of 0.5 mg/kg body weight per day along with topical emollients yielded remarkable improvement of hyperkeratotic plaques and erythema in a 2-year-old boy with EKV. No significant side effects were observed during continued treatment over the next 6 months. The author concludes that low-dose therapy with isotretinoin is better tolerated, has fewer side effects, and is cheaper compared with high-dose therapy.

Both low-dose arotinoid ethylester and acitretin are effective in the treatment of familial erythrokeratoderma variabilis

Zhang L, Hong Y, Zheng S, Huo W, Qi R, Geng L, et al. *Dermatol Ther* 2014; 27: 240–3.

Two siblings clinically diagnosed with EKV reached clearing of skin lesions within 2 weeks/2 months with systemic therapy with either 0.03 mg/day arotinoid ethylester or 30 mg acitretin/day, respectively, and remained symptom free with reduced dosage for up to 6 to 12 months. Upon cessation of systemic treatment, relapse occurred after 3 or 6 months, respectively.

Erythrokeratoderma variabilis with adult onset: report of a sporadic case unresponsive to systemic retinoids

Erbagci Z, Tuncel AA, Deniz H. *J Dermatol Treat* 2006; 17: 187–9.

An unusual case with onset of fixed erythrokeratoderma at 23 years of age. Topical steroids, topical PUVA for 3 months, and keratolytics (10% salicylic acid) did not yield satisfactory results. Subsequent systemic isotretinoin (0.7 mg/kg/day) combined with topical ointments containing 20% urea did not show improvement after 3

months. Acitretin (0.5 mg/kg/day) for 5 months also did not achieve a significant therapeutic response. However, sedating oral H₁-antihistamines were beneficial for relief of pruritus.

Third-Line Therapies

• PUVA	E
• H ₁ -antihistamines	E

Erythrokeratoderma variabilis: successful treatment with retinoid plus psoralen and ultraviolet A therapy

Yüksek J, Sezer E, Köseoglu D, Marcoç F, Yildiz H. Jpn Dermatol Assoc J 2010; 725–7.

A female with EKV was first treated with 10 mg/day acitretin. After 1 week, PUVA therapy was added with 0.5 J/cm² UVA twice weekly, with incremental increases by 0.5 J/cm² UVA up to a cumulative dose of 129 J/cm². A significant improvement of hyperkeratosis and erythema was achieved after 3 months; then PUVA was stopped, and acitretin was continued for up to 9 months. Dry lips were the only side effects observed. Follow-up after discontinued Re-PUVA was not reported.

Gottron's erythroderma congenitalis progressiva symmetrica

Levi L, Beneggi M, Crippa D, Sala GP. Hautarzt 1982; 33: 605–8.

In one family with PSEK an adult patient was treated with an aromatic retinoid for 8 weeks, whereas her child received PUVA therapy for a total of 63 J/cm² UVA. Both treatments were effective and reduced hyperkeratosis, but PUVA achieved superior results.

Erythrokeratoderma variabilis: case report and review of literature

Papadavid E, Koumantaki E, Dawber RPR. J Eur Acad Dermatol

Venereol 1998; 11: 180–3.

A good therapeutic response to systemic etretinate with an initial dosage of 25 mg/day and a maintenance dosage of 10 mg/day. Regular use of an oral H₁-antihistamine was helpful in controlling the pruritus associated with the erythematous component of EKV.

Erythromelalgia

Cato Mørk, and Knut Kvernebo

Erythromelalgia (*erythros* – redness; *melos* – extremity; *algos* – pain) is an uncommon neurovascular disorder characterized by redness, increased skin temperature, and pain that usually occurs in the extremities. Pain is aggravated by warming and relieved by cooling. Symptoms and findings are usually intermittent and often missing during examination. Between attacks acrocyanosis, perniosis, and Raynaud phenomenon may occur. Severity of symptoms varies from mild discomfort (most common) to disabling pain and gangrene. The diagnosis is often missed in cases with mild symptoms, whereas severe erythromelalgia is a rare condition.

Erythromelalgia can be a primary condition, or secondary to a primary microvascular event, or due to a primary autonomic nervous

dysfunction. Regardless of etiology, the final common pathway of the pathogenesis includes maldistribution of skin perfusion with increased deep plexus thermoregulatory perfusion and a relative lack of papillary nutritive perfusion with a corresponding degree of skin hypoxia.

Some erythromelalgia patients have a family history with genetic variants within the *SCN9A* gene encoding for the Na_v1.7, a voltage-gated sodium channel located on nerve endings. These mutations substantially alter an individual's perception of pain secondary to detection and transmission of noxious stimuli by the peripheral nervous system. The genetic variants within this gene can also cause other diseases.

Management Strategy

Before beginning a treatment regimen, the patient's condition should be classified according to whether it is primary or secondary, the etiology (for secondary cases), and its severity. Erythromelalgia may be secondary to underlying diseases, such as myeloproliferative, connective tissue, cardiovascular, infectious, and neurologic diseases, diabetes mellitus, vasculitis, and neoplasia. If present, a primary condition should be optimally treated. There are many reports of remission after treatment of myeloproliferative disorders. Drug-induced erythromelalgia has been reported secondary to substances that may alter vasomotor tone, such as calcium channel blockers, bromocriptine, norepinephrine (noradrenaline), pergolide, ticlopidine, ciclosporin, iodine contrast, and mushroom and mercury poisoning.

All patients benefit from local *skin cooling* (applying cold towels or wet sand, walking on cold floors or even in the snow, air-conditioned rooms, or immersion in cooled water) and from elevation of the affected limb. Aggressive cooling may cause injury and worsen the erythromelalgia. Comfortable shoes to relieve pressure over the soles can help. Aggravating factors such as warmth, exercise, dependency of the extremity, tight shoes and gloves, and alcohol intake in some cases should be avoided.

No single medication or other treatment modality has been found to be universally helpful. Spontaneous remissions have occurred without treatment. There is a marked variation in therapeutic

responses. Few controlled clinical trials have been published. The main reason may be the low prevalence, the heterogeneity of patients, and the lack of laboratory diagnostic methods.

Analgesics, including opiate analgesics, often have limited effect. Numerous drugs have been used with varying success. A few patients become free of symptoms with *acetylsalicylic acid*. Case reports or series of patients have shown beneficial effect with *vasodilators* (prostaglandin E₁/prostacyclin or analogs, sodium nitroprusside, naftidrofuryl, calcium channel blockers). Other drugs that may be of benefit are *sodium channel blockers*, *antidepressants*, and *anticonvulsants*.

Numerous treatment alternatives based on case reports have been presented in the literature, such as topical *amitriptyline/ketamine*, *lidocaine*, *capsaicin*, *midodrine*, and *nitroglycerin*. Anecdotally, *ketanserin*, *methysergide*, *pizotifen*, β -blockers, *cypheptadine* or other *antihistamines*, *carbamazepine*, *clonazepam*, *corticosteroids* or other *immunosuppressants*, *pentoxifylline*, *phenoxybenzamine*, *opiates*, *prazosin*, and *pregabalin* have been presented as effective. *Hyperbaric oxygen* treatment, *spinal cord stimulation*, *thalamic stimulation*, and *epidural blocks* have also been proposed. *Sympathectomy* has been beneficial in some patients and in other patients caused worsening of symptoms. Treatment modalities such as *hypnosis*, *biofeedback*, and learning to avoid triggers can be beneficial for coping with pain. A survey of members of The Erythromelalgia Association (TEA, www.erythromelalgia.org) shows that more than 50 therapeutic regimens have been tried out. TEA is a nonprofit organization that may be helpful in providing information, awareness, and support.

Specific Investigations

- Full blood count with white cell differential count
- Serum chemistry, including blood sugar
- Antinuclear antibody and relevant rheumatologic tests
- Skin biopsy may be considered

Nonspecific capillary proliferation and vasculopathy indicate skin hypoxia in erythromelalgia

Kalgaard OM, Clausen OP, Mellbye OJ, Hovig T, Kvernebo K. Arch Dermatol 2011; 147: 309–14.

Platelet-mediated erythromelalgic, cerebral, ocular and coronary microvascular ischemic and thrombotic manifestations in patients with essential thrombocythemia and polycythemia vera: a distinct aspirin-responsive and Coumadin-resistant arterial thrombophilia

Michiels JJ, Berneman Z, Schroyens W, Koudstaal PJ, Lindemans J, Neumann HA, et al. Platelets 2006; 17: 528–44.

Erythromelalgia—a thrombotic complication in chronic myeloproliferative disorders

Tarach JS, Nowicka-Tarach BM, Matuszek B, Nowakowski A. Med Sci Monit 2000; 6: 204–8.

Erythromelalgia is seen secondary to platelet aggregation and peripheral microvascular occlusion in myeloproliferative disorders and, untreated, may progress to painful acrocyanosis and even peripheral gangrene. Remission is observed after treatment of the myeloproliferative disorder.

First-Line Therapies

• Treatment of underlying disease	C
• Aspirin	D
• Prostaglandins/prostacyclin or oral analogs	A

Treatment of secondary erythromelalgia addresses treatment of the accompanying diseases, conditions, and elimination of pharmacologic substances. A beneficial effect on the symptoms of erythromelalgia after successful treatment or elimination of the primary condition indicates a causal relationship.

Aspirin-responsive, migraine-like transient cerebral and ocular ischemic attacks and erythromelalgia in JAK2-positive essential thrombocythemia and polycythemia vera

Michiels JJ, Berneman Z, Gadisseur A, Lam KH, De Raeve H, Schroyens W. Acta Hematol 2015; 133:56–63.

Aspirin 250 to 500 mg daily or less may completely abolish the symptoms in erythromelalgia secondary to myeloproliferative conditions. The response is probably due to the antiplatelet effect. A reduction of platelet numbers by cytostatic treatment may also lead to relief.

The Erythromelalgia Association Survey 2003

www.erythromelalgia.org.

In a survey, 128 respondents had used aspirin (80–250 mg daily): 4 reported complete, 17 moderate, and 22 minimal relief; 78 had no improvement; and 6 reported worsening of their symptoms.

Aspirin should be tried in all patients with erythromelalgia without contraindications to its use.

Erythromelalgia—a condition caused by microvascular arteriovenous shunting

Kvernebo K. Vasa 1998; 27: 3–39.

Based on the hypothesis of arteriovenous shunting, prostaglandin E₁ (PGE₁) and prostacyclin were tried as an intravenous infusion to enhance nutritive skin perfusion in severe erythromelalgia. In 9 of 10 patients, PGE₁ given as a continuous infusion for 3 days, starting with 6 ng/kg/min, then 10 ng/kg/min, and finally 12 ng/kg/min, induced remission from 3 months to 2 years. Two children were cured (observation time after treatment >25 years).

Prostacyclin reduces symptoms and sympathetic dysfunction in erythromelalgia in a double-blind randomized pilot study

Kalgaard OM, Mørk C, Kvernebo K. Acta Derm Venereol 2003; 83: 442–4.

Significant reduction in symptoms and sympathetic dysfunction were demonstrated in eight patients treated with prostacyclin infusion compared with four patients with placebo infusion.

The prostaglandin E₁ analog misoprostol reduces symptoms and microvascular arteriovenous shunting in erythromelalgia—a double-blind, crossover, placebo-compared study

Mørk C, Salerud EG, Asker CL, Kvernebo K. J Invest Dermatol 2004; 122: 587–93.

Oral misoprostol (0.4–0.8 mg/day) reduced symptoms significantly

more than placebo. Misoprostol is recommended as a first-line treatment, although many patients do not respond.

Second-Line Therapies

• Sodium channel blockers (lidocaine, mexiletine, bupivacaine, XEN402)	C, D
• Gabapentin	D
• Antidepressants (venlafaxine, sertraline)	D
• Sodium nitroprusside	D

Treatment of Na_v1.7-mediated pain in inherited erythromelalgia using novel sodium channel blocker

Goldberg YP, Price N, Namdari R, Cohen CJ, Lamers MH, Winters C, et al. *Pain*. 2012; 153: 80–5.

An exploratory, randomized, double-blind, two-period, crossover pilot study was conducted in four *SCN9A* mutation-proven inherited erythromelalgia patients using the orally administered Na_v1.7 antagonist XEN402 400 mg twice daily or placebo for 2 days, separated by a 2-day washout period. Alleviation of erythromelalgia-associated pain was demonstrated. The result is interesting, but XEN402 is not commercially available.

Mexiletine as a treatment for primary erythromelalgia: normalization of biophysical properties of mutant L858F NaV 1.7 sodium channels

Gregg R, Cox JJ, Bennett DL, Wood JN, Werdehausen R. *Br J Pharmacol* 2014; 171: 2255–63.

Mexiletine has a normalizing effect on the pathologic gating properties of the L858F gain-of-function mutation in NaV 1.7.

Lidocaine patch for pain of erythromelalgia: follow-up of 34 patients

Davis MD, Sandroni P. *Arch Dermatol* 2005; 141: 1320–1.

Anesthetic agents (lidocaine, bupivacaine, mexiletine) that block the sodium channels may be used topically, intravenously, orally, epidurally, or intrathecally. A 90% reduction in pain was

demonstrated with lidocaine IV infusion, but hospitalization is required. A 5% lidocaine patch for 12 hours/day was found helpful as first-line and adjunctive treatment of severely affected patients with erythromelalgia. Sixteen patients had no improvement, but 18 patients had a 5% to 90% improvement in pain score.

Pediatric erythromelalgia: a retrospective review of 32 cases evaluated at Mayo Clinic over a 37-year period

Cook-Norris RH, Tollefson MM, Cruz-Inigo AD, Sandroni P, Davis MDP, Davis DMR. J Am Acad Dermatol 2012; 66: 416–23.

Earlier treatment with gabapentin (2/6) and antidepressants (4/10) was reported very or somewhat helpful.

Treatment of familial erythromelalgia with venlafaxine

Firmin D, Roduedas AM, Greco M, Morvan C, Legoupil D, Fleuret C, et al. J Eur Acad Dermatol Venereol 2007; 21: 836–7.

Venlafaxine helped the mother. She had two sons with erythromelalgia—the drug did not help one son, and the other son discontinued the medication after 1 week because of a stomachache and vertigo.

Erythromelalgia—a condition caused by microvascular arteriovenous shunting

Kvernebo K. Vasa 1998; 27: 3–39.

Sodium nitroprusside intravenously for 7 days in increasing doses (1, 3, and 5 µg/kg/min) was successful in two patients with severe acute-onset erythromelalgia. The effect was accompanied by normalization of skin perfusion and transcutaneous oximetry.

Third-Line Therapies

Other therapies

- | | |
|--|----------|
| <ul style="list-style-type: none">• Oral: calcium channel blockers, magnesium, pregabalin,• Topical: amitriptyline/ketamine, midodrine, capsaicin | C |
|--|----------|

Erythromelalgia: new theories and new therapies

Cohen JS. J Am Acad Dermatol 2000; 43: 841–7.

Various calcium channel blockers may be helpful in about 25% of patients with erythromelalgia ($n = 43$). As they can cause or exacerbate symptoms, they should be used with caution and with the use of short-acting drugs initially.

They are frequently used, but documentation for beneficial effect is sparse (6 of 14 patients). Their mechanism of action may be smooth muscle relaxation and reduced vascular responses elicited by β_2 -adrenoceptors.

High-dose oral magnesium treatment of chronic, intractable erythromelalgia

Cohen JS. Ann Pharmacother 2002; 36: 255–60.

Magnesium is a naturally occurring calcium channel blocker. Eight of 13 patients reported improvement, 4 no response, and 1 deterioration using magnesium in various doses (up to 1000 mg/day) and forms.

Erythromelalgia

Davis MD, Rooke T. Curr Treat Options Cardiovasc Med 2006; 8: 153–65.

A review paper.

Response of primary erythromelalgia to pregabalin therapy

Kalava K, Roberts C, Adair JD, Raman V. J Clin Rheumatol 2013; 19: 284–5.

Using pregabalin at a dose of 100 mg three times a day, improvement was noted within 6 weeks in a 14-year-old girl.

Topical amitriptyline combined with ketamine for the treatment of erythromelalgia: a retrospective study of 36 patients at Mayo Clinic

Potrucha TJ, Weiss WT, Warndahl RA, Rho RH, Sandroni P, Davis MD, et al. J Drugs Dermatol 2013; 12: 308–10.

The authors reported 75% improvement in pain with topical application of a compounded amitriptyline–ketamine formulation. The medication was well tolerated.

Topically applied midodrine, 0.2%, an α_1 -agonist, for the treatment of erythromelalgia

Davies MD, Morr CS, Warndahl RA, Sandroni P. JAMA Dermatol 2015; 151: 1025–6.

Eleven of 12 improved, with only 2 of 12 having adverse reactions (one gastrointestinal discomfort, and the other displaying an increase in blood pressure).

The use of capsaicin cream in a case of erythromelalgia

Muhiddin KA, Gallen IW, Harries S, Pearce VR. Postgrad Med J 1994; 70: 841–3.

A 68-year-old woman with erythromelalgia responded to a twice-daily application of capsaicin cream 0.025% within 48 hours.

Erythropoietic protoporphyrria

Maureen B. Poh-Fitzpatrick

In this metabolic disorder, a genetically determined deficiency of ferrochelatase enzyme activity in bone marrow erythroid cells causes abnormally high protoporphyrin levels in erythrocytes, plasma, liver, bile, and feces. Protoporphyrin is a photoactive intermediary of heme synthesis. In the skin, its exposure to long-wave ultraviolet (UV) or visible light radiation can elicit oxygen-dependent acute cutaneous

phototoxicity. Protoporphyrin undergoes hepatobiliary excretion, facilitating cholelithiasis. Protoporphyrin hepatotoxicity may develop and progress to irreversible liver failure. Hypochromic microcytic anemia, when present, is typically mild and rarely requires treatment. A rare phenotypically similar disorder (X-linked dominant protoporphyria), arising from gain-of-function mutations in the erythroid-specific 5-aminolevulinic acid synthase gene, has a larger ratio of excess erythrocyte zinc-protoporphyrin to metal-free protoporphyrin than does erythropoietic protoporphyria. It is amenable to the same therapies.

Management Strategy

Protoporphyrinic photosensitivity typically requires *sun avoidance* (lifestyle changes, protective clothing, physical barriers), which may lead to vitamin D deficiency. *Topical sunscreens* containing *titanium dioxide*, *zinc oxide*, *iron oxide*, or *dihydroxyacetone* block or filter long-wave UV and visible-light spectra, but offer limited relief. Epidermal melanization and hyperplasia achieved with *ultraviolet B (UVB)* or *psoralen plus ultraviolet A (PUVA) phototherapy*, or an α -melanocyte-stimulating hormone analog (*afamelanotide*), can increase sunlight tolerance. Oral agents believed to photoprotect by quenching excited oxygen species include β -carotene, cysteine, vitamin E, vitamin C, flavonoids, and possibly pyridoxine. Antihistamines may attenuate phototoxic flaring. Gallstones are managed *surgically*. Exacerbators of protoporphyrin-induced hepatotoxicity (alcohol, cholestatic drugs, dietary carbohydrate restriction) are best avoided. Vaccination against hepatitis A and B is recommended. Deteriorating liver function is only sporadically reversible by *enteric sorbents* (*cholestyramine*, *activated charcoal*) that interrupt enterohepatic porphyrin circulation, *bile acids* (to stimulate biliary protoporphyrin secretion), *blood transfusion or exchange*, *hematin infusion*, *glucose loading* (to retard endogenous porphyrinogenesis), *iron* (to increase protoporphyrin conversion to heme), or various combinations thereof. *Cimetidine* is postulated to inhibit porphyrinogenesis. End-stage liver disease warrants *liver transplantation*, aided by measures to reduce preoperative, intraoperative, and postoperative porphyrin levels (*exchange transfusion*, *hematin infusion*, *plasmapheresis*, *vitamin E*). Operating room lamps should be filtered to exclude wavelengths damaging to porphyrin-photosensitized skin and internal organs. *Hematopoietic cell*

transplantation has been curative in highly selected cases and is optimal prevention for protoporphyric hepatopathy in native or transplanted livers.

Specific Investigations

- Porphyrin analyses in erythrocytes (including metal-free: zinc protoporphyrin ratio), serum or plasma, urine, feces
- Hematologic profile, iron studies if anemic
- Liver function profile, liver imaging, liver biopsy as clinically indicated
- Mutation analysis (for diagnostic confirmation and family counseling)
- Vitamin D assessment, bone density scan

Liver failure occurs in <5% of all cases. Because urine is typically free of excess porphyrins in uncomplicated protoporphyria, surveillance for coproporphyrinuria may identify patients with asymptomatic hepatic dysfunction.

Erythropoietic protoporphyria

Lecha M, Puy H, Deybach JC. Orphanet J Rare Dis 2009; 4: 19.

A comprehensive review of protoporphyria.

First-Line Therapies

• Topical sunscreens, physical barriers	C
• β -Carotene	B
• Afamelanotide	A
• Vitamin D and calcium	D

Efficiency of opaque photoprotective agents in the visible light range

Kaye ET, Levin JA, Blank IH, Arndt KA, Anderson RR. Arch Dermatol 1991; 127: 351–5.

Efficacy and cosmetic quality of sunscreens containing zinc oxide, titanium dioxide, and iron oxide.

Erythropoietic protoporphyria: IV. Protection from sunlight

Fusaro RM, Runge WJ. Br Med J 1970; 1: 730–1.

Seven patients had prolonged sunlight tolerance after applying a 3% dihydroxyacetone and 0.13% lawsone skin cream causing brown coloration of the stratum corneum.

Beta-carotene therapy for erythropoietic protoporphyria and other photosensitivity diseases

Mathews-Roth MM, Pathak MA, Fitzpatrick TB, Harber LH, Kass EH. Arch Dermatol 1977; 113: 1229–32.

Of 133 patients with protoporphyria, 84% had a threefold increase in sunlight tolerance after ingesting pharmaceutical-grade β -carotene now available without prescription (Lumitene, Tischcon). Doses producing serum levels of $\sim 800 \mu\text{g/dL}$ (children: 30–120 mg/day, adults: 120–300 mg/day, in two to three doses with meals) should be started 4 to 6 weeks before seasonal symptoms are anticipated. Efficacy varies and is often nil. Contraindicated in smokers due to increased lung cancer among heavy smokers treated with β -carotene in cancer prevention trials.

Long-term observational study of afamelanotide in 115 patients with erythropoietic protoporphyria

Biolcati G, Marchesini E, Sorge F, Barbieri L, Schneider-Yin X, Minder EI. Br J Dermatol 2015; 172: 1601–12.

Afamelanotide for erythropoietic protoporphyria

Langendonk JG, Balwani M, Anderson KE, Bonkovsky HL, Anstey AV, Bissell DM, et al. N Engl J Med 2015; 373: 48–59.

Afamelanotide increases skin melanization and may have other beneficial effects. Clinical trials of a subcutaneously implantable form have involved ~ 300 protoporphyria patients worldwide. It is available by prescription in Europe and pending Food and Drug Administration (FDA) approval in the United States.

Bone mineral density and vitamin D levels in erythropoietic

protoporphyria

Allo G, del Carmen Garrido-Astray M, Méndez M, De Salamanca RE, Martínez G, Hawkins F. *Endocrine* 2013; 44: 803–7.

Nine of 10 protoporphyria patients had low vitamin D levels, and 8 had low bone mineral density. Monitoring of serum vitamin D levels and supplementation with vitamin D and calcium are recommended.

Second-Line Therapies

• Phototherapy (UVB, PUVA)	D
----------------------------	----------

Narrow-band (TL-01) UVB phototherapy: an effective preventative treatment for the photodermatoses

Collins P, Ferguson J. *Br J Dermatol* 1995; 132: 956–63.

Six patients with protoporphyria had increased sunlight tolerance after serial narrowband UVB treatments.

Photo(chemo)therapy and general management of erythropoietic protoporphyria

Roelandts R. *Dermatology* 1995; 190: 330–1.

PUVA can increase sun tolerance; other treatments are reviewed.

Third-Line Therapies

• Cysteine	A
• Antihistamines	D
• Vitamin E	D
• Vitamin C	A
• Pyridoxine	E
• Flavonoids	E
• Iron	D
• Cholestyramine, activated charcoal	D
• Blood transfusion or exchange	D
• Hematin infusion	D
• Plasmapheresis	D
• Bile acids	D
• Liver transplantation	B
• Hematopoietic cell transplantation	D

Long-term treatment of erythropoietic protoporphyria with cysteine

Mathews-Roth MM, Rosner B. Photodermatol Photoimmunol Photomed 2002; 18: 307–9.

Forty-seven patients received placebo for 1 month, then cysteine 500 mg twice daily in this phase III 3-year trial. Patient history forms and light exposure diaries were kept; some patients were phototested. Cysteine significantly increased light tolerance subjectively and

objectively.

Inhibition of photosensitivity in erythropoietic protoporphyria with terfenadine

Farr PM, Diffey BL, Matthews JNS. Br J Dermatol 1990; 122: 809–15.

Terfenadine 60 to 120 mg twice daily for 48 days significantly reduced the flare surrounding, but not the erythema within, blue light phototest sites on seven subjects, compared with pretreatment reactions.

Antihistamines have not provided much relief in clinical practice.

Cimetidine reduces erythrocyte protoporphyrin in erythropoietic protoporphyria

Yamamoto S, Hirano Y, Horie Y. Am J Gastroenterol 1993; 88: 1465–6.

This H₂ receptor antagonist (800 mg four times daily orally) was given to a patient with protoporphyrin liver disease. Erythrocyte protoporphyrin fell from 16,000 µg/dL to 11,000 µg/dL during treatment. Inhibition of heme synthesis by cimetidine was postulated.

Only three porphyrin measurements were obtained: before and immediately after 2 weeks of cimetidine and 2 weeks after discontinuation.

Novel Treatment Using Cimetidine for Erythropoietic Protoporphyria in Children. Briefly reported improved photosensitivity, erythrocyte protoporphyrins and hepatic transaminases after cimetidine treatment of 3 children calls for confirmatory studies. (Tu JH, Sheu SL, Teng JM. JAMA Dermatol 2016; 152: 1258–61).

A case of erythropoietic protoporphyria with liver cirrhosis suggesting a therapeutic value of supplementation with alpha-tocopherol

Komatsu H, Ishii K, Imamura K, Maruyama K, Yonei Y, Masuda H, et al. Hepatol Res 2000; 18: 298–309.

A patient with severe protoporphyrin hepatopathy received intravenous vitamin E 500 IU/day. Erythrocyte protoporphyrin decreased significantly, and liver function improved. Sixteen weeks later, full clinical and biochemical recovery was noted.

Vitamin E has been used sporadically in protoporphyria, usually as adjunctive therapy.

A double-blind, placebo-controlled, crossover trial of oral vitamin

C in erythropoietic protoporphyria

Boffa MJ, Ead RD, Reed P, Weinkove C. Photodermatol Photoimmunol Photomed 1996; 12: 27–30.

Vitamin C 1 g/day orally for 4 weeks was subjectively assessed by 9 of 12 patients to be associated with less photosensitivity than placebo, but the data did not reach significance.

Antioxidants such as vitamins C and E are postulated to quench porphyrin-generated oxyradicals in vivo.

Relief of the photosensitivity of erythropoietic protoporphyria by pyridoxine

Ross JB, Moss MA. J Am Acad Dermatol 1990; 22: 340–2.

Two patients given oral pyridoxine dosages varying from 100 mg to 1 g/day reported increased sunlight tolerance.

Treatment of erythropoietic protoporphyria with hydroxyethylrutosides

Schoemaker JH, Bousema MT, Zijlstra H, van der Horst FA. Dermatology 1995; 191: 36–8.

A flavonoid mixture was ingested by a patient for 3 months, during which time phototesting and subjective assessment indicated reduced photosensitivity.

Iron therapy for hepatic dysfunction in erythropoietic protoporphyria

Gordeuk VR, Brittenham GM, Hawkins CW, Mukhtar H, Bickers DR. Ann Intern Med 1986; 105: 27–31.

Carbonyl iron 400 to 4000 mg/day orally was given for 15 weeks to a patient with protoporphyria, iron-deficiency anemia, and liver dysfunction. Erythrocyte porphyrin fell, photosensitivity improved, and liver function normalized.

In the same case, oral ferrous sulfate 300 mg/day was given when liver function and porphyrin levels worsened again. Liver function again normalized and remained stable for several years.

Symptomatic response of erythropoietic protoporphyria to iron supplementation

Holme SA, Thomas CL, Whatley SD, Bentley AV, Badminton MN. J Am Acad Dermatol 2007; 56: 1070–2.

A patient reported greater sunlight tolerance while taking oral

ferrous sulfate 200 mg twice daily.

Erythropoietic protoporphyria and iron therapy

McClements BM, Bingham A, Callendar ME, Trimble ER. Br J Dermatol 1990; 122: 423–4.

Oral ferrous fumarate 580 mg/day was followed by florid photosensitivity in a patient previously tolerant of iron supplements. Abnormal liver enzymes improved and erythrocyte protoporphyrin diminished after iron discontinuation.

In ferrochelatase-deficient protoporphyria patients, ALAS2 expression is enhanced and erythrocytic protoporphyrin concentration correlates with iron availability

Barman-Aksözen J, Minder EI, Schubiger C, Biolcati G, Schneider-Yin X. Blood Cells Mol Dis 2015; 54: 71–7.

It is been postulated that mild iron deficiency may limit protoporphyrin excess in erythropoietic protoporphyria and that iron should be repleted only when symptoms of iron deficiency are incapacitating.

Iron supplementation in protoporphyria is contentious, as patients have been both better and worse after iron. Fortunately, the mild iron-deficiency anemia is usually asymptomatic.

Fecal protoporphyrin excretion in erythropoietic protoporphyria: effect of cholestyramine and bile acid feeding

McCullough AJ, Barron D, Mullen KD, Petrelli M, Mukhtar H, Bickers DR. Gastroenterology 1988; 94: 177–81.

Ingesting cholestyramine 12 g daily, but not bile acids 300 to 900 mg, increased fecal protoporphyrin excretion threefold in one patient with hepatic dysfunction. Liver function and photosensitivity improved after 1 year of cholestyramine.

Bile acid ingestion has been reported to be associated with improved liver function and erythrocyte porphyrin levels in another patient who eventually succumbed to liver failure. Efficacy remains uncertain, but bile acids in conjunction with an enteric sorbent in selected cases are rational therapy.

Liver failure in protoporphyria: long-term treatment with oral charcoal

Gorchein A, Foster GR. Hepatology 1999; 29: 995–6.

A patient with deteriorating hepatic function given activated

charcoal 10 to 12.5 g orally four times a day for 2 years exhibited improved liver function, and blood porphyrin and photosensitivity diminished. Other treatments included blood transfusions, vitamin supplements, amiloride, ranitidine, and lactulose, so it is difficult to assess their relative merits.

Liver disease in erythropoietic protoporphyria: insights and implications for management

Anstey AV, Hift RJ. Gut 2007; 56: 1009–18.

A detailed review of the pathogenesis of protoporphyric hepatopathy and recommendations for its monitoring and treatment.

Liver transplantation for erythropoietic protoporphyria liver disease

Mcguire BM, Bonkovsky HL, Carithers RL, Chung RT, Goldstein LI, Lake JR, et al. Liver Transpl 2005; 11: 1590–6.

Experience with 20 patients receiving liver transplants in the United States from 1999 to 2004 is reviewed, including preoperative use of hematin, with or without plasmapheresis.

Liver transplantation for erythropoietic protoporphyria in Europe

Wahlin S, Stal P, Adam R, Karam V, Porte R, Seehofer D, et al. Liver Transpl 2011; 17: 1021–6.

A comparable European review of 35 liver transplants performed from 1983 to 2008. Hematopoietic stem cell transplantation was performed for three patients to prevent graft loss due to disease recurrence. Offering curative stem cell transplantation to patients at high risk for liver failure to forestall transplantation is suggested.

Perioperative measures during liver transplantation for erythropoietic protoporphyria

Meerman L, Verwer R, Sloof MJH, van Hattum J, Beukeveld GJ, Kleibeuker JH, et al. Transplantation 1994; 57: 155–8.

Protocols for exchange transfusion and shielding of operating room lamps.

The value of intravenous heme-albumin and plasmapheresis in reducing postoperative complications of orthotopic liver transplantation for erythropoietic protoporphyria

Reichheld JH, Katz E, Banner BF, Szymanski IO, Saltzman JR,

Bonkovsky HL. Transplantation 1999; 67: 922–8.

Three months of heme infusions (4 g daily to weekly), a high-carbohydrate diet (300 mg/day), intravenous glucose, ursodeoxycholic acid (900 mg/day orally), and cholestyramine (10 g thrice daily orally) initially improved severe liver dysfunction in a patient who then deteriorated and required urgent transplantation. Intensive heme infusions (daily for 18 days), plasmapheresis (exchanges of 1–1.5 × total plasma volume performed 12 times over 19 days), and blood transfusions (14 units packed cells over 19 days) reduced blood porphyrins before successful transplantation was performed in an illumination-filtered environment to exclude 300- to 480-nm wavelengths.

A barrage of medical therapy is typical in protoporphyric crises, when it is rational to consider any treatments that might reverse deterioration or contribute to successful transplantation. Subsequently, recurrent liver dysfunction was again successfully managed with heme-albumin and plasmapheresis (Do KD, Banner BF, Katz E, Szymanski IO, Bonkovsky HL. Transplantation 2002; 73: 469–7).

Treatment of recurrent allograft dysfunction with intravenous hematin after liver transplantation for erythropoietic protoporphyria

Dellon ES, Szczepiorkowski ZM, Dzik WH, Graeme-Cook F, Ades A, Bloomer JR, et al. Transplantation 2002; 73: 911–5.

Hematin given intermittently for 2 years after protoporphyric hepatopathy recurred 700 days after transplantation was well tolerated and aided the achievement and maintenance of disease remission in the allograft.

Erythropoietic protoporphyria: altered phenotype after bone marrow transplantation for myelogenous leukemia in a patient heteroallelic for ferrochelatase gene mutations

Poh-Fitzpatrick MB, Wang X, Anderson K, Bloomer JR, Bolwell B, Lichten AE. J Am Acad Dermatol 2002; 46: 861–6.

A symptomatic woman harboring two ferrochelatase gene mutations developed leukemia. Bone marrow transplantation from a mildly affected sibling with only one mutation and minimally elevated blood porphyrin resulted in marked reduction of the recipient's protoporphyrin levels and cutaneous photosensitivity, as well as leukemia remission.

Sequential liver and bone marrow transplantation for treatment of erythropoietic protoporphyria

Rand ER, Bunin ER, Cochran W, Ruchelli E, Olthoff KM, Bloomer JR. *Pediatrics* 2006; 118: e1896–9.

Bone marrow transplanted 6 months after a liver transplant corrected the severe phenotype of a 14-year-old boy and halted further protoporphyrin-induced liver graft damage.

Curative bone marrow transplantation in erythropoietic protoporphyria after reversal of severe cholestasis

Wahlin S, Aschan J, Björnstedt M, Broomé U, Harper P. *J Hepatol* 2007; 46: 174–9.

Eighty days of medical management normalized liver biochemistry and improved histology in a man who then received a bone marrow transplant. Ten months later, liver and porphyrin tests were normal; no photosensitivity was reported.

Extramammary Paget disease

Lori D. Prok, and James E. Fitzpatrick

Courtesy of Fitzsimons Army Medical Center

Extramammary Paget disease (EMPD) was first described by Crocker in 1889, when he noted skin lesions affecting the penis and scrotum of a male patient that were identical to the nipple disease described by Paget in 1874. Although an uncommon malignancy,

EMPD should be included in the clinical differential diagnosis of any chronic dermatitis of the groin or perineum. EMPD most commonly affects postmenopausal Caucasian women but can also be seen in men and all ethnicities. It typically presents as chronic, often sharply demarcated, erythematous scaling plaques on apocrine gland-bearing skin, including the genitalia, axillae, umbilicus, and external auditory canal. Pruritus is the most common presenting symptom. Primary EMPD results from epidermal infiltration of neoplastic glandular cells that share histologic and immunoperoxidase features of cells of apocrine origin. Recent evidence supports the role of Toker cells (clear cells found in 10% of normal nipples and recently identified in tissue of the milk line and the vulva) as the probable pathologic cell of origin. Secondary EMPD accounts for approximately 25% of cases and is the result of direct cutaneous extension of an underlying adenocarcinoma, most commonly of the genitourinary system or from the anal canal.

Management Strategy

Clinical suspicion of EMPD should prompt an immediate skin biopsy. Histologically, neoplastic cells are characterized by pale vacuolated cytoplasm and large pleomorphic nuclei, which can be seen infiltrating all levels of the epidermis. Extension into adnexal structures is common. In addition to hematoxylin and eosin (H&E) studies, the diagnosis is confirmed by utilizing a panel of immunoperoxidase studies that might include carcinoembryonic antigen (CEA), epithelial membrane antigen, CK7, gross cystic disease fluid protein-15, and/or Ber-EP4 to differentiate EMPD from pagetoid variants of squamous cell carcinoma in situ and melanoma in situ. Recent studies have also demonstrated that HER2/neu overexpression is useful, both in helping to establish a diagnosis of EMPD and in identifying invasive cases that might be responsive to trastuzumab. The biopsy also establishes whether there is extension into the dermis, which is useful in identifying the subset of patients who should be considered for sentinel lymph node biopsy.

A full-body skin examination and lymph node evaluation should be performed in all patients with EMPD. Patients should then have appropriate evaluation for underlying malignancy, including age- and gender-appropriate screening (Papanicolaou smear, fecal occult blood, colonoscopy, cystoscopy, and prostate-specific antigen).

Additional investigations (imaging, colposcopy, etc.) are guided by screening results and the anatomic location of cutaneous lesions.

EMPD is treated locally with *surgical excision*, with adjuvant therapies in selected cases. *Mohs micrographic surgery* is the preferred technique, offering the most reliable margin control, maximal tissue preservation, and lowest recurrence rates. However, this technique is still limited by noncontiguous tumor spread and the high likelihood of EMPD involving clinically normal-appearing skin.

Specific Investigations

- Skin biopsy
- Full-body skin examination and lymph node evaluation
- Cancer screening appropriate for age and gender (Papanicolaou smear, fecal occult blood, colonoscopy, cystoscopy, and prostate-specific antigen)
- Sentinel lymph node biopsy in patients with dermal and/or lymphatic extension

Extramammary Paget's disease: treatment, prognostic factors and outcome in 76 patients

Hatta N, Yamada M, Hirano T, Fujimoto A, Morita R. Br J Dermatol 2008; 158: 313–8.

Retrospective review of 76 patients with EMPD. Surgical margin was not correlated with local recurrence. Seventeen percent developed systemic metastases; 10 patients died. Nodules in the primary tumor, clinical lymph node swelling, elevated CEA levels, depth of tumor invasion, and lymph node metastasis were significant prognostic factors. Depth of tumor invasion and CEA level were associated with reduced survival.

Usefulness of sentinel lymph node biopsy for the detection of metastasis in the early stages of extramammary Paget's disease

Kusatake K, Harada Y, Mizumoto K, Kaneko S, Niihara H, Chinuki Y, et al. Eur J Dermatol 2015; 25: 156–61.

Eighteen patients with primary EMPD were enrolled in this prospective study. Nine of the 18 patients had histologic evidence of dermal extension of tumor cells. Of the patients with dermal extension of the tumor, 3/9 (33%) had a positive sentinel lymph node

biopsy, and none of the patients with intraepidermal involvement only had a positive sentinel lymph node biopsy. The authors conclude that sentinel lymph node biopsy is useful to detect lymph node metastasis.

First-Line Therapies

• Wide local excision, with or without lymph node dissection	B
• Frozen section–guided wide local excision	B
• Mohs micrographic surgery	B

Indications for lymph node dissection in the treatment of EMPD

Tsutsumida A, Yamamoto Y, Minakawa H, Yoshida T, Kokubu I, Sugihara T. *Dermatol Surg* 2003; 29: 21–4.

A prospective study of 34 patients with genital or perineal EMPD treated with wide local excision. Patients with clinical or histologic evidence of metastatic disease underwent lymph node dissection. No patients with carcinoma in situ or microscopic papillary dermal invasion had lymph node metastasis; all had 100% 5-year survival. Tumor invasion into the reticular dermis correlated with 33% 5-year survival. Tumor invasion into the subcutaneous tissue correlated with 100% lymph node metastasis and death.

Clinicopathological study of invasive extramammary Paget's disease: subgroup comparison according to invasion depth

Shiomi T, Noguchi T, Nakayama H, Yoshida Y, Yamamoto O, Hayashi N, et al. *J Eur Acad Dermatol Venereol* 2013; 27: 589–92.

Retrospective review of 51 surgical specimens of primary invasive EMPD. Cases were divided into subgroups according to invasion depth: dermal invasion ≤ 1 mm (minimal invasion) and dermal invasion > 1 mm in depth. Lymph node metastases were detected in two (7.7%) of 26 patients with minimal invasion and nodal metastases in 22/25 (88%) of patients with invasion > 1 mm in depth. The authors conclude there is evidence to suggest that a cut-off depth of 1 mm of invasion is useful in staging patients for prognosis and treatment.

Frozen section-guided wide local excision in the treatment of penoscrotal EMPD

Zhu Y, Ye D, Chen Z, Zhang SL, Qin XJ. BJU Int 2007; 100: 1282–7.

Retrospective review of 38 patients with primary penoscrotal EMPD who received wide local excision with intraoperative frozen-section analysis. Thirty-two percent had positive frozen-section margins and required immediate extended excision. Forty percent of patients had positive surgical margins after traditional wide local excision with 2-cm margins. At a mean follow-up of 33 months 16% of patients had recurrent disease, and four patients had systemic involvement.

Comparison of Mohs micrographic surgery and wide excision for EMPD

O'Connor W, Lim K, Zalla M. Dermatol Surg 2003; 29: 723–7.

Retrospective review of 95 patients at the Mayo Clinic comparing tumor recurrence in patients treated with Mohs micrographic surgery (8%) and those with wide local excision (22%). Surgeons used intraoperative staining with CK7.

Second-Line Therapies

• Photodynamic therapy	B
• Radiation therapy	B
• Systemic chemotherapy	B
• Topical imiquimod	B

Photodynamic therapy with M-ALA as nonsurgical treatment option in patients with primary extramammary Paget's disease

Fontanelli R, Papadia A, Martinelli F, Lorusso D, Grijuela B, Merola

M, et al. *Gynecol Oncol* 2013; 130: 90–4.

Prospective study of 32 women with vulvar EMPD who were treated with aminolevulinic-acid methyl-ester photodynamic therapy (M-ALA PD). Patients received at least three cycles and were then evaluated as to whether they would receive additional therapy. After three cycles, 3 patients had a complete response (9%), 25 patients (78%) had a partial response, and the remaining 4 patients (13%) had stable disease. The authors concluded that M-ALA PD, although not usually curative, is useful to control EMPD and preserve cosmetic and/or functional anatomy.

Radiation therapy for extramammary Paget's disease: treatment outcomes and prognostic factors

Hata M, Koike I, Wada H, Miyagi E, Kasuya T, Kaizu H, et al. *Ann Oncol* 2014; 25: 291–7.

Retrospective review of the outcomes of 41 patients with EMPD, including 15 patients with regional lymph node metastases. Total doses of 46 to 80.2 Gy (median = 60 Gy) were utilized with a median of 33 fractions. The local progression-free and disease-free rates were 82% and 46% at 5 years. Five patients (12%) died because of tumor progression. The authors conclude that radiation therapy is effective and safe, with this being a curative option for patients who are inoperable.

Combination chemotherapy for metastatic extramammary Paget disease

Oashi K, Tsutsumida A, Namikawa K, Tanaka R, Omata W, Yamamoto Y, et al. *Br J Dermatol* 2014; 170: 1354–7.

The authors studied seven patients with metastatic EMPD who were treated with combination chemotherapy composed of epirubicin, mitomycin C, and vincristine on day 1 followed by carboplatin on day 2 and 5-fluorouracil on days 2 to 6. All seven patients had at least a partial response or shrinkage in tumor size; however, there were no complete responses. The 1-year survival rate was 43%. The authors concluded that this combination chemotherapy may be a treatment option for patients with metastatic EMPD.

Combination chemotherapy of low-dose 5-fluorouracil and cisplatin for advanced extramammary Paget's disease

Tokuda Y, Arakura F, Uhara H. *Int J Clin Oncol* 2015; 29: 194–7.

Retrospective study of 22 patients with advanced (metastatic) EMPD who were treated with combination chemotherapy consisting of infusions of 5-fluorouracil and cisplatin. The overall survival rate ranges were 5 to 51 months, with 13 of 22 patients demonstrating a complete or partial response to therapy. Three of the 22 patients demonstrated progressive disease. The authors concluded that this is a relatively effective treatment option of advanced EMPD.

Usefulness of docetaxel as first-line chemotherapy for metastatic extramammary Paget's disease

Yoshino K, Fujisawa Y, Kiyohara Y, Kadono T, Murata Y, Uhara H, et al. *J Dermatol* 2016; 43: 633–7.

Retrospective multicenter analysis of 13 patients with metastatic EMPD who were treated with docetaxel with average number of treatment cycles of 9.1 (one treatment per month). Seven patients (58%) demonstrated a partial response, 3 patients had stable disease (25%), and 2 patients (17%) had progressive disease. The authors concluded that docetaxel is a promising treatment for metastatic EMPD but that a prospective clinical trial is needed to confirm these findings.

Effects of imiquimod on vulvar Paget's disease: a systematic review of the literature

Machida H, Moenini A, Roman LD, Matsuo K. *Gynecol Oncol* 2015; 139: 165–71.

This is a systematic review of the literature for cases of vulvar Paget disease treated with topical imiquimod that included 63 cases of untreated and recurrent EMPD. The treatment regimens were highly variable, but the most common regimen was topical application three or four times per week and a median treatment duration of 4 months. A complete response at 6 months was present in 35 of 63 (72%) of the patients. Of the complete responders, 3 of 35 women had a disease recurrence.

Treatment of extramammary Paget disease of the vulva with imiquimod: a retrospective, multicenter study by the German Colposcopy Network

Luyten A, Sörgel P, Clad A, Giesecking F, Maass-Poppenhusen K, Lellé RJ, et al. *J Am Acad Dermatol* 2014; 70: 644–50.

Retrospective multicenter analysis of 21 women with first-time or

recurrent vulvar EMPD treated with topical imiquimod. The dose and duration varied from patient to patient; however, the mean duration of treatment exceeded 16 weeks. Eleven of 21 patients (52%) had a complete response, 6 of 21 (29%) had a partial response, with the remaining 4 patients having stable disease. The authors concluded that topical imiquimod is a useful treatment option for recurrent EMPD to avoid extensive mutilating surgical procedures.

Third-Line Therapies

• Androgen receptor antagonist	E
• Intralesional interferon- α_{2b}	E
• Topical 5-fluorouracil and retinoic acid	E
• Trastuzumab	E

Androgen-deprivation regimen for multiple bone metastases of EMPD

Yoneyama K, Kamada N, Kinoshita K. Br J Dermatol 2005; 153: 853–5.

Case report of EMPD with multiple bone metastases successfully suppressed with antiandrogen bicalutamide and LH-RH agonist leuporelin. Tumor markers decreased and bone scintigraphy evidence of metastasis disappeared within 2 months. When tumor markers rose at day 70, other antiandrogens and systemic chemotherapy failed, and the patient ultimately died 14 months after the start of antiandrogen therapy. The authors postulate that the rapid development of resistance to the androgen-deprivation therapy suggests that mutation or amplification in the androgen receptor gene occurred in this case, as seen in cases of prostate cancer.

Intralesional interferon alfa-2b as neoadjuvant treatment for perianal EMPD

Panasiti V, Bottoni U, Devirgilis V, Mancini M, Rossi M, Curzio M, et al. J Eur Acad Dermatol Venereol 2008; 22: 522–3.

Report of a patient with perianal EMPD who, after refusing surgical excision, was treated with intralesional IFN- α_{2b} at a dose of 1 million IU three times per week for 3 weeks. At 7 weeks the tumor had decreased in diameter, and surgical resection was performed. Patient had no clinical disease at 108 months' follow-up.

EMPD resistant to surgery and imiquimod monotherapy but responsive to imiquimod combination topical chemotherapy with 5-fluorouracil and retinoic acid: a case report

Ye J, Rhew D, Yip F, Edelstein L. *Cutis* 2006; 7: 245–50.

Report of a patient with EMPD (recurrent after surgery and resistant to topical imiquimod alone) that resolved after treatment with a combination of imiquimod and topical 5-fluorouracil and retinoic acid.

Metastatic extramammary Paget's disease of scrotum responds completely to single agent trastuzumab in a hemodialysis patient: case reports, molecular profiling and brief review of the literature

Barth P, Dulaimi Al-Saleem E, Edwards KW, Millis SZ, Wong Y-N, Geynisman DM. *Case Rep Oncol Med* 2015; 2015: 895151.

Case report of metastatic EMPD with Her2/neu overexpression that was treated with trastuzumab as a single agent. The patient had a complete response. The authors note that this option is only available in the 30% to 40% of EMPD that overexpress Her2/neu.

Fabry disease

Jaya Ganesh, Rhonda E. Schnur, and Fiona Child

Fabry disease (or Anderson–Fabry disease, OMIM 301500) is a progressive, X-linked lysosomal storage disorder caused by the deficiency or absence of the enzyme α -galactosidase A (GLA). This results in the accumulation of globotriaosylceramide (Gb3) and related glycosphingolipids within lysosomes. Systemic manifestations of Fabry disease include renal dysfunction, cardiomyopathy and arrhythmias, cerebrovascular complications, corneal and lenticular opacities, tinnitus and hearing loss, gastrointestinal disturbances, pulmonary disease, osteopenia, and depression. Causes of death include end-stage renal disease (ESRD), cardiac disease, or stroke.

Males are more severely affected, but female carriers may exhibit symptoms depending on the pattern of X-chromosome inactivation (lionization).

Cutaneous features include angiokeratoma, hypohidrosis (53% males and 28% females), telangiectasia (23% males and 9% females), and lymphedema (16% males and 6% females).

Diffuse angiokeratomas are a characteristic cutaneous manifestation of Fabry disease and should alert the clinician to the possibility of the diagnosis. They typically cluster symmetrically around the umbilicus, hips, back, thighs, buttocks, penis, and scrotum (bathing trunk distribution); increase in number and size over time; and may correlate with the severity of the systemic manifestations of disease. Diffuse angiokeratomas may also be seen in other lysosomal storage diseases including fucosidosis, sialidosis, aspartylglucosaminuria, and β -galactosidase deficiency. Acroparesthesia produces episodic burning, severe pain, and a constant tingling of the palms and soles. Pain crises result from glycolipid accumulation in the autonomic nervous system and vascular endothelium. A similar mechanism underlies Fabry-associated hypohidrosis.

Management Strategy

Comprehensive medical therapy for Fabry disease requires a multidisciplinary approach that includes a combination of *enzyme replacement therapy* and *conventional medical treatment*.

Angiokeratomas due to Fabry disease are typically asymptomatic; when indicated they can be treated with *surgical excision*, *electrocoagulation*, and *cryosurgery* and do not require targeted therapy. Various *lasers* have been utilized, including the CO₂, argon, copper vapor, and flashlamp-pumped-dye lasers. Copper vapor lasers are superior to argon because of their wavelength specificity for hemoglobin. However, the flashlamp-pumped-dye laser may produce less pain and bleeding and pigmentary change.

Neuropathic pain and acroparesthesias may benefit from avoidance of triggers, including physical exertion and temperature changes. *Diphenylhydantoin*, *carbamazepine*, *gabapentin*, *topiramate*, and *tricyclic antidepressants* are used for analgesia. Nonsteroidal antiinflammatory drugs (NSAIDs) are generally ineffective, and narcotics should be

avoided if possible.

Used in conjunction with ERT, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may reduce proteinuria and stabilize glomerular filtration rate (GFR). Peritoneal dialysis, hemodialysis, and renal transplantation are utilized for patients with renal failure.

Gastrointestinal complications, including delayed gastric emptying and dyspepsia, have been treated with metoclopramide, pancrelipase, loperamide, and H₂ blockers. Hearing aids assist in moderate hearing loss, whereas profound deafness requires cochlear implantation. Aspirin or clopidogrel is recommended for cardiovascular disease prophylaxis. Conventional treatments are also utilized in the management of cardiovascular symptoms in Fabry disease.

Two human enzyme products have been utilized in ERT: *agalsidase-β* (*Fabrazyme*, Sanofi-Genzyme Corporation) and *agalsidase-α* (*Replagal*, Shire Genetic Therapies). Both were approved by the European Agency for Evaluation of Medical Products in 2001, but only *agalsidase-β* is approved by the Food and Drug Administration (FDA) for use in the United States. The enzymes are administered intravenously biweekly at a dose of 0.2 mg/kg for *agalsidase-α* and 1.0 mg/kg for *agalsidase-β*. No clear difference in clinical effect between the two preparations was demonstrated in a randomized, controlled, prospective study.

ERT stabilizes or slows progression of renal and cardiac disease, reduces neuropathic pain, stabilizes hearing loss, and improves sweat function and quality of life. Patients treated with ERT have a slowing of progression to “major” clinical events (ESRD, myocardial infarction, stroke, or death). In a recent analysis of 969 male and 442 female patients enrolled in the longitudinal Fabry Registry, patients with more advanced disease before initiating ERT were at a significantly higher risk of sustaining a severe Fabry-related clinical event compared with those who had milder disease and earlier institution of ERT. ERT has been associated with immunogenicity leading to antibody-mediated infusion reactions that may also reduce its efficacy.

New, improved, and more effective treatment approaches are actively being studied. A promising therapeutic strategy involves small molecules called *active site-specific chaperones* that may be useful with certain types of mutations. In Fabry disease, missense mutations can cause misfolding of the mutant GLA enzyme and retention of the misfolded enzyme in the endoplasmic reticulum. The retained

enzyme is then degraded rather than being trafficked to the appropriate location in the cell, the lysosome. Chaperones are orally active molecules that selectively bind to the misfolded enzyme, promote correct folding, and aid in delivery to lysosomes. Some mutant forms of the enzyme are more amenable to targeting and are responsive to migalastat (*1-deoxygalactonojirimycin* [DGJ], Amicus Therapeutics, NJ, USA). Migalastat is an orally administered molecular chaperone that was assigned orphan drug status by the FDA in 2004. It is administered orally on alternate days. In a cohort of 67 patients, 75% had mutations deemed responsive to migalastat. In that group, improvements included the arrest of decline in GFR, left ventricular mass index, and gastrointestinal symptoms.

Substrate reduction therapy is an alternative investigative approach that involves inhibiting the production of Gb3 that accumulates as a result of GLA deficiency. A glucosylceramide synthase inhibitor slows the rate of Gb3 synthesis, thus decreasing storage within the lysosomes. Eliglustat tartrate (Genz 112638) is an immunosugar analog under investigation as a glucosylceramide synthase inhibitor for treating Gaucher disease and other lysosomal storage disorders including Fabry disease.

Fabry disease has now been added to the list of disorders screened for by newborn screening panels in some states in the United States.

Specific Investigations

Diagnostic workup

- Obtain family history
- Enzyme analysis (quantitation in plasma and white blood cells [WBCs], cultured cells, blood spot filter paper screening) (most definitive method in males, not reliable for females)
- *GLA* molecular DNA analysis (nearly 100% sensitivity in affected males; most reliable method for females)
- Preimplantation genetic diagnosis or prenatal diagnosis via amniocentesis or chorionic venous sampling (enzymatic and/or molecular assay)

Systemic workup (male and female)

- Renal function studies including urinalysis and assessment of 24-hour microalbuminuria and creatinine clearance

- Cardiac evaluation with electrocardiogram, echocardiography, 24-hour Holter monitoring, and cardiac magnetic resonance imaging (MRI)
- Dermatology evaluation
- Urine GB3, LysoGB3 (Fabry-associated lysosphingolipid) levels in blood
- Audiology
- Fundoscopy and slit-lamp examination
- Neurologic evaluation with surveillance MRI
- Pulmonary function studies
- Gastrointestinal examination with endoscopy as indicated

Angiokeratoma: decision making aid for the diagnosis of Fabry disease

Zampetti A, Orteu CH, Antuzzi D, Bongiorno MR, Manco S, Gnarr M, et al. and the Interdisciplinary Study Group on Fabry Disease. *Br J Dermatol* 2012; 166: 712–20.

This article proposes an algorithm for the diagnosis of Fabry disease and reviews clinical and histologic features of angiokeratomas in detail. The algorithm uses personal and family history, the number and distribution of angiokeratomas, skin biopsy, dermoscopy (to detect more subtle lesions), electron microscopy, and genetic studies as sequential tools in the diagnostic process.

Treatment of Fabry disease: current and emerging strategies

Rozenfeld P, Neumann PM. *Curr Pharm Biotechnol* 2011; 12: 916–22.

This is an excellent overview of therapeutic options, including new treatments such as chaperone therapy.

Fabry disease and the skin: data from FOS, the Fabry Outcome Survey

Orteu CH, Jansen T, Lidove O, Jaussaud R, Hughes DA, Pintos-Morell G, et al. *Br J Dermatol* 2007; 157: 331–37.

The Fabry Outcome Survey (FOS), a multicenter European database, was used to capture longitudinal multicenter data on patients with Fabry disease. This paper discusses the dermatologic manifestations present in that cohort.

A case of multiple angiomas without any angiokeratomas in a female heterozygote with Fabry disease

Mirceva V, Hein R, Ring J, Möhrenschrager M. *Australas J Dermatol* 2010; 51: 36.

Case report wherein multiple angiomas were the only visible cutaneous manifestation of Fabry disease in an oligosymptomatic female.

Fabry disease

Germain DP. *Orphanet J Rare Dis* 2010; 5: 30.

This is a very comprehensive overview of the clinical characteristics of Fabry disease, current treatment modalities, and therapies on the horizon.

Fabry disease: a review of current management strategies

Mehta A, Beck M, Eyeskens F, Feliciani C, Kantola I, Ramaswami U, et al. *Q J Med* 2010; 103: 641–59.

This review, written by a panel of experts with extensive clinical experience in Fabry disease, summarizes the recent literature and registry data to aid in providing therapy recommendations.

Human Gene Mutation Database: 2008 update

Stenson PD, Mort M, Ball EV, Howells K, Phillips AD, Thomas NST, et al. *Genome Med* 2009; 1: 13. <http://www.hgmd.org>. The Institute of Medical Genetics, Cardiff, United Kingdom, 2011. Accessed Sept 5, 2016.

Over 800 mutations in the *GLA* gene have been identified, including missense and loss of function mutations. Mutation information is used for diagnosis, particularly in female heterozygotes, prenatal testing, and partial correlation with clinical phenotype. Mutation specificity also has major implications for pharmacogenomic management, for example, for the potential use of chaperone therapy in patients with missense mutations that cause protein misfolding.

Fabry disease

Mehta A, Hughes DA. In: Pagon RA, Adam MP, Ardinger HH, Wallace SE, Amemiya A, Bean LJH, et al, eds. *GeneReviews*, Seattle, WA: University of Washington.

This easily accessed, frequently updated database provides a comprehensive review of the clinical, biochemical, and molecular aspects of Fabry disease, with links to information about diagnostic testing and patient resources.

Fabry disease in infancy and early childhood: a systematic literature review

Laney DA, Peck DS, Atherton AM, Manwaring LP, Christensen KM, Shankar SP, et al. *Genet Med* 2015; 17: 323–30.

The authors performed a systematic retrospective analysis of 120 peer-reviewed publications and case reports about the pediatric Fabry population. Forty-one individual patients younger than 5 years of age were identified. Acroparesthesia was the most common clinical symptom, reported in nine patients. Other symptoms in very young children included heat sensitivity and gastrointestinal disease, especially recurrent abdominal pain and diarrhea. Importantly, renal damage, including foot process effacement, was noted to occur even before there was clinically evident proteinuria.

First-Line Therapies

• Enzyme replacement therapy	A
• Laser therapy	E
• Intense pulsed light	E
• Surgical excision	E
• Diphenylhydantoin	B
• Cryotherapy	E

Enzyme replacement therapy for Anderson–Fabry disease

El Dib RP, Pastores GM. *Cochrane Database Syst Rev* 2010; 5: CD006663.

This Cochrane review summarizes the available evidence with regard to five randomized-controlled clinical trials (representing 23 publications) involving agalsidase- α and agalsidase- β . The authors

concluded that ERT can modify disease course in treated patients with Fabry disease, improving neuropathic pain, cardiac morphology, and renal function. There is also a positive influence on quality of life. Treatment is generally well tolerated, although neutralizing antibodies may affect clinical outcome. Longer-term effects on morbidity and mortality remain to be established.

Response of women with Fabry disease to enzyme-replacement therapy: comparison with men, using data from the FOS – the Fabry Outcome Survey

Hughes DA, Barba Romero MÁ, Hollak CE, Giugliani R, Deegan PB. *Mol Genet Metab* 2011; 103: 207–14.

Data were obtained from the Fabry Outcome Survey of 78 affected women and 172 men. Clinical outcomes studied included cardiac structure and function, renal function, quality of life, pain, and a variety of other clinical features and quantifiable measures. Both sexes responded to agalsidase- α similarly. Anhidrosis improved, whereas angiokeratomas did not.

Agalsidase beta treatment is associated with improved quality of life in patients with Fabry disease: findings from the Fabry registry

Watt T, Burlina A, Cazzorla C, Shonfeld D, Banikazemi M, Hopkin RJ, et al. *Genet Med* 2010; 12: 703–12.

Seventy-one men and 59 women treated with agalsidase- β had baseline and posttreatment quality of life measurements. Health-related quality of life improved in both sexes, although the effect was more pronounced in men.

Four-year prospective clinical trial of agalsidase alfa in children with Fabry disease

Schiffmann R, Martin RA, Reimschisel T, Johnson K, Castaneda V, Lien YH, et al. *J Pediatr* 2010; 156: 832–7.

Seventeen of the 24 children who initially completed the 6-month open-label agalsidase- α study enrolled in this 3.5-year extension study. Pain severity and Gb3 levels were reduced, and heart rate variability improved. Kidney function and left ventricular mass remained stable.

Risk factors for severe clinical events in male and female

patients with Fabry disease treated with agalsidase beta enzyme replacement therapy: data from the Fabry Registry

Hopkin RJ, Cabrera G, Charrow J, Lemay R, Martins AM, Mauer M, et al. *Mol Genet Metab* 2016; 119: 151–9.

This article provides an in-depth review of risk factors for developing severe clinical events in a large cohort of patients treated with ERT, highlighting the need for multidisciplinary care and adjuvant therapies.

Angiokeratomas in Fabry's disease and Fordyce's disease: successful treatment with copper vapor laser

Lapins J, Emtestam L, Marcusson JA. *Acta Derm Venereol* 1993; 73: 133–5.

Angiokeratomas in two treated subjects were undetected at 3-month follow-up; treated skin was smooth, with minimal pigmentary alteration.

Successful treatment of angiokeratoma with potassium titanyl phosphate laser

Gorse SJ, James W, Murison MSC. *Br J Dermatol* 2004; 150: 620–1.

Excellent results using this laser were seen in two subjects with angiokeratomas.

Angiokeratomas of Fabry successfully treated with intense pulsed light

Morais P, Santos AL, Baudrier T, Mota AV, Oliveira JP, Azevedo F. *J Cosmet Laser Ther* 2008; 10: 218–22.

There was almost complete clearance of angiokeratomas in one severely affected subject without recurrence at 12-month follow-up.

Fabry disease: recognition and management of cutaneous manifestations

Mohrenschlager M, Braun-Falco M, Ring J, Abech D. *Am J Clin Dermatol* 2003; 4: 189–96.

Review article about current laser treatments for the angiokeratomas of Fabry disease, including variable pulse width 532-nm neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, 578-nm copper vapor laser, and flashlamp-pulsed-dye laser.

Intravenous infusion of phenytoin relieves neuropathic pain: a

randomized, double-blinded, placebo-controlled, crossover study

McCleane GJ. Anesth Analg 1999; 89: 985–8.

This study evaluated 20 patients with acute flare-ups of neuropathic pain. Phenytoin reduced burning sensation, shooting pain, sensitivity, numbness, and overall pain.

Second-Line Therapies

• Gabapentin	D
• Carbamazepine	D

Use of gabapentin to reduce chronic neuropathic pain in Fabry disease

Ries M, Mengel E, Kutschke G, Kim KS, Birklein F, Krummenauer F, et al. J Inherit Metab Dis 2003; 26: 413–4.

Six patients with Fabry disease experienced less pain than at baseline with few side effects after 4 weeks of treatment.

Carbamazepine in Fabry's disease: effective analgesia with dose-dependent exacerbation of autonomic dysfunction

Filling-Katz MR, Merrick HF, Fink JK, Miles RB, Sokol J, Barton NW. Neurology 1989; 39: 598–600.

Five of seven patients had moderate to complete relief of pain based upon self-assessment. Complications included exacerbation of preexisting autonomic dysfunction, ileus, urinary retention, and gastrointestinal disturbance.

Third-Line and Future Therapies

• Site-specific molecular chaperone therapy (migalastat)	A
• Substrate reduction therapy (eliglustat tartrate, Genz 112638)	
• Gene replacement therapy	
• Renal transplantation/hemodialysis	C

Co-administration with the pharmacological chaperone AT1001 increases recombinant human α -galactosidase A tissue uptake and improves substrate reduction in Fabry mice

Benjamin ER, Khanna R, Schilling A, Flanagan JJ, Pellegrino LJ, Brignol N, et al. Mol Ther 2012; 20: 717–26.

This study evaluated the efficacy of combined ERT and chaperone therapy. Coincubation of Fabry fibroblasts with recombinant human α -galactosidase A (rh α -Gal A) and AT1001 (1-deoxygalactonojirimycin, migalastat hydrochloride) resulted in up to fourfold higher levels of cellular α -Gal A and approximately 30% greater Gb3 reduction compared with ERT alone. In rats, AT1001 increased the circulating half-life of rh α -Gal A by >2.5-fold, and in GLA knockout mice resulted in up to fivefold higher α -Gal A levels and fourfold greater GL-3 reduction.

Treatment of Fabry's disease with the pharmacologic chaperone migalastat

Germain DP, Hughes DA, Nicholls K, Bichet DG, Wilcox WR, Feliciani C, et al. New Eng J Med 2016; 375: 545–55.

Sixty-seven patients with Fabry disease who had never received ERT or had not received ERT within 6 months before enrollment were randomized to 6 months of treatment with migalastat or placebo followed by an open-label migalastat for 6 to 12 months plus an additional year. All patients were genotyped, and 50 patients had mutant enzyme suitable for targeting by migalastat. Beneficial effects were observed in annualized rates of change in GFRs, reduction in left ventricular mass index (a significant predictor of adverse cardiac events), and improvement in gastrointestinal symptoms that are frequently debilitating. None of the migalastat-treated patients progressed to end-stage kidney disease, had strokes, or had cardiac-related mortality during the study.

Kidney transplant outcomes in patients with Fabry disease

Shah T, Gill J, Malhotra N, Takemoto SK, Bunnapradist S.
Transplantation 2009; 87: 280–5.

This study evaluated 197 renal transplant recipients with Fabry disease and ESRD from 1987 to 2007. Rates of graft loss and death were compared with renal transplant recipients with other (non-Fabry) causes of ESRD, as well as a 10:1 matched cohort of transplant recipients with other causes of ESRD. Patients with Fabry disease had a superior graft survival and similar patient survival compared with other (non-Fabry) ESRD patients. However, they had a higher risk of death compared with a matched cohort.

Flushing

Jennifer A. Sopkovich, and Jonathan K. Wilkin

Flushing is a transient reddening of the face and frequently other areas, including the neck, upper chest, pinna, and epigastric area. Flushing is the visible sign of a generalized increase in cutaneous blood flow despite the limited distribution of the erythema.

Management Strategy

The initial step in the management of a patient with a flushing disorder is to make a specific diagnosis. The first algorithmic step is to distinguish between autonomic neural-mediated flushing, in which eccrine sweating occurs at the time of the flushing (“wet flushing”), and direct vasodilator-mediated flushing, in which there is no accompanying eccrine sweating (“dry flushing”). The dry flushing reactions are further divided into those with prominent dysesthesia and those without.

Dry flushing without dysesthesia is due to circulating vasodilators, either exogenous or endogenous. Exogenous vasodilators are almost always elicited from the patient’s history. A diary listing all foods, beverages, medications, activities, etc., can help pinpoint the inciting agent. Avoidance of the vasodilator agent is the treatment of choice. However, there are some exceptions where antifleushing treatment is initiated and the vasodilator is continued, such as niacin (nicotinic acid) therapy for hyperlipidemia and tamoxifen for breast cancer.

Endogenous circulating vasodilator agents, typically from underlying neoplasias, are suggested by both multiple stimuli that provoke flushing and prominent associated features (e.g., itching, urticaria, hypertension, sweating, and diarrhea). Prominent features associated with flushing can occur with cholinergic urticaria, cholinergic erythema, anxiety reactions, intolerance to foods, menopausal flushing, the dumping syndrome, diabetes mellitus, pancreatic cholera, medullary carcinoma of the thyroid, pheochromocytoma, multiple endocrine neoplasia syndromes II and III, mastocytosis, and carcinoid syndrome.

Specific Investigations

- 5-Hydroxyindoleacetic acid urine
- Histamine urine
- Serotonin blood/platelet
- Histamine plasma
- Tryptase serum

The red face: flushing disorders

Wilkin JK. Clin Dermatol 1993; 11: 211–23.

It is important to establish a diagnosis of flushing and rule out other causes of red face such as photosensitivity, lupus erythematosus, seborrhea, and other conditions before proceeding with a flushing workup and treatment. This review describes the three types of blushing, including the type that responds to a low-dose, long-acting nonselective β -blocker (nadolol 40 mg every morning). The use of aspirin to block niacin-induced flushing and amitriptyline to treat facial dysesthesia is described.

Red face revisited: flushing

İkizoğlu G. Clin Dermatol 2014; 32: 800–8.

This article reviews the differential diagnosis for facial flushing, including common benign disorders and uncommon but serious diseases. Medication-induced flushing is also discussed.

Influence of a serotonin- and dopamine-rich diet on platelet serotonin content and urinary excretion of biogenic amines and their metabolites

Kema IP, Schellings AM, Meiborg G, Hoppenbrouwers CJ, Muskiet FA. Clin Chem 1992; 38: 1730–6.

No diet restrictions are necessary during workup of catecholamine-secreting tumors. Avoidance of serotonin-containing foods is recommended before urinary 5-Hydroxyindoleacetic acid (5-HIAA) collection in the workup of carcinoid. Platelet serotonin is more sensitive and is not affected by diet.

The quantitative 24-hour urinary 5-HIAA level is useful in the follow-up of carcinoid tumors with a high serotonin production rate. It is also useful initially for diagnosis but only when it is positive during a low-serotonin diet. If the urinary 5-HIAA level is not elevated in a patient with flushing and other features characteristic of carcinoid, the platelet or blood serotonin level should be obtained.

Mastocytosis: the puzzling clinical spectrum and challenging diagnostic aspects of an enigmatic disease

Gülen T, Hägglund H, Dahlén B, Nilsson G. J Intern Med 2016; 279: 211–28.

Facial flushing is a chief complaint in mastocytosis. Attacks may include flushing, palpitations, dizziness, and hypotension. Serum tryptase levels are the first step in diagnosis.

Comparison of clinical trials with sildenafil, vardenafil and tadalafil in erectile dysfunction

Doggrell SA. Expert Opin Pharmacother 2005; 6: 75–84.

Flushing was identified as an adverse effect in the clinical trials of each of these selective phosphodiesterase-5 (PDE-5) inhibitors.

Facial flushing response to alcohol and the risk of esophageal squamous cell carcinoma: a comprehensive systematic review and meta-analysis

Andrici J, Hu SX, Eslick GD. Cancer Epidemiol 2016; 40: 31–8.

The alcohol-induced facial flushing response, common among East Asians, is associated with an increased risk of esophageal squamous cell carcinoma in moderate to heavy drinkers.

Heat urticaria: a revision of published cases with an update on classification and management

Pezzolo E, Peroni A, Gisondi P, Girolomoni G. Br J Dermatol 2016; 175: 473–8.

Heat urticaria, which presents as wheals immediately after heat exposure, may also be associated with flushing and other systemic symptoms.

Scombroid fish poisoning, Pennsylvania, 1998

Centers for Disease Control and Prevention. MMWR Morb Mortal Wkly Rep 2000; 49: 398–400.

Four adults in Pennsylvania had facial flushing, nausea, diarrhea, sweating, headache, metallic taste, and burning sensations in the mouth after eating tuna. Scombroid fish poisoning has been associated primarily with the consumption of tuna, mahi-mahi, and bluefish.

First-Line Therapies

• Ice chips	B
• Aspirin	B
• Hormone replacement	A
• Brimonidine	A

Oral thermal-induced flushing in erythematotelangiectatic rosacea

Wilkin J. J Invest Dermatol 1981; 76: 15–8.

It is heat, not caffeine, that causes the flushing from drinking hot coffee and tea.

Sucking on ice chips can abort mild menopausal, thermal, or spicy food-induced flushing.

Aspirin blocks nicotinic acid-induced flushing

Wilkin JK, Wilkin O, Kapp R, Donachie R, Chernosky ME, Buckner J. Clin Pharmacol Ther 1982; 31: 478–82.

Aspirin and other cyclooxygenase inhibitors (nonsteroidals) block prostaglandin-mediated flushing without reducing the lipid-lowering effect of niacin.

A substantial number of patients taking niacin are taking a nonsteroidal agent. Patients should be instructed to change time of dosing to 1 hour before niacin.

Aspirin attenuation of alcohol-induced flushing and intoxication in Oriental and Occidental subjects

Truitt EB, Gaynor CR, Mehl DL. Alcohol 1987; 1: 595–9.

Eight Oriental and three Occidental subjects sensitive to alcohol manifested as facial flushing had markedly reduced flushing after 0.64 g of aspirin 1 hour before alcohol consumption.

Combined versus sequential hormonal replacement therapy: a

double-blind, placebo-controlled study on quality of life-related outcome measures

Bech P, Munk-Jensen N, Obel EB, Ulrich LG, Eiken P, Nielsen SP. *Psychother Psychosom* 1998; 67: 259–65.

Hormone replacement therapy (HRT) was superior to placebo for many symptoms, including hot flashes in early postmenopausal women.

Although effective for controlling hot flashes, HRT has associated risks and is contraindicated for many women.

Brimonidine gel 0.33% rapidly improves patient-reported outcomes by controlling facial erythema of rosacea: a randomized, double-blind, vehicle-controlled study

Layton AM, Schaller M, Homey B, Hofmann MA, Bewley AP, Lehmann P, et al. *J Eur Acad Dermatol Venereol* 2015; 29: 2405–10.

Brimonidine gel, an alpha-2 adrenergic agonist, is approved for the topical treatment of erythema associated with rosacea. Once-daily application significantly improves persistent facial erythema of rosacea.

Dermatological adverse events associated with topical brimonidine gel 0.33% in subjects with erythema of rosacea: a retrospective review of clinical studies

Holmes AD, Waite KA, Chen MC, Palaniswamy K, Wiser TH, Draelos ZD, et al. *J Clin Aesthet Dermatol* 2015; 8: 29–35.

A retrospective review of adverse events associated with topical brimonidine demonstrated flushing and erythema as the most commonly reported side effects. These events were described as uncommon and transient.

Second-Line Therapies

• H ₁ and H ₂ antihistamines	C
• Clonidine	A
• Selective serotonin reuptake inhibitors	A
• Serotonin–norepinephrine reuptake inhibitors	A

Histamine receptor antagonism of intolerance to alcohol in the Oriental population

Miller NS, Goodwin DW, Jones FC, Pardo MP, Anand MM, Gabrielli WF, et al. J Nerv Mental Dis 1987; 175: 661–7.

Seventeen subjects received placebo, diphenhydramine 50 mg, and cimetidine 300 mg, singly and in combination, 1 hour before drinking ethanol. Cimetidine given alone blocked the flushing significantly more than diphenhydramine alone or placebo but less than the combined antihistamines.

Patients should be screened for alcohol abuse and warned about gastritis and sedation before combination pretreatment consisting of cimetidine and a nonsteroidal is prescribed.

Primary care for survivors of breast cancer

Burstein HJ, Winer EP. N Engl J Med 2000; 343: 1086–94.

A variety of nonestrogenic agents, including selective serotonin reuptake inhibitors, selective serotonin and norepinephrine reuptake inhibitors, and clonidine, are noted to ameliorate hot flashes in breast cancer survivors.

Clonidine patches are frequently associated with contact dermatitis, so the author favors oral clonidine.

Nonhormonal therapies for menopausal hot-flashes

Nelson HD, Vesco KK, Haney E, Fu R, Nedrow A, Miller J, et al. JAMA 2006; 295: 2057–71.

In a review of published randomized controlled trials, there was evidence for the effectiveness of selective serotonin reuptake inhibitors, serotonin–norepinephrine reuptake inhibitors, clonidine, and gabapentin in controlling menopausal hot flashes. However, the efficacy of these nonhormonal treatments was less than that of

estrogen.

Treatment strategies for reducing the burden of menopause-associated vasomotor symptoms

Umland EM. J Manag Care Pharm 2008; 14: S14–9.

Vasomotor symptoms are reported to be the most bothersome symptoms during menopause. Nonpharmacologic modalities, including relaxation techniques, avoiding overheating, weight loss, exercise, and smoking cessation, may reduce these symptoms.

Third-Line Therapies

• Somatostatin analogs	E
• Excision for carcinoid tumors	D
• Sympathectomy for severe, refractory blushing	B
• β -Blockers	D
• Topical oxymetazoline	E
• Botulinum toxin	D
• Pulsed dye laser	D
• Ibuprofen gel	B

Treatment of type II gastric carcinoid tumors with somatostatin analogs

Tomassetti P, Migliori M, Caletti GC, Fusaroli P, Corinaldesi R, Gullo L. N Engl J Med 2000; 343: 551–4.

This is a report of three patients with multiple type II gastric carcinoids treated with lanreotide or octreotide acetate. In all three patients there was a reduction in size and number of the carcinoid tumors after 6 months of somatostatin analog treatment and complete disappearance of tumors after 1 year. A report of regression of a type III gastric carcinoid with octreotide is also cited.

Management of facial blushing

Licht PB, Pilegaard HK. Thorac Surg Clin 2008; 18: 223–8.

Blushing, specifically facial redness due to emotion and social stress, is discussed in this article. Thorascopic sympathectomy is a surgical treatment option for facial blushing that fails medical management.

Carvedilol for the treatment of refractory facial flushing and persistent erythema of rosacea

Hsu CC, Lee JY. Arch Dermatol 2011; 147: 1258–60.

Although there is a lack of objective laboratory evidence for the direct effects β -blockers have on cutaneous blood vessels during episodes of flushing, fewer symptoms have been observed in patients taking β -blockers. Low-dose carvedilol may be an effective treatment for severe rosacea flushing with less risk of hypotension than traditional β -blockers.

Symptomatic treatment of idiopathic and rosacea-associated cutaneous flushing with propranolol

Craige H, Cohen JB. J Am Acad Dermatol 2005; 53: 881–4.

Eight of nine patients experienced diminished symptoms and flushing episodes while taking various doses of propranolol.

Side effects must be monitored such as hypotension, bradycardia, dizziness, fatigue, somnolence, and sexual dysfunction.

Successful treatment of the erythema and flushing of rosacea using a topically applied selective alpha 1-adrenergic receptor agonist, oxymetazoline

Shanler SD, Ondo AL. Arch Dermatol 2007; 143: 1369–71.

Two patients with treatment-resistant erythrotelangiectatic rosacea experienced improvement in erythema, decrease of erythematous flares (flushing), and symptomatic relief of burning and stinging with once-daily topical oxymetazoline, without rebound flares or tachyphylaxis.

Topical oxymetazoline hydrochloride 1% cream was approved by the FDA in January 2017.

Impact of intradermal abobotulinumtoxinA on facial erythema of rosacea

Bloom BS, Payongayong L, Mourin A, Goldberg DJ. Dermatol Surg

2015; 41: S9–16.

Botulinum toxin injections were both safe and effective at treating the erythema of rosacea.

Idiopathic flushing with dysesthesia: treatment with the 585 nm pulsed dye laser

Fogelman JP, Stevenson ML, Ashinoff R, Soter NA. *J Clin Aesthet Dermatol* 2015; 8: 36–41.

The 585-nm pulsed dye laser was effective in decreasing dysesthesia symptoms and flushing episodes in patients suffering from idiopathic flushing.

Topical ibuprofen inhibits blushing during embarrassment and facial flushing during aerobic exercise in people with a fear of blushing

Drummond PD, Minosora K, Little G, Keay W. *Eur Neuropsychopharmacol* 2013; 23: 1747–53.

In this trial 30 subjects applied ibuprofen gel to a small patch on one cheek and the other cheek was used as a control.

Phytoestrogens for vasomotor menopausal symptoms

Lethaby A, Marjoribanks J, Kronenberg F, Roberts H, Eden J, Brown J, et al. *Cochrane Database Syst Rev* 2007; 4: CD001395.

The current evidence indicates no clinically meaningful effect for phytoestrogens.

Follicular mucinosis

Mary Sommerlad, and Malcolm Rustin

Follicular mucinosis is characterized histologically by mucinous degeneration of the follicular outer root sheaths and sebaceous glands with an inflammatory infiltrate composed of lymphocytes, histiocytes, and eosinophils. Lesions consist of erythematous, scaly, and infiltrated plaques with follicular papules or prominent follicular orifices and alopecia (alopecia mucinosa). Benign follicular mucinosis tends to affect younger patients (under 40 years), with fewer lesions, usually situated on the head and neck. Although lesions may resolve spontaneously within 2 years, a more generalized form, with lesions

on the trunk and extremities, may run a chronic relapsing course over many years. Follicular mucinosis is associated with lymphoma, particularly mycosis fungoides, in 15% to 30% of cases. It is still unclear whether follicular mucinosis is a transitional state evolving into mycosis fungoides in these cases. No single clinical or histologic feature predicts which patients will have a benign course, although those found to have mycosis fungoides rarely had initial lesions on the head and neck. Associated lymphoma tends (not invariably) to be associated with age over 30 years, a wider distribution of lesions, and possibly systemic features such as night sweats, weight loss, or lymphadenopathy.

Management Strategy

There is no standard therapy, and because spontaneous resolution occurs in the benign forms, *observation* alone is certainly justified, particularly in the younger patient with limited disease. However, the need for *follow-up and evaluation to exclude lymphoma* must be emphasized. Follicular mucinosis associated with mycosis fungoides or other neoplastic or inflammatory disorders is managed by treating the underlying associated condition.

Specific Investigations

- Skin biopsy
- Immunohistochemistry and T-cell gene receptor analysis may be helpful adjuncts
- Consider investigations to rule out lymphoma or other underlying disorders, depending on the presenting clinical features (general examination, plain radiology, and computed tomography [CT] scans)

The cutaneous mucinoses

Truhan AP, Roenigk HH. J Am Acad Dermatol 1986; 14: 1–18.

Follicular mucinosis: a clinicopathologic, histochemical, immunohistochemical and molecular study comparing the primary benign form and the mycosis fungoides-associated follicular mucinosis

Rongioletti F, De Lucchi D, Meyes D, Mora M, Rebora A, Zupo S, et al. J Cutan Pathol 2010; 37: 15–9.

Two excellent reviews of the follicular mucinosis literature, including histopathology and investigation.

Pediatric follicular mucinosis: presentation, histopathology, molecular genetics, treatment and outcomes over an 11-year period at the Mayo Clinic

Alikhan A, Griffin J, Nguyen N, Davis D, Gibson L. Pediatr Dermatol 2013; 30: 192–8.

A review of the clinical and histopathologic findings as well as the treatment and clinical outcomes in children with follicular mucinosis with and without mycosis fungoides.

First-Line Therapies

• Topical and intralesional corticosteroids	D
• Dapsone	E
• Mepacrine	E
• Tetracycline	E

Follicular mucinosis: a study of 47 patients

Emmerson RW. Br J Dermatol 1969; 81: 395–413.

Topical or intralesional corticosteroids improved surface eczematous change in 8 of 22 patients with benign disease whose lesions resolved spontaneously, independently of treatment, within 2 years. Six of 10 patients with benign chronic disease of more than 2 years' duration showed slight improvement with topical or intralesional corticosteroids.

Neonatal follicular mucinosis

Dalle S, Marrou K, Balme B, Thomas L. Br J Dermatol 2007; 157: 609–10.

A solitary pink plaque on the occipital scalp of a 21-day-old

newborn responded to mild-potency topical corticosteroid with resolution within 2 months.

Urticaria-like follicular mucinosis responding to dapsone

Al Harthi F, Kudwah A, Ajlan A, Nuaim A, Shehri F. *Acta Derm Venereol* 2003; 83: 389–90.

Itchy urticaria-like papules on the face, chest, and back of a 25-year-old man for 2 years responded to dapsone 100 mg daily long term after previously failing to respond to oral prednisolone. Attempts to reduce the dosage resulted in recurrence.

Atypical follicular mucinosis controlled with mepacrine

Sonnex TS, Ryan T, Dawber RPR. *Br J Dermatol* 1981; 105: 83–4.

Facial lesions in a 39-year-old man responded to mepacrine 100 mg twice daily. Lesions redeveloped on cessation of therapy.

A case of follicular mucinosis treated successfully with minocycline

Yotsumoto S, Uchimiya H, Kanzaki T. *Br J Dermatol* 2000; 142: 841–2.

A 36-year-old man presented with itchy papular lesions on his head, neck, and chest. After histologic confirmation of the diagnosis, indomethacin was tried (no time specified) but was not effective. Minocycline 100 mg daily for 6 weeks induced complete remission.

Follicular mucinosis: clinical, histologic and molecular remission with minocycline

Parker S, Murad M. *J Am Acad Dermatol* 2010; 62: 139–41.

A 28-year-old man with follicular mucinosis and a clonal rearrangement of the T-cell receptor gamma chain gene treated with minocycline 100 mg twice daily for 1 year had clinical, histologic, and molecular remission.

Second-Line Therapies

• Isotretinoin	E
• Psoralen and UVA (PUVA)	E
• UVA1	E
• Indomethacin	E
• Interferon	E
• Systemic corticosteroids	E
• Superficial radiotherapy	D
• Photodynamic therapy	E
• Hydroxychloroquine	D
• Topical tacrolimus	E
• Topical pimecrolimus	E
• Topical bexarotene	E
• Topical imiquimod 5%	E

Follicular mucinosis presenting as an acneiform eruption: report of four cases

Wittenberg GP, Gibson LE, Pittelkow MR, el-Azhary RA. J Am Acad Dermatol 1998; 38: 849–51.

Two women under 40 years of age had acneiform facial lesions.

One had reduced numbers and size of lesions after tretinoin gel 0.01% daily and oral pentoxifylline 400 mg three times daily, followed 2 years later by isotretinoin 40 mg daily. The second significantly improved after isotretinoin 40 mg daily and intermittent clobetasol cream.

Follicular mucinosis treated with PUVA

Kenicer KJA, Lakshmipathi T. Br J Dermatol 1982; 107: 48–9.

A 79-year-old woman with facial, truncal, and limb papules with no evidence of systemic disease failed to respond to topical corticosteroids and localized radiotherapy (100 Gy over 5 days). After 98 sessions of psoralen and ultraviolet A (PUVA) over 5 months (total dose 45.4 J/cm²) she remained disease free.

Treatment of idiopathic mucinosis follicularis with UVA1 cold light phototherapy

Von Kobyletzki G, Kreuter JA, Nordmeier R, Stücker M, Altmeyer P. Dermatology 2000; 201: 76–7.

A 26-year-old Caucasian woman with itchy follicular papules on the trunk for 7 months was diagnosed histologically and started on potent corticosteroids with no success. A ultraviolet A1 (UVA1) cold light source (340–530 nm) was used five times a week for 3 weeks and induced remission that had been sustained at 3 months.

Follicular mucinosis: response to indomethacin

Kodama H, Umemura S, Nohara N. J Dermatol 1988; 15: 72–5.

Plaques and papules on the face and back of a 48-year-old man with no signs of cutaneous lymphoma were unresponsive to topical corticosteroids, UVA, or dapsone. Topical indomethacin 1% in white petrolatum was applied until the lesions disappeared. Oral indomethacin 75 mg daily reduced untreated lesions but was not tolerated. The patient was lesion free 5 years later.

Successful treatment of recalcitrant primary follicular mucinosis with indomethacin and low-dose intralesional interferon alpha

Kim KR, Lee JY, Kim MK, Yoon TY. Ann Dermatol 2009; 21: 285–7.

A 52-year-old woman with plaques on both cheeks failed to respond to minocycline, dapsone, topical steroids, and methotrexate. A remarkable improvement was achieved with indomethacin 25 mg twice daily and intralesional corticosteroid administration after 3

months. Intralesional steroids were discontinued, and half-dose indomethacin maintained remission for a further 4 months until lack of availability led to its discontinuation. A rebound flare was controlled with intralesional interferon alpha-2a 3×10^6 biweekly for 5 weeks with subsequent increase in the injection interval to four times a week. Complete remission was achieved after 6 months with no recurrence 4 months later.

Acneiform follicular mucinosis

Passaro EMC, Silveira MT, Valente NYS. Clin Exp Dermatol 2004; 29: 396–8.

A 36-year-old man presented with a 1-year history of acneiform follicular mucinosis and was commenced on 40 mg prednisolone for 20 days. His symptoms improved quickly, and the prednisolone was weaned off by day 48. He had been clear for 7 months at the time of writing.

Alopecia mucinosa: a follow-up study

Coskey RJ, Mehregan AH. Arch Dermatol 1970; 102: 193–4.

Patients with one or two facial lesions were given superficial x-ray therapy in a weekly dose of 7.5 Gy for 4 weeks (three cases) or a combination of x-ray therapy and topical corticosteroid cream (six cases). In all cases lesions resolved.

Primary follicular mucinosis: excellent response to treatment with photodynamic therapy

Fernandez-Guarino M, Harto Castano A, Cariilo R. J Eur Acad Dermatol Venereol 2008; 22: 393–404.

A 74-year-old woman with a 4-year history of recalcitrant facial plaques cleared with one session of photodynamic therapy (topical methyl-aminolevulinic acid, red light source, 630 nm, 37 J/cm², 7.5 minutes). She had previously been recalcitrant to topical corticosteroids, narrowband ultraviolet B (UVB), and sulfone. She remained clinically clear 9 months post treatment.

Treatment of so-called idiopathic follicular mucinosis with hydroxychloroquine

Schneider SW, Metze D, Bonsmann G. Br J Dermatol 2010; 163: 420–3.

Six patients were treated with hydroxychloroquine 200 mg three times daily for 10 days with subsequent adjustment for weight,

usually to 200 mg twice daily. All patients demonstrated clinical improvement within 6 weeks and complete remission within 2 to 5 months with full hair regrowth. Individual patients were observed for 3 to 23 years, and no relapses were seen.

Follicular mucinosis treated with topical 0.1% tacrolimus ointment

Kluk J, Krassilnik N, McBride S. Clin Exp Dermatol 2014; 39: 227–8.

A 36-year-old man treated with topical 0.1% tacrolimus ointment twice daily for lesions affecting the central forehead, upper cheeks, chin, and neck. Dramatic improvement was observed at 10 days. Topical 0.1% tacrolimus ointment was then tapered over 4 weeks, and remission has been maintained at 1 year.

A case of follicular mucinosis treated successfully with pimecrolimus

Gorpelioglu C, Sarifakioglu E, Bayrak R. Clin Exp Dermatol 2008; 34: 86–7.

A 24-year-old man applied topical 1% pimecrolimus twice daily to a plaque on his chin after lack of response to local corticosteroids. Complete remission was achieved within 1 month, and treatment was discontinued. He remained clear at 7 months' follow-up.

A case of idiopathic follicular mucinosis treated with bexarotene gel

Heyl J, Mehregan D, Kado J, Campbell M. Int J Dermatol 2014; 53: 838–41.

A 34-year-old man who had treatment failure with clobetasol 0.05% ointment and narrow-band UVB applied topical bexarotene gel twice daily to affected areas on the shins for 6 weeks and then reduced to once daily due to local erythema (known side effect of bexarotene). Complete hair regrowth on shins at 26 weeks.

Treatment of primary follicular mucinosis with imiquimod 5% cream

Alonso de Celada R, Feito Rodriguez F, Noguero Morel L, Beato Merino M, De Lucas Laguna R. Pediatr Dermatol 2014; 31: 406–8.

A 10-year-old child who had treatment failure with clobetasol propionate applied topical imiquimod 5% daily for 8 weeks, achieving full resolution. Complete remission persists after 3 years of

follow-up.

Folliculitis

Chen “Mary” Chen, and Robert G. Phelps

Folliculitis is defined as the inflammation of the pilosebaceous unit. When inflammation is limited to the superficial portion of the follicle, it clinically presents with erythematous papules and pustules. Deeper inflammation manifests with furuncles and abscesses. Etiologic factors include both infectious and noninfectious agents. Bacterial pathogens are the predominant causes of infectious folliculitis; these include gram-positive *Staphylococcus aureus* and gram-negative

Pseudomonas. Herpes and molluscum cause viral folliculitis, and *Candida* and *Pityrosporum* cause fungal folliculitis. Parasitic folliculitis may be due to *Demodex*, scabies, or larva migrans.

Diagnosis is achieved through identification of the infectious agent, as well as thorough history and physical examination. There should be a high index of suspicion for gram-negative folliculitis in acne patients treated with long-term antibiotics. Exposure to contaminated water in pools or Jacuzzis can lead to folliculitis by *Pseudomonas aeruginosa*. *Pityrosporum* folliculitis, favoring the upper trunk, is more commonly found in hot and humid climates. *Demodex* folliculitis can be seen in rosacea-like lesions on the face with periorificial accentuation. This is common among young pubescent patients but may also be associated with human immunodeficiency virus (HIV) infection or leukemia. Immunocompromised patients, most notably with HIV infection, develop not only widespread folliculocentric lesions caused by bacteria, viruses, or parasites but also a characteristic sterile eosinophilic pustular folliculitis, which is paradoxically related to both immune suppression and reconstitution.

Noninfectious folliculitis may be associated with mechanical factors (friction, occlusion, or trauma), including epilation. Cutting oils and coal tar can cause irritant folliculitis, and sun exposure causes actinic folliculitis. Other associations include rheumatologic disorders (Behçet disease, Reiter syndrome, systemic lupus erythematosus, rheumatoid arthritis, and mixed connective tissue disease), inflammatory bowel disease, lymphoproliferative disease, and pregnancy. Perforating folliculitis is not only associated with diabetes mellitus and renal failure but also with tumor necrosis factor alpha (TNF α) inhibitors (infliximab). Agents responsible for drug-induced folliculitis include epidermal growth factor receptor (EGFR) inhibitors, TNF α inhibitors, trastuzumab, sorafenib, lithium, halogens, and corticosteroids.

Management Strategy

Infectious folliculitis is best managed with an optimally directed antimicrobial regimen. Therapeutic options include *antiseptics and topical or systemic antibiotics*. Early coverage for *Staphylococcus aureus* (MRSA) in high-risk populations and areas should be considered. Eosinophilic folliculitis may resolve with topical agents. EGFR inhibitor–induced folliculitis responds well to *tetracyclines*.

Noninfectious folliculitis will improve when the precipitant is removed, although the improvement may be delayed for weeks to months. Intramuscular immunoglobulin and photodynamic therapy have been suggested as novel treatment options for refractory folliculitis.

Specific Investigations

- Clinical history, including medication usage, concurrent diseases, sun exposure, and family history
- Bacterial, fungal, or viral culture and polymerase chain reaction (PCR) methods with drug sensitivity testing
- Gram stain, Tzanck smear, potassium hydroxide (KOH) preparation
- Tissue biopsy for histologic examination with microorganism stains
- Complete blood count, workup for immunodeficiencies, blood chemistries, renal function test, HIV status
- Nasal culture in chronic bacterial cases

First-Line Therapies

Topical therapy

• Mupirocin, clindamycin, and retapamulin for <i>S. aureus</i>	A
• Mupirocin for eradication of <i>S. aureus</i> colonization of the nares	A
• Daily chlorhexidine or tea tree oil soap body wash for recurrent <i>Staphylococcus</i> spp.	B
• Selenium sulfide shampoo or propylene glycol for <i>Pityrosporum</i> spp.	C
• Permethrin, ivermectin, or metronidazole for <i>Demodex</i> spp.	D
• Corticosteroid or tacrolimus for eosinophilic pustular folliculitis	C, D

Oral therapy

• Dicloxacillin or cephalexin for methicillin-sensitive <i>S. aureus</i> (MSSA)	B
• Trimethoprim/sulfamethoxazole, clindamycin, doxycycline, or linezolid for <i>MRSA</i>	B
• Ciprofloxacin for <i>Pseudomonas</i>	C
• Ampicillin, trimethoprim/sulfamethoxazole, or ciprofloxacin for gram-negative bacteria	B
• Itraconazole or fluconazole for <i>Pityrosporum</i> spp.	A
• Acyclovir, valacyclovir, or famciclovir for herpes	A
• Ivermectin and metronidazole (combination therapy) for <i>Demodex</i> spp.	A
• Indomethacin or cyclosporin for eosinophilic pustular folliculitis	C
• Tetracycline for EGFR inhibitor–induced folliculitis	B

Facial bacterial infections: folliculitis

Laureano AC, Schwartz RA, Cohen PJ. Clin Dermatol 2014; 32: 711–4.

Dicloxacillin (250–500 mg four times per day) or cephalexin (250–500 mg four times per day) for 7 to 10 days is usually sufficient in eradicating conventional facial folliculitis.

Topical retapamulin ointment, 1%, versus sodium fusidate ointment, 2%, for impetigo: a randomized, observer-blinded, noninferiority study

Oranje AP, Chosidow O, Sacchidanand S, Todd G, Singh K, Scangarella N, et al. Dermatology 2007; 215: 331–40.

Retapamulin was equally efficacious with sodium fusidate in the topical treatment of superficial skin infections.

Practice guidelines for the diagnosis and management of skin and soft tissue infections: 2014 update by the Infectious Diseases Society of America

Infectious Diseases Society of America, Stevens DL, Bisno AL, Chambers HF, Dellinger EP, Goldstein EJ, Gorbach SL, et al. Clin Infect Dis July 15, 2014; 59(2): e10–52.

The expert panel's recommendations include a decolonization regimen of 5 days of topical mupirocin and daily chlorhexidine body washes plus daily decontamination of personal items to prevent recurrences.

Demodex mites: facts and controversies

Elston DM. Clin Dermatol. 2010; 28: 502–4.

Topical permethrin 5% cream, oral ivermectin, and oral

metronidazole are reasonable treatments.

Recalcitrant papulopustular rosacea in an immunocompetent patient responding to combination therapy with oral ivermectin and topical permethrin

Kallen KJ, Davis CL, Billings SD, Mousdicas N. *Cutis* 2007; 80: 149–51.

Resolution of the folliculitis was noted with treatment combination of 5% permethrin and ivermectin.

Successful treatment of eosinophilic pustular folliculitis with topical tacrolimus 0.1% ointment

Ng SS, Tay YK. *Dermatol Online J* 2012; 18: 10.

Folliculitis in a patient showed improvement with twice-daily application of 0.1% tacrolimus ointment for 2 weeks. Complete resolution was noted after 1 month.

Community-acquired methicillin-resistant *Staphylococcus aureus* skin infections: implications for patients and practitioners

Cohen PR. *Am J Clin Dermatol* 2007; 8: 259–70.

A 10- to 14-day course of oral trimethoprim/sulfamethoxazole (1–2 tablets twice daily), clindamycin (300–450 mg four times per day), or doxycycline (100 mg twice daily) is most useful.

Treatment of methicillin-resistant *staphylococcus aureus* (MRSA) soft tissue infections: an overview

Morgan M. *Injury, Int. J. Care Injured* 2011; 42: S11–7.

Suggested antimicrobials for folliculitis include cotrimoxazole, clindamycin, doxycycline, linezolid, rifampicin, and fusidic acid.

Folliculitis: recognition and management

Luelmo-Aguilar J, Santandreu MS. *Am J Clin Dermatol* 2004; 5: 301–10.

Pseudomonas folliculitis can resolve within 7 to 10 days with good skin hygiene and avoidance of contaminated water. Oral ciprofloxacin (250–750 mg twice daily) can be used for severe cases or immunocompromised patients.

Short-term treatment of pityrosporum folliculitis: a double blind placebo-controlled study

Parsad D, Saini R, Negi KS. J Eur Acad Dermatol Venereol 1998; 11: 188–90.

A randomized trial showed remarkable response to itraconazole (200 mg per day for 7 days) compared with placebo in 26 patients after 5 weeks.

Evidence-based Danish guidelines for the treatment of *Malassezia*-related skin diseases

Hald M, Arendrup MC, Svejgaard EL, Lindskov R, Foged EK, Saunte DM. Acta Derm Venereol 2015; 95: 12–9.

Despite the greater evidence for efficacy of itraconazole, oral fluconazole is still more used due to its more favorable side effect profile and lower risk for drug interactions.

Evaluation of the efficacy of oral ivermectin in comparison with ivermectin-metronidazole combined therapy in the treatment of ocular and skin lesions of *Demodex folliculorum*

Salem DA, El-Shazly A, Nabih N, El-Bayoumy Y, Saleh S. Int J Infect Dis 2013; 17: e343.

In this trial of 120 patients with skin lesions and blepharitis, combination therapy with oral ivermectin and oral metronidazole was more effective for reducing mite counts than oral ivermectin monotherapy.

Therapeutic effectiveness of various treatments for eosinophilic pustular folliculitis

Fukamachi S, Kabashima K, Sugita K, Kobayashi M, Tokura Y. Acta Derm Venereol 2009; 89: 155–9.

Oral cyclosporin was highly effective, as was indomethacin, in alleviating the folliculitis of 11 patients.

Folliculitis induced by epidermal growth factor receptor (EGFR) inhibitors, preventive and curative efficacy of tetracyclines in the management and incidence rates according to the type of EGFR inhibitor administered

Bachet JP, Peuvrel L, Bachmeyer C, Reguiat Z, Gourraud PA, Bouché O, et al. Oncologist 2012; 17: 555–68.

A tetracycline (doxycycline 200 mg/day) should be prophylactically prescribed together with an EGFR inhibitor to prevent folliculitis.

Second-Line Therapies

Antimicrobial therapies

• Topical fusidic acid for <i>S. aureus</i>	A
• Topical benzoyl peroxide washes and bleach baths for recurrent <i>Staphylococcus</i>	B
• Oral tigecycline and vancomycin for MRSA	A

Other treatment modalities

• Intramuscular immunoglobulin	B
• Photodynamic therapy	D

High usage of topical fusidic acid and rapid clonal expansion of fusidic acid-resistant *Staphylococcus aureus*: a cautionary tale

Williamson DA, Monecke S, Heffernan H, Ritchie SR, Roberts SA, Upton A, et al. Clin Infect Dis 2014; 59: 1451.

Topical fusidic acid was once a first-line treatment option, but increasing resistance of *S. aureus* to fusidic acid has been observed, and the drug is not as readily available in the United States.

Efficacy and safety of tigecycline compared with vancomycin or linezolid for treatment of serious infections with methicillin-resistant *Staphylococcus aureus* or vancomycin-resistant *Enterococci*: a Phase III, multicenter, double-blind, randomized study

Florescu I, Beuran M, Dimov R, Razbadauskas A, Bochan M, Fichev G, et al. J Antimicrob Chemother 2008; 62(Suppl 1): i17–28.

Tigecycline and vancomycin showed similar clinical cure rates in patients with skin and skin structure infections caused by MRSA.

Intramuscular immunoglobulin for recalcitrant suppurative diseases of the skin: a retrospective review of 63 cases

Goo B, Chung HJ, Chung WG, Chung KY. Br J Dermatol 2007; 157: 563–8.

Intramuscular human immunoglobulin injections reduced the severity and the appearance of new lesions in patients with intractable suppurative skin diseases, including folliculitis.

Topical methyl aminolevulinate photodynamic therapy for the treatment of folliculitis

Horn M, Wolf P. Photodermatol Photoimmunol Photomed 2007; 23: 145–7.

Six of seven patients with recalcitrant folliculitis had significant reduction in inflammation with one session of methyl aminolevulinate photodynamic therapy.

Folliculitis decalvans

Nekma Meah, and Matthew Harries

Folliculitis decalvans (FD) is a rare, neutrophilic, inflammatory scalp condition presenting as single or multiple areas of alopecia associated with pustule formation, erythema, and increased scale with “tufted” hair follicles evident at the edge of the scarring hair loss patch. Folliculitis decalvans can involve any areas of the scalp, although the vertex and occiput are most commonly affected and nonscalp involvement is uncommon. Folliculitis decalvans tends to

run a chronic, progressive course. Multivariate analysis from one large retrospective case series suggests that onset at <25 years of age and presence of pustules are independently associated with severe disease.

The condition can occur in either sex but has a predilection for adult men. Frequent isolation of *Staphylococcus aureus* from lesional skin and observed improvement with anti-staphylococcal therapy has implicated this bacterium in disease development, perhaps through an abnormal host response in genetically susceptible individuals. However, recent identification of nonstaphylococcal bacterial biofilms deeper in lesional hair follicles may suggest alternative microbial factors contributing to disease activity.

Management Strategy

The main aim of treatment in FD is to arrest the inflammatory process and prevent extension of alopecia. Initial investigations should exclude other conditions known to mimic FD (e.g., tinea capitis). A bacteriology swab from lesional skin is advised to determine culture and sensitivity as bacterial resistance is common. Nasal staphylococcal eradication should also be considered in confirmed carriers.

There are no reported randomized controlled trials for treatment in FD. Efficacy data are available from case reports, case series, and small studies only. *Systemic antibiotics* remain the mainstay of initial therapy, although relapses are common on stopping treatment. The combination of oral *rifampicin* and *clindamycin* administered as a 10-week course has been shown to reduce activity and induce remission and as such is regarded by many as the most effective treatment for FD. *Rifampicin* monotherapy is not advised due to the risk of developing drug resistance.

Dapsone at a dose of 75 to 100 mg may also produce a satisfactory outcome, with low-dose maintenance therapy required to sustain remission. Oral *isotretinoin* is another potentially effective treatment reported to have lower relapse rates than antibiotics on treatment cessation. Oral *zinc sulfate*, as monotherapy or combined with *fusidic acid*, is also suggested in FD.

Topical, intralesional, and oral corticosteroids are adjunctive therapies that can temporarily suppress inflammation, although side effects preclude long-term use. Topical *tacrolimus ointment*, *photodynamic*

therapy, and human immunoglobulin therapy may also be effective. More recently, the anti-TNF agents *adalimumab* and *infliximab* have been successfully used in patients with severe recalcitrant disease.

In those unresponsive to medical therapy surgical interventions, such as *scalp excision*, *laser epilation* or superficial *radiotherapy* may be considered to permanently epilate the scalp, thereby removing the inflammatory focus of the condition.

Specific Investigations

- Scalp skin swab for bacteriology
- Nasal swab for bacteriology
- Scrapings and plucked hairs for mycology
- Scalp biopsy
- Consider immunodeficiency screen

How not to get scar(r)ed: a guide to diagnosis in primary cicatricial alopecias

Harries MJ, Trueb R, Messenger A, Tosti A, Chaudhry I, Sinclair R, et al. *Br J Dermatol* 2009; 160: 482–501.

A systematic approach is presented to accurately diagnose scarring alopecias, including FD.

Tinea capitis mimicking folliculitis decalvans

Tangjaturonrusamee C, Piraccini BM, Vincenzi C, Starace M, Tosti A. *Mycoses* 2011; 54: 87–8.

A case of tinea capitis caused by *Microsporum canis* mimicking FD.

Folliculitis decalvans and cellular immunity – 2 brothers with oral candidiasis

Shitara A, Igareshi R, Morohashi M. *Jpn J Dermatol* 1974; 28: 133.

Severe FD in two siblings who also had chronic oral candidiasis; defective cell-mediated immunity was demonstrated.

First-Line Therapies

Topical antibiotics

• Fusidic acid, clindamycin, erythromycin, mupirocin	E
--	----------

Systemic antibiotics

• Rifampicin and clindamycin	C
• Tetracycline antibiotics, flucloxacillin, and third-generation cephalosporins	C
• Azithromycin	D

Management of primary cicatricial alopecias: options for treatment

Harries MJ, Sinclair RD, MacDonald-Hull S, Whiting DA, Griffiths CE, Paus R. Br J Dermatol 2008; 159: 1–22.

A thorough evidence-based review on the range of treatment options for primary cicatricial alopecias.

Folliculitis decalvans: a multicentre review of 82 patients

Vañó-Galván S, Molina-Ruiz AM, Fernández-Crehuet P, Rodrigues-Barata AR, Arias-Santiago S, Serrano-Falcón C, et al. J Eur Acad Dermatol Venereol 2015; 29: 1750–7.

A retrospective review of 82 patients with FD. Ninety percent to 100% of patients on either oral doxycycline 100 mg daily, azithromycin 500 mg three times a daily, or combination of clindamycin and rifampicin demonstrated improvement.

Effective treatment of folliculitis decalvans using selected antimicrobial agents

Sillani C, Bin Z, Ying Z, Zeming C, Jian Y, Xingqi Z. Int J Trichology 2010; 2: 20–3.

Thirteen patients with mild to moderate FD. Minocycline 100 mg twice daily as monotherapy was effective in six patients, with a further three patients responding to minocycline and rifampicin in combination.

Folliculitis decalvans including tufted folliculitis: clinical, histological and therapeutic findings

Powell JJ, Dawber RPR, Gatter K. Br J Dermatol 1999; 140: 328–33.

Eighteen patients with folliculitis decalvans were treated with oral

rifampicin 300 mg twice daily and oral clindamycin 300 mg twice daily combination for 10 weeks. All patients reported improvement during treatment, with 10 patients achieving a lasting remission.

Second-Line Therapies

• Fusidic acid and oral zinc sulfate	E
• Dapsone	E
• Systemic/intralesional corticosteroids	D
• Isotretinoin	D

Folliculitis decalvans. Long-lasting response to combined therapy with fusidic acid and zinc

Abeck D, Korting HC, Braun-Falco O. Acta Derm Venereol 1992; 72: 143–5.

Three patients responded to oral fusidic acid (500 mg three times a day) and topical fusidic acid cream for 3 weeks combined with oral zinc sulfate 200 mg twice a day for 6 months and once a day thereafter. Disease relapse coincided with stopping zinc sulfate.

Dapsone treatment of folliculitis decalvans

Paquet P, Pierard GE. Ann Dermatol Venereol 2004; 131: 195–7.

Two patients treated with dapsone 75 to 100 mg daily showed clinical response 1 to 2 months into treatment. A maintenance dose of 25 mg daily resulted in sustained remission.

Retrospective review of folliculitis decalvans in 23 patients with course and treatment analysis of long-standing cases

Bunagan MJ, Banka N, Shapiro J. J Cutan Med Surg 2015; 19: 45–9

The combination of oral tetracycline, intralesional triamcinolone every 4 to 6 weeks, and clobetasol lotion resulted in remission in 7 out of 10 patients on this regimen.

Oral isotretinoin as the most effective treatment in folliculitis decalvans: a retrospective comparison of different treatment regimens in 28 patients

Tietze JK, Heppt MV, von Preußen A, Wolf U, Ruzicka T, Wolff H, et al. J Eur Acad Dermatol Venereol 2015; 29: 1816–21.

Nine of 10 patients receiving oral isotretinoin (0.2–0.5 mg/kg daily for 5–7 months followed by 10 mg daily two to three times a week) achieved complete remission. Three patients required low-dose isotretinoin long term.

Third-Line Therapies

• Surgical excision	E
• Shaving of scalp	E
• Superficial radiotherapy	E
• Laser epilation	E
• Oral L-tyrosine	E
• Tacrolimus 0.1% ointment	E
• Keratolytics and tar shampoo	E
• Anti-TNF- α therapy	E
• Immunoglobulin therapy	E
• Photodynamic therapy	C

Tufted hair folliculitis

Tong AK, Baden HP. J Am Acad Dermatol 1989; 21: 1096–9.
Tufted folliculitis successfully treated by surgical excision.

Treatment of folliculitis decalvans using intensity-modulated radiation via tomotherapy

Elsayad K, Kriz J, Haverkamp U, Plachouri KM, Jeskowiak A, Sunderkötter C, et al. Strahlenther Onkol 2015; 191: 883–8.

A case of recalcitrant FD responding to 11 Gy delivered in two radiation series.

Nd:YAG laser treatment of recalcitrant folliculitis decalvans

Parlette EC, Kroeger N, Ross EV. Dermatol Surg 2004; 30: 1152–4.

Remission achieved with laser epilation in a patient with Fitzpatrick skin type VI.

Treatment of folliculitis decalvans with tacrolimus ointment

Bastida J, Valeron-Almazan P, Santana-Molina N, Medina-Gil C. Int J Dermatol 2012; 51: 216–20.

Tacrolimus 0.1% ointment applied twice daily in four patients with recalcitrant disease. A favorable outcome was achieved in all four cases.

Successful use of infliximab in a patient with recalcitrant folliculitis decalvans

Mihaljevic N, von den Driesch P. J Dtsch Dermatol Ges 2012; 10: 589–92.

Treatment with infliximab (5 mg/kg) resulted in rapid remission in a patient with treatment-resistant FD. No relapse occurred in the 12-month follow-up period.

Therapy-resistant folliculitis decalvans and lichen planopilaris successfully treated with adalimumab

Kreutzer K, Effendy I. J Dtsch Dermatol Ges 2014; 12: 74–6.

Two patients with FD responded well to adalimumab 40 mg administered fortnightly. Marked improvement was noted after 8 to 12 weeks.

Intramuscular immunoglobulin for recalcitrant suppurative diseases of the skin: a retrospective review of 63 cases

Goo B, Chung HJ, Chung WG, Chung KY. Br J Dermatol 2007; 157:

563–8.

Three patients with FD were rated to have a “good response” after intramuscular human immunoglobulin administered once a month.

Intravenous human immunoglobulin for treatment of folliculitis decalvans

Ismail N, Ralph N, Murphy G. *J Dermatol Treat* 2015; 26: 471–2.

Intravenous human immunoglobulin (2 g/kg for the first month, followed by 1 g/kg for the second to fourth months) resulted in clinical improvement.

Treatment of folliculitis decalvans with photodynamic therapy: results in 10 patients

Miguel-Gomez L, Vano-Galvan S, Perez-Garcia B, Carrillo-Gijon R, Jaen-Olasolo P. *J Am Acad Dermatol* 2015; 72: 1085–7.

Prospective study of topical photodynamic therapy delivered every 4 weeks. Nine patients (90%) achieved clinical improvement at 16 weeks.

Fox–Fordyce disease

Ian Coulson

Obliteration of the follicular infundibulum with keratin in the apocrine gland-bearing skin is the cause of this rare, paroxysmally intensely itchy condition. Apocrine sweat retention and rupture of the gland duct under periods of apocrine sudomotor stimulation,

particularly emotional stress, results in the development of an itchy, spongiotic intraepidermal vesicle. It mainly affects women between the ages of 13 and 35 years but has rarely been reported before puberty, after menopause, and in men. Itchy, dome-shaped, flesh-colored or keratotic papules that develop peripubertally in the apocrine areas of the axillae, pubic, periumbilical, and periareolar skin characterize this condition. Sparsity of axillary hair and hypohidrosis is usual, although rarely it can be exacerbated by hyperhidrosis. Improvement in pregnancy and during the administration of the oral contraceptive pill has led to speculation regarding an endocrine etiology, but this has been unsubstantiated by blood sex hormone investigations. Very few reports in twins and within families suggest a possible genetic component. It can occur after laser hair removal and has been reported in Turner syndrome.

Management Strategy

There are no controlled trials of any agents in Fox–Fordyce disease (FFD).

Topical and intralesional corticosteroids are frequently tried and may be of limited benefit, but atrophy in the axillary area will limit their potency and duration of use. Topical *tretinoin* and *adapalene* have been reported to reduce itch, but alternation with a mild corticosteroid may be needed to reduce retinoid irritancy. *Clindamycin* lotion may be of help. The *oral contraceptive pill (OCP)* may bring relief to some women. Oral *isotretinoin* may give temporary help. *Electrocautery* and *excision* of the periareolar skin may offer permanent solutions. A recent report advocates an ingenious method of removal of the apocrine glands using a microliposuction cannula. There is a single report of axillary disease responding to intralesional botulinum toxin injection.

Specific Investigation

- Biopsy

Fox–Fordyce disease: diagnosis by transverse histologic sections

Stashower ME, Krivda SJ, Turiansky GW. J Am Acad Dermatol 2000; 42: 89–91.

Transverse sectioning demonstrates the follicular plugging and infundibular spongiosis more readily than conventional sections.

Patterns histopathologic of Fox–Fordyce disease

Böer A. Am J Dermatopathol 2004; 26: 482–92.

An exhaustive review of the subtleties of the dermatopathology of Fox–Fordyce disease.

Dilation of apocrine glands. A forgotten but helpful histopathological clue to the diagnosis of axillary Fox-Fordyce disease

Macarenco RS, Garces S JC. Am J Dermatopathol 2009; 31: 393–7.

Apocrine gland dilation may be used as a low-power magnification clue, which should be followed by a search for further histologic changes to confirm or rule out the diagnosis.

Clinicopathological study of Fox-Fordyce disease

Kao PH, Hsu CK, Lee JY. J Dermatol 2009; 36: 485–90.

Focal spongiosis in the upper infundibulum with perifollicular fibrosis and lymphohistiocytic infiltrate were consistent features in their case series.

Axillary perifollicular xanthomatosis resembling Fox–Fordyce disease

Kossard S, Dwyer P. Australas J Dermatol 2004; 45: 146–8.

Fox-Fordyce-like disease following laser hair removal appearing on all treated areas

Helou J, Maatouk I, Moutran R, Obeid G. Lasers Med Sci 2013; 28: 1205–7.

The most recent of reports highlighting that laser epilation in several anatomic sites may induce FFD.

Perifollicular xanthomatosis as a key histologic finding in Fox–Fordyce disease

Mataix J, Silvestre JF, Niveiro M, Lucas A, Pérez-Crespo M. Actas Dermosifiliogr 2008; 99: 145–8.

There are occasional conditions to consider in the differential diagnosis! There is even controversy as to whether perifollicular xanthomatosis is part of the spectrum of this disorder.

First-Line Therapies

• Topical and intralesional corticosteroids	D
• Topical clindamycin	E
• Oral contraceptive pill	D
• Topical retinoids	D
• Ultraviolet B (UVB)	D
• Topical pimecrolimus and tacrolimus	D

A new treatment of Fox–Fordyce disease

Helfamn RJ. South Med J 1962; 55: 681–4.

A single report of successful symptom relief of axillary lesions with 10 mg/mL triamcinolone diluted with an equal volume of 1% lidocaine to four sites on nine occasions over 3 months.

Fox–Fordyce disease – successful treatment with topical clindamycin in alcoholic propylene glycol solution

Feldmann R, Masouye I, Chavaz P, Saurat JH. Dermatology 1992; 184: 310–3.

A single report of FFD in the axillary, pubic, and inguinal areas responding to 1% clindamycin in an alcoholic propylene glycol solution within 1 month (clindamycin 10 mg/mL; propylene glycol 50 mg/mL; isopropyl alcohol 0.5 mg/mL; water). Nine months later the treatment was stopped, and no recurrence was observed. The authors speculate that the keratolytic effect of propylene glycol may have been responsible for the therapeutic effect.

Fox–Fordyce disease. Treatment with an oral contraceptive

Kronthal HI, Pomeranz JR, Sitomer G. Arch Dermatol 1965; 91: 243–5.

Two female patients responded to a high-estrogen-dose combined OCP, norethynodrel, and mestranol.

Fox–Fordyce disease. Control with tretinoin cream

Giacobetti R, Caro WA, Roenigk HH Jr. Arch Dermatol 1979; 115: 1365–6.

A single report of 0.1% tretinoin cream applied to the axillae on alternate nights resulting in reduction of itch and regrowth of hair. Local retinoid irritation was controlled with 1% hydrocortisone cream.

Fox-Fordyce disease: response to adapalene 0.1%

Kassuga LE, Medrado MM, Chevrant NS, Salles Sde A, Vilar EG. An Bras Dermatol 2012; 87: 329–31.

0.1% adapalene cream produced satisfactory improvement of the signs and symptoms of a single patient with FFD. In acne, this product is less irritating than tretinoin, so it may be a more tolerable topical retinoid option.

Treatment of Fox–Fordyce disease

Pinkus H. JAMA 1973; 223: 924.

Erythemogenic doses of UVB (once weekly for 4–6 weeks) produced long-lasting relief to several patients.

Pimecrolimus is effective in Fox–Fordyce disease

Pock L, Svrcková M, Machácková R, Hercogová J. Int J Dermatol 2006; 45: 1134–5.

A series of three patients who benefited from topical pimecrolimus.

Clinical effects of topical tacrolimus on Fox-Fordyce disease

Kaya Erdoğan H, Bulur I, Kaya Z. Case Rep Dermatol Med 2015: 205418.

Two case reports, one with a successful response in terms of itch, from twice-daily 0.1% tacrolimus ointment applied for 3 months.

The treatment of Fox–Fordyce disease

Shelley WB. JAMA 1972; 222: 1069.

A concise review of the therapies available to that date. The master of dermatologic therapy admits that sometimes all fails and that relief may only come at menopause!

Second-Line Therapies

• Oral isotretinoin	E
• Electrocautery	D
• Excision	D
• Apocrine gland removal using microliposuction	E
• Botulinum toxin	E

Fox–Fordyce disease in a male patient – response to oral retinoid treatment

Effendy I, Ossowski B, Happle R. Clin Exp Dermatol 1994; 19: 67–9.

Oral treatment with isotretinoin (30 mg daily for 8 weeks and then 15 mg daily for 2 months) resulted in temporary relief. Relapse occurred 3 months after discontinuation.

Fox–Fordyce disease in the postmenopausal period treated successfully with electrocoagulation

Pasricha JS, Nayyar KC. Dermatologica 1973; 147: 271–3.

Electrocoagulation to a level of 3 to 4 mm under local anesthetic produced a permanent resolution of symptoms in the axillae of two patients.

Surgical treatment of areolar hidradenitis suppurativa and Fox–Fordyce disease

Chavoin J-P, Charasson T, Barnard J-D. Ann Chir Plast Esthet 1994; 39: 233–8.

A simple technique involving dermal detachment of the areola, excision of the underlying apocrine glands, and reattachment of the areola with good cosmetic results.

This treatment has not proved beneficial long term.

Axillary Fox–Fordyce disease treated with liposuction-assisted curettage

Chae KM, Marschall MA, Marschall SF. Arch Dermatol 2002; 138: 452–4.

A novel technique of curettage removal of the apocrine glands using a small liposuction cannula with symptom relief, great cosmesis, and a follow-up at publication of 8 months. A liposuction cannula was introduced through a stab incision in the axilla and, with the aperture of the cannula turned up toward the underside of the dermis, the deeper dermis was curetted to create inflammation and subsequent fibrosis. The same technique can be used to treat axillary hyperhidrosis.

Successful treatment of refractory pruritic Fox-Fordyce disease with botulinum toxin type A

González-Ramos J, Alonso-Pacheco ML, Goiburú-Chenú B, Mayor-Ibarguren A, Herranz-Pinto P. *Br J Dermatol* 2016; 174: 458–9.

A single case report of a woman receiving 100 U of Botox to each axilla; itching completely abated and papules partially regressed, and the response was sustained over 8 months of follow-up after a single treatment.

Furunculosis

Charles A. Gropper, and Karthik Krishnamurthy

Furunculosis, commonly referred to as *boils*, is a deep infection of the pilosebaceous unit. Lesions may occur on any hair-bearing surface, including the nares. When many hair follicles are involved, the term *carbuncle* is used. These large, suppurative lesions are usually very tender and may have multiple draining sites.

Management Strategy

The infectious agent most commonly implicated is *Staphylococcus aureus*; methicillin-resistant strains of *S. aureus* (MRSA) are now recognized as the dominant isolate overall. In recent years, the designations of community-acquired MRSA (CA-MRSA) versus hospital-acquired MRSA (HA-MRSA) have become blurred due to a convergence in both antibiotic susceptibility profiles and risk of sequelae. Delay in diagnosis and appropriate therapy can lead to systemic involvement, including rare reports of epidural abscess, bacterial endocarditis, and pulmonary infection.

Other culprits such as group A beta-hemolytic *Streptococcus* and gram-negative bacteria should remain in the differential diagnosis. In addition, *Mycobacterium* spp., especially *M. fortuitum*, have been implicated in nonresponsive furunculosis in patients using footbaths in beauty salons.

Nasal, pharyngeal, axillary, perineal, and rectal pathogen carriage is implicated in recurrent disease. In rare cases, patients with impaired neutrophil function and immunodeficiency syndromes, such as common variable immunodeficiency and hyper-IgE syndrome, also present with recurrent furunculosis.

Isolated lesions should be *incised and drained*. Multiple, mostly observational, studies indicate high postsurgical cure rates (85%–90%) whether or not an active antibiotic is used. Therefore according to the Centers for Disease Control (2006) and Infectious Diseases Society of America (2011), empiric antibiotics should be reserved for those with

- Severe or extensive disease (e.g., involving multiple sites of infection)
- Rapid progression in presence of associated cellulitis
- Signs and symptoms of systemic illness
- Associated comorbidities/immunosuppression (diabetes mellitus, human immunodeficiency virus, neoplasm)
- Extremes of age
- Abscess in area difficult to drain completely (e.g., face, hand, and genitalia)
- Associated septic phlebitis
- Lack of response to incision and drainage alone

Swabs of any purulent discharge should be collected for bacterial culture; antibiotic therapy may be redirected based on sensitivities and clinical scenario. Acid-fast staining and culture may be warranted

if a temporal relationship to a pedicure is noted. Currently, antibiotics carrying a Food and Drug Administration (FDA) indication for use against MRSA include *linezolid*, *ceftaroline* ("advanced"-generation cephalosporin), *telavancin* (similar to vancomycin), *tigecycline* (derivative of minocycline), and *teicoplanin*. These are mainly reserved for complicated infections requiring hospitalization. Other antibiotics with anti-MRSA activity include *trimethoprim/sulfamethoxazole* (TMP-SX), *daptomycin*, *vancomycin*, *doxycycline*, *minocycline*, *clindamycin*, *rifampin*, and *quinupristin-dalfopristin*. Evidence of nasal carriage of staphylococci should be sought in those with recurrent disease and eradicated with either *oral rifampicin* (not as monotherapy) or *nasal mupirocin* or *fusidic acid*.

Specific Investigations

- Culture and sensitivity of purulent drainage
- Acid-fast stain and culture (if indicated)
- Moistened nasal swab for culture (if recurrent)
- Neutrophil count and immunoglobulin levels (if relevant and/or recurrent)

First-Line Therapy

- | | |
|----------------------------------|----------|
| • Surgery: incision and drainage | A |
|----------------------------------|----------|

Randomized, double-blind, placebo-controlled trial of cephalexin for treatment of uncomplicated skin abscesses in a population at risk for community-acquired methicillin-resistant *Staphylococcus aureus* infection

Rajendran PM, Young D, Maurer T, Chambers H, Perdreau-Remington F, Ro P, et al. *Antimicrob Agents Chemother* 2007; 51: 4044–8.

Randomized, double-blind trial of 166 outpatient subjects comparing placebo to cephalexin at 500 mg orally four times daily for 7 days after incision and drainage of skin and soft tissue abscesses.

The primary outcome was clinical cure or failure 7 days after incision and drainage. Of the isolates tested 87.8% were MRSA. Clinical cure rates were 90.5% (95% confidence interval [CI], 0.82–0.96) in the 84 placebo recipients and 84.1% (95% CI, 0.74–0.91) in the 82 cephalexin recipients (difference in the two proportions, 0.0006; 95% CI, –0.0461–0.0472; $p = 0.25$). Provides strong evidence that antibiotics may be unnecessary after surgical drainage of uncomplicated skin and soft tissue abscesses caused by community strains of MRSA.

Second-Line Therapies

• Doxycycline or minocycline	B
• Trimethoprim/sulfamethoxazole	B
• Clindamycin	B
• Linezolid	B

Adjunctive for patients meeting criteria listed in the “Management Strategy” section.

Clinical practice guidelines by the Infectious Diseases Society of America for the treatment of methicillin-resistant *Staphylococcus aureus* infections in adults and children: executive summary

Liu C, Bayer A, Cosgrove SE, Daum RS, Fridkin SK, Gorwitz RJ, et al. Clin Infect Dis 2011; 52: 285–92.

Oral antibiotics that may be used as empiric therapy for CA-MRSA include TMP-SMX, doxycycline (or minocycline), clindamycin, and linezolid. Several observational studies and one small randomized trial suggest that TMP-SMX, doxycycline, and minocycline are effective for such infections. Clindamycin is effective in children with CA-MRSA skin and soft tissue infection (SSTI). Linezolid is FDA-approved for SSTI but is not superior to less expensive alternatives.

Tetracyclines as an oral treatment option for patients with

community onset skin and soft tissue infections caused by methicillin-resistant *Staphylococcus aureus*

Ruhe JJ, Menon A. Antimicrob Agents Chemother 2007; 51: 3298–303.

Retrospective study of 276 outpatients. The median percentage of patients infected with MRSA strains that were susceptible to tetracycline was 95%. A total of 225 patients (80%) underwent incision and drainage. Doxycycline or minocycline was administered in 90 episodes (32%); the other 192 SSTI were treated with beta-lactams. Receipt of beta-lactam antibiotics was associated with treatment failure.

Prevalence, severity, and treatment of community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) skin and soft tissue infections in 10 medical clinics in Texas: a South Texas Ambulatory Research Network (STARNet) study

Forcade NA, Parchman ML, Jorgensen JH, Du LC, Nyren NR, Treviño LB, et al. J Am Board Fam Med 2011; 24: 543–50.

Ten primary care clinics took part in this prospective, community-based study. Overall, 73 of 119 (61%) patients presenting with SSTIs meeting eligibility requirements had CA-MRSA. Most received incision and drainage plus an antibiotic (64%). Antibiotic monotherapy was frequently prescribed: TMP-SMX (78%), clindamycin (4%), doxycycline (2%), and mupirocin (2%). The rest received TMP-SMX in combination with other antibiotics. Isolates were 93% susceptible to clindamycin and 100% susceptible to TMP-SMX, doxycycline, vancomycin, and linezolid.

Trimethoprim-sulfamethoxazole or clindamycin for treatment of community-acquired methicillin-resistant *Staphylococcus aureus* skin and soft tissue infections

Hyun DY, Mason EO, Forbes A, Kaplan SL. Pediatr Infect Dis J 2009; 28: 57–9.

A retrospective study of 508 patients who had MRSA isolated either from surgically obtained drainage or from spontaneous drainage of the infection site; 215 patients were prescribed oral TMP-SMX therapy, and 200 were prescribed oral clindamycin. No significant differences were observed in the percentage who returned because of worsening or incomplete resolution. Most of the patients had incision and drainage (94% of TMP-SMX patients, 86% of clindamycin patients) so results may more likely reflect improvement from

incision and drainage than antibiotic choice.

Third-Line Therapies/Prevention

• Topical nadifloxacin	B
• Nasal mupirocin	B
• Bleach bath	E
• Colonization with less pathogenic staphylococci	E
• Retapamulin	E
• Fusidic acid	B

Efficacy and safety of nadifloxacin for bacterial skin infections: results from clinical and postmarketing studies

Narayanan V, Motlekar S, Kadhe G, Bhagat S. *Dermatol Ther* 2014; 4: 233–48.

A total of 272 subjects were enrolled in the study, and subjects were randomly assigned to one of the three treatment groups: 92 in the nadifloxacin group, 90 in the mupirocin group, and 90 in the framycetin group. A significant reduction in the mean scores for bacterial infection symptoms in the nadifloxacin groups was observed compared with the mupirocin, framycetin, and fusidic acid groups. No adverse events (AEs) were reported in the clinical studies.

Randomized controlled trial of chlorhexidine gluconate for washing, intranasal mupirocin, and rifampin and doxycycline versus no treatment for the eradication of methicillin-resistant *Staphylococcus aureus* colonization

Simor AE, Phillips E, McGeer A, Konvalinka A, Loeb M, Devlin HR, et al. *Clin Infect Dis* 2007; 44: 178–85.

Treatment with this regimen for 7 days was safe and effective in eradicating MRSA colonization in hospitalized patients for at least 3 months.

Hypochlorite killing of community-associated methicillin-

resistant *Staphylococcus aureus*

Fisher RG, Chain RL, Hair PS, Cunnion KM. *Pediatr Infect Dis J* 2008; 27: 934–5.

In vitro study of hypochlorite (bleach) against CA-MRSA. Maximal killing was found after 5 minutes in 2.5 $\mu\text{L/mL}$ bleach. A 2.5- $\mu\text{L/mL}$ bleach solution is approximately equivalent to one-half cup of bleach in one-quarter tub of water. In vivo studies will be required to show clinical effectiveness.

Recurrent staphylococcal infection in families

Steele R. *Arch Dermatol* 1980; 116: 189–90.

Fifteen of 17 families inoculated with less pathogenic strains of *S. aureus* remained disease free at 6 months, whereas only 4 of the 15 control families had no recurrences.

In vitro activity of retapamulin against *Staphylococcus aureus* isolates resistant to fusidic acid and mupirocin

Woodford N, Afzal-Shah M, Warner M, Livermore DM. *J Antimicrob Chemother* 2008; 766–8.

Retapamulin inhibited 99.9% of all *S. aureus* isolates. Further in vivo studies are indicated to assess efficacy in the treatment of furunculosis.

Treatment and prevention of recurrent staphylococcal furunculosis: clinical and bacteriologic follow-up

Hedstrom SA. *Scand J Infect Dis* 1985; 17: 55–8.

Sodium fusidate ointment was used twice daily for a month as prophylaxis for nasal furunculosis with cessation of furuncles in 10 of 20 cases. Controls took antibiotics systemically, and 3 of 20 had no furuncles. After a year, those who used topical therapy had fewer recurrent lesions.

Condyloma acuminata

Brian Berman, Sadegh Amini, and Andrea Maderal

External anogenital warts develop on the skin and mucosal surfaces of the genitalia and perianal areas. They are caused by the human papillomavirus (HPV), sexually transmitted in approximately 65% of cases, with at least 40 of the more than 100 types identified capable of infecting the genital tract. Condyloma acuminata (CA), the classic

form of anogenital warts, are frequently associated with “benign” HPV types 6 and 11 (up to 95%) but may also be caused by oncogenic HPV types such as 16, 18, 31, 33, and 35.

Management Strategy

Most cases are asymptomatic; however, they can be disfiguring; lead to physical discomfort; induce psychological suffering, guilt, and anger; and severely affect quality of life. Untreated genital warts may increase in size or number, remain unchanged, or resolve spontaneously.

Current treatments focus on stimulation of the host’s immune response to enhance virus recognition. Treatments are categorized as either patient applied (i.e., *podofilox*, *imiquimod*, and *sinecatechin*) or provider administered. Podofilox (podophyllotoxin) is applied twice daily for 3 days and then no treatment for 4 days for four to six cycles, if necessary.

Imiquimod 5%, 3.75%, or 2.5% cream stimulates the host’s immune response. Imiquimod 5% is applied overnight and washed off 6 to 10 hours after application, three times a week, until clearance of the warts or a maximum of 16 weeks. Imiquimod 3.75% is applied nightly for up to 8 weeks.

Sinecatechin 15% ointment extract of green tea from *Camellia sinensis* contains epigallocatechin gallate, exhibiting antiviral, antitumor, and immunostimulatory properties. It is applied three times a day until clearance of the warts or a maximum of 16 weeks.

Provider-administered therapies are either topically applied or surgical. Topical modalities include *podophyllin resin*, *podofilox* (podophyllotoxin), *bichloroacetic acid* (BCA), *trichloroacetic acid* (TCA), *intralesional bleomycin*, and *ingenol mebutate*. Surgical treatments include *cryotherapy*, *surgical removal* either by tangential shave using a cold knife or tangential scissor excisions, *curettage* with or without *electrosurgery*, and *lasers* (CO₂ and pulsed dye laser, PDL). *Intralesional interferon-α* and *bleomycin* are also effective therapies. *Podophyllin* resin is applied for 1 to 6 hours and is less effective on dry areas such as the penile shaft, scrotum, and labia majora.

The safety of podofilox, imiquimod, and sinecatechin (all category C) during pregnancy has not been established. Both TCA and BCA 80% to 90% solutions are applied weekly as needed.

Cryotherapy causes thermolysis and necrosis of keratinocytes hosting HPV. Liquid nitrogen either with cryospray or cryoprobe usually requires one to two freeze–thaw cycles per session for two to three sessions. However, HPV deoxyribonucleic acid (DNA) is detectable up to 1 cm from the wart periphery, and recurrence rates are up to 40%.

Surgery and *CO₂ lasers* are useful for treating extensive giant (i.e., Buschke–Lowenstein tumor) intraurethral and recalcitrant warts.

Recombinant HPV quadrivalent (6–11–16–18) vaccine is safe and efficacious in decreasing the incidence of persistent anogenital warts and cervical cancer by 90% and, within 6 years of introduction, has shown a 64% decrease in prevalence of those HPV types in females 14 to 19 years of age. A 9-valent HPV vaccine was also recently approved.

Estimates of clearance and recurrence rates with various therapies are difficult due to differences in method of analysis, patient population, and duration of follow-up. No available therapy can be guaranteed to clear genital warts without any recurrence. Combination therapy using an immunomodulator after physical ablative therapy reduces recurrence rates; however, the possibility of additive adverse events should be considered.

Specific Investigations

- Papanicolaou (Pap) smear
- HPV typing (not standard of care)
- Biopsy
- Acetic acid 3% to 5% (not recommended)

Evaluation of human papillomavirus testing in primary screening for cervical abnormalities: comparison of sensitivity, specificity, and frequency of referral

Kulasingam SL, Hughes JP, Kiviat NB, Mao C, Weiss NS, Kuypers JM, et al. JAMA 2002; 288: 1749–57.

HPV DNA testing has higher sensitivity but lower specificity than thin-layer Pap screening. In some settings (i.e., long or haphazard screening intervals), HPV DNA screening may be an alternative to cytology-based screening in women of reproductive age.

Evidence-based treatment and prevention of external genital warts in female pediatric and adolescent patients

Thornsberry L, English JC. J Pediatr Adolesc Gynecol 2012; 25: 150–4.

The diagnosis of anogenital warts is generally clinical. HPV DNA typing and 3% to 5% acetic acid testing to reveal subclinical lesions are not recommended. Anoscopy and/or speculum examination are useful for evaluation of the anal canal, vagina, or cervix. A biopsy is not indicated for typical condylomas but must be performed for atypical-looking and recalcitrant lesions or in immunocompromised patients.

First-Line Therapies

• Imiquimod (5%, 3.75%)	A
• Podofilox (podophyllotoxin)	A
• Sinecatechin extract of green tea	A
• Cryotherapy	A
• Podophyllin	B

Imiquimod, a patient-applied immune response modifier for treatment of external genital warts

Beutner KR, Tying SK, Trofatter KF Jr, Douglas JM Jr, Spruance S, Owens ML, et al. Antimicrob Agents Chemother 1998; 42: 789–94.

A multicenter, double-blind, vehicle-controlled, trial ($n = 279$) evaluated daily application of imiquimod for 16 weeks. At week 16, 52% of 5% imiquimod-treated patients, 14% of 1% imiquimod, and 4% of vehicle-treated patients cleared the warts ($p < 0.0001$). Recurrence rate after a complete response was 19% with 5% imiquimod.

Imiquimod cream 2.5% and 3.75% applied once daily to treat external genital warts in men

Rosen T, Nelson A, Ault K. *Cutis* 2015; 96: 277–82.

Two multicenter, randomized, double-blind, placebo-controlled studies evaluated 447 patients randomized to imiquimod cream 3.75% or 2.5% or placebo once daily until complete clearance or maximum of 8 weeks. Complete clearance at end of study period was 18.6% in the 3.75% imiquimod group and 14.3% in the 2.5% imiquimod group. Both groups were significantly superior to placebo in one study.

Human papillomavirus (HPV) viral load and HPV type in the clinical outcome of HIV-positive patients treated with imiquimod for anogenital warts and anal intraepithelial neoplasia

Sanclemente G, Herrera S, Tyring SK, Rady PL, Zuleta JJ, Correa LA, et al. *J Eur Acad Dermatol Venereol* 2007; 21: 1054–60.

Imiquimod 5% was evaluated in 37 HIV-positive males with anogenital warts or anal intraepithelial neoplasia (AIN). Imiquimod was applied three times per week for at least 8 hours overnight for 16 weeks. At week 20, 46% of patients cleared 100%, whereas 14 patients had >50% clearance. Recurrences occurred in 29% of patients who cleared 100%. Clearance was independent of patient's CD4 count, wart location, HIV viral load, or HPV viral load.

A multicenter, randomised, double-blind, placebo controlled study of cryotherapy versus cryotherapy and podophyllotoxin cream as treatment for external anogenital warts

Gilson RJ, Ross J, Maw R, Rowen D, Sonnex C, Lacey CJ. *Sex Transm Infect* 2009; 85: 514–9.

Patients ($n = 140$) received cryotherapy plus podophyllotoxin or cryotherapy alone. Podophyllotoxin cream or placebo was applied twice daily for 3 days per week for up to 4 weeks, with weekly cryotherapy continued to week 12 if required. Complete clearance rates with the combination versus cryotherapy alone were 60.0% and 45.7%, respectively (no statistical difference). At week 24 both groups had similar clearance rates, with new and recurrent lesions in 16.7% and 18.8% of patients, respectively.

Safety and efficacy of 0.5% podofilox gel in the treatment of anogenital warts

Tyring S, Edwards L, Cherry LK, Ramsdell WM, Kotner S, Greenberg MD, et al. *Arch Dermatol* 1998; 134: 33–8.

In a double-blind, multicenter, vehicle-controlled trial, 326 patients

applied podofilox twice daily for 3 consecutive days followed by a 4-day treatment-free period (one treatment cycle). Treatment was repeated by the patient until all study warts had cleared, for a minimum of two and maximum of eight cycles. At week 8, 88.4% of warts in the vehicle-treated group and 35.9% in the podofilox-treated group remained ($p = 0.001$).

Efficacy, safety and tolerability of green tea catechins in the treatment of external anogenital warts: a systematic review and meta-analysis

Tzellos TG, Sardeli C, Lallas A, Papazisis G, Chourdakis M, Kouvelas D. J Eur Acad Dermatol Venereol 2011; 25: 345–53.

Three double-blind studies ($n = 1247$) evaluated sinecatechin ointment, obtaining complete clearance ranging from 52.6% to 64.6%. Recurrence ranged from 5.9% to 10.6%.

Sinecatechin ointment is applied three times a day for up to 16 weeks.

A single-blinded randomized controlled study to assess the efficacy of twice daily application of sinecatechins 1% ointment when used sequentially with cryotherapy in the treatment of external genital warts

On SC, Linkner RV, Haddican M, Yaroshinsky A, Gagliotti M, Singer G, et al. J Drugs Dermatol 2014; 13: 1400–5.

Single-blinded, randomized controlled trial of 42 subjects treated with cryotherapy alone versus cryotherapy with sinecatechin 15% ointment twice daily for up to 16 weeks. There was a reduction in the number of lesions in the combination group compared with cryotherapy alone (–5 lesions vs. –2.1 lesions, $p = 0.07$).

Treatment of external genital warts: a randomized clinical trial comparing podophyllin, cryotherapy, and electrodesiccation

Stone KM, Becker TM, Hadgu A, Kraus SJ. Genitourin Med 1990; 66: 16–9.

All treatments were provided weekly until clearance or until a total of six treatments had been administered. Patients were instructed to wash off the podophyllin 2 hours after the first treatment; this interval was lengthened by 2 hours to a maximum of 12 hours with each successive treatment. After evaluating 450 patients, complete clearance was observed in 41% of podophyllin-treated, 79% of cryotherapy-treated, and 94% of electrodesiccation-treated patients.

The 3-month clearance rates were 17%, 55%, and 71%, respectively.

Cryotherapy is safe to use during pregnancy. Podophyllin, however, has been demonstrated to have severe systemic toxicity and should not be used in pregnant women.

Second-Line Therapies

• Surgical excision (with cold knife or scissors)	B
• Lasers (CO ₂ and PDL)	B
• Loop electrosurgical excisional procedure	B
• Electrodesiccation (see also earlier)	B
• Trichloroacetic acid (see also earlier)	B

Comparison of podophyllin application with simple surgical excision in clearance and recurrence of perianal condyloma acuminata

Jensen SL. Lancet 1985; 2: 1146–8.

Patients ($n = 60$) randomly received podophyllin applied for 6 hours weekly for 6 weeks or surgery. Clearance rate was 76.6% and 93.3%, respectively. At 3 months, the cumulative recurrence rates were 43% and 18%, respectively.

Human papilloma virus type and recurrence rate after surgical clearance of anal condylomata acuminata

D'Ambrogio A, Yerly S, Sahli R, Bouzourene H, Demartines N, Cotton M, et al. Sex Transm Dis 2009; 36: 536–40.

Patients ($n = 140$) with anal canal condylomas had surgery followed by cauterization. Recurrence rate was 25% after day 120 of follow-up. HPV type 11 was statistically associated with higher recurrence rates.

CO(2) laser therapy versus cryotherapy in treatment of genital warts; a randomized controlled trial (RCT)

Azizjalali M, Ghaffarpour G, Mousavifard B. Iran J Microbiol 2012; 4: 187–90.

Patients ($n = 160$) with genital warts were treated with CO₂ laser or cryotherapy. Complete clearance was achieved in 95% treated by CO₂ laser and 46.2% treated with cryotherapy ($p < 0.001$). Laser therapy was associated with less recurrence compared with cryotherapy (0.05% vs. 0.18%).

Treatment of genital warts in males by pulsed dye laser

Badawi A, Shokeir HA, Salem AM, Soliman M, Fawzy S, Samy N, et al. J Cosmet Laser Ther 2006; 8: 92–5.

Patients ($n = 174$) with 550 uncomplicated anogenital warts underwent flashlamp-pumped PDL. Complete resolution was achieved in 96% of lesions, with a recurrence rate of 5%.

Treating vaginal and external anogenital condylomas with electrosurgery vs. CO₂ laser ablation

Ferenczy A, Behelak Y, Haber G, Wright TC Jr, Richart RM. J Gynecol Surg 1995; 148: 9–12.

In 208 patients, the efficacy and adverse effects of loop electrosurgical excision procedure (LEEP) were similar to those associated with laser ablation. LEEP adverse events included bleeding and scarring.

Scarring of the penis can result in dysfunction; therefore most physicians prefer CO₂ laser ablation or cryotherapy for penile warts.

Treatment of external genital warts comparing cryotherapy and trichloroacetic acid

Abdullah AN, Walzman M, Wade A. Sex Transm Dis 1993; 20: 344–5.

In this trial ($n = 86$), complete clearance was 86% with cryotherapy versus 70% with 95% TCA after up to six treatments. Application site reactions developed in 30% of the TCA-treated patients.

Third-Line Therapies

• Intralesional interferon- α	A
• Interferon- β gel	A
• Oral isotretinoin	B
• Intralesional fluorouracil/epinephrine gel	A
• Cidofovir	B
• aminolevulinic acid (ALA)–photodynamic therapy	B
• Intralesional bleomycin	C
• Ingenol mebutate	C

Natural interferon alfa for treatment of condyloma acuminata

Friedman-Kien AE, Eron LJ, Conant M, Growdon W, Badiak H, Bradstreet PW, et al. JAMA 1988; 259: 533–8.

In this double-blind, placebo-controlled trial, complete clearance was 62% (with intralesional interferon- α injections twice weekly for up to 8 weeks) versus 21% (placebo).

Combinations of interferon with cryosurgery, podophyllin, or laser ablation have been promising.

Treatment of condylomata acuminata with oral isotretinoin

Tsambaos D, Georgiou S, Monastirli A, Sakkis T, Sagriotis A, Goerz G. J Urol 1997; 158: 1810–2.

Oral isotretinoin 1 mg/kg daily during a 3-month period achieved complete response in 39.6% of 56 male patients with history of refractory condyloma acuminata. Oral isotretinoin may be considered an effective alternative treatment for immature and small condyloma acuminata.

Topical cidofovir (HPMPC) is an effective adjuvant to surgical treatment of anogenital condylomata acuminata

Coremans G, Margaritis V, Snoeck R, Wyndaele J, De Clercq E, Geboes K. Dis Colon Rectum 2003; 46: 1103–8.

Patients were treated with repetitive electrocoagulations ($n = 27$) (control) or cidofovir ($n = 20$) 1% cream applied to warts daily for 5 hours for 5 consecutive days per week, repeated weekly for up to 18

weeks or until complete clearance. Complete and partial responses with cidofovir were 32% and 60%, respectively. Fewer patients had remaining lesions after cidofovir. Recurrence rates were 3.7% and 55%, respectively.

Combined surgery and cidofovir is an effective treatment for genital warts in HIV-infected patients

Orlando G, Fasolo MM, Beretta R, Merli S, Cargnel A. AIDS 2002; 16: 447–50.

Seventy-four HIV-positive patients received electrocautery or cidofovir 1% gel applied 5 days per week for up to 6 weeks or electrocautery plus cidofovir for 5 days per week for 2 weeks within 1 month of cautery. Complete response was achieved in 93.1%, 76.2%, and 100% of patients, respectively ($p = 0.033$). After 6 months the recurrence rates were 73.68%, 35.24%, and 27.27% ($p = 0.018$).

Evaluation of photodynamic therapy using topical aminolevulinic acid hydrochloride in the treatment of condylomata acuminata: a comparative, randomized clinical trial

Liang J, Lu XN, Tang H, Zhang Z, Fan J, Xu JH. Photodermatol Photoimmunol Photomed 2009; 25: 293–7.

In a trial 91 patients received ALA–PDT or CO₂ laser. Complete response was 95.93% and 100%, respectively ($p > 0.05$). At week 12 of follow-up, 9.38% and 17.39% had recurrent lesions ($p < 0.05$). Adverse reactions were 8.82% and 100%, respectively ($p < 0.05$).

Preliminary study of intralesional bleomycin injection for the treatment of genital warts

Lee JY, Kim CW, Kim SS. Ann Dermatol 2015; 27: 239–41.

Fifteen patients with a total of 164 refractory genital warts were treated with intralesional bleomycin 1.5 mg/mL every 2 weeks until clearance. Clearance was achieved in 73.3%.

Ingenol mebutate gel is effective against anogenital warts – a case series in 17 patients

Schopf RE. J Eur Acad Dermatol Venereol 2016; 30: 1041–3.

The patients were treated with one to three applications with complete response in 16/17 patients.

Geographic tongue

Jennifer K. Chen, and Janellen Smith

Geographic tongue is a reactive mucosal inflammatory condition characterized by arcuate or annular alternating hypertrophic or atrophic filiform papillae producing a geographic pattern. Synonyms include *benign migratory glossitis* and *glossitis areata migrans*.

Geographic tongue may be an asymptomatic incidental finding. Similar changes may occur in oral sites other than the tongue (geographic stomatitis or benign migratory stomatitis).

Management Strategy

Geographic tongue is a common glossitis that affects 2% of the population. There is no racial predilection, and the condition may be seen in patients of all ages, more often children than adults. If asymptomatic, no treatment is necessary other than reassurance that the condition is benign and usually not a sign of systemic illness. Geographic tongue often will remit spontaneously but may persist for years. Occasionally, patients may complain of a burning discomfort, particularly in atrophic areas. Effective therapy can be challenging.

Geographic tongue has been associated with psoriasis (especially pustular psoriasis); reactive arthritis; pityriasis rubra pilaris; atopic diathesis; Down syndrome; nutritional deficiency; diabetes; hormonal changes; and medications including lithium, oral contraceptives, and vascular endothelial growth factor or multikinase inhibitors such as bevacizumab, sunitinib, and sorafenib. The clinician should also consider acute or chronic atrophic candidiasis.

For symptomatic patients, measures that may be considered include the avoidance of hot, spicy, or acidic foods; gentle brushing of the tongue; avoidance of harsh antibacterial mouthwashes, chewing gum, and breath mints; and soothing rinses with saline solutions. Occasionally, the topical application of *fluorinated corticosteroids* or *diphenhydramine elixir* after meals and at bedtime may be recommended. *Topical anesthetic rinses or gels* provide temporary relief. *Antiyeast treatments* may be palliative.

Specific Investigations

- Culture for candidiasis
- If symptomatic, consider complete blood cell count, iron panel, vitamin B, folate, and zinc levels; glucose; and hemoglobin A_{1c}
- No investigation necessary in asymptomatic patients

Geographic stomatitis: a critical review

Hume WJ. J Dent 1975; 3: 25–43.

The topic and the differential diagnosis are carefully reviewed.

Culture of the tongue for yeast organisms may help direct therapy. Some patients require reassurance that they do not have a systemic illness.

Screening for diabetes mellitus or nutritional deficiency (vitamin B, folate, zinc, or iron) would be reasonable to exclude systemic associations.

First-Line Therapies

• Avoidance of spicy food, mouthwashes, chewing gum, and breath mints	D
• Topical corticosteroids (e.g., fluocinonide 0.05% gel, dexamethasone elixir)	C
• Topical antihistamines (e.g., diphenhydramine elixir 12.5 mg/5 mL diluted 1:4 with water)	C
• Antiyeast therapy	E

Symptomatic benign migratory glossitis: report of two cases and literature review

Sigal MJ, Mock D. *Pediatr Dent* 1992; 14: 392–6.

Management with topical corticosteroids and topical antihistamines is discussed.

Common tongue conditions in primary care

Reamy BV, Derby R, Bunt CW. *Am Fam Physician* 2010; 81: 627–34.

Glossitis and other tongue disorders

Byrd JA, Bruce AJ, Rogers RS III. *Dermatol Clin* 2003; 21: 123–34.

A review of geographic and other tongue disorders.

Painful geographic tongue (benign migratory glossitis) in a child

Menni S, Boccardi D, Crosti C. *J Eur Acad Dermatol Venereol* 2004; 18: 737–8.

The authors report a case of painful geographic tongue in a child in whom the only acceptable treatment was mometasone furoate cream. Treatment can be challenging in children because of the unpleasant taste of creams and difficulty with using mouthwashes.

Prevalence of fungi in cases of geographic tongue and fissured tongue

Dudko A, Kurnatowska AJ, Kurnatowski P. *Ann Parasitol* 2013; 59:

113–7.

In this case series, fungal cultures most commonly grew *Candida* species, which were more sensitive to nystatin than miconazole. The prevalence of fungi was highest in those who do not brush the tongue.

Second-Line Therapies

• Topical anesthetics	C
• Topical tretinoin	E
• Discontinue dentifrices and other oral flavoring agents	D
• Topical tacrolimus	E

The treatment of geographic tongue with topical Retin-A solution
Helfman RJ. *Cutis* 1979; 24: 179–80.

The use of topical Retin-A solution is described in three cases.

Anecdotally we have found that tretinoin gel is longer acting and better tolerated by patients.

Geographic tongue treated with topical tacrolimus

Ishibashi M, Tojo G, Watanabe M, Tamabuchi T, Masu T, Aiba S. *J Dermatol Case Rep* 2010; 4: 57–9.

Topical tacrolimus 0.1% ointment twice daily for 2 weeks cleared symptoms in two cases.

Third-Line Therapy

• Ciclosporin	E
----------------------	----------

Successful treatment with cyclosporine administration for

persistent benign migratory glossitis

Abe M, Sogabe Y, Syuto T, Ishibuchi H, Yokoyama Y, Ishikawa O. J Dermatol 2007; 34: 340–3.

A patient with a 5-year history of refractory pain responded to ciclosporin 3 mg/kg/day for 2 months and then 1.5 mg/kg/day maintenance.

Gianotti–Crosti syndrome

Carlo Gelmetti

Gianotti–Crosti syndrome (GCS) was described in 1955 by Ferdinando Gianotti as a disease characterized by an exanthematic papular rash symmetrically distributed on the face, buttocks, and extremities. The disease had mild constitutional symptoms and a quite long but benign course. The term is now used to include all eruptive acrolocated dermatoses characterized by papular or

papulovesicular lesions caused by microorganisms or vaccines. The first association was with hepatitis B (HBV); today, Epstein–Barr virus (EBV) is the etiology most frequently reported in the literature. As the number of immunizations increases and more combinations will be available, an increasing number of postimmunization cases are expected.

Synonyms include papular acrodermatitis of childhood, infantile papular acrodermatitis, and papulovesicular acrolocated syndrome.

Management Strategy

The diagnosis of GCS is clinical. Like other viral exanthems, it mainly affects children of preschool age. The typical eruption consists of monomorphic, lentil-sized lesions symmetrically distributed on the face, buttocks, and limbs. The lesions are papular or papulovesicular, sometimes edematous, and rarely purpuric. They may coalesce over the elbows and knees. A transient rash may be noted on the trunk in the early stage. Mucous membranes are not affected. In the eruptive phase, the Koebner phenomenon may be elicited. The eruption develops within a week, typically beginning on the thighs and buttocks, then involving the extensor aspects of the arms, and finally the face. Lesions vary in color from rose to red-brown. The pruritus is usually mild, and excoriation is rare. The lesions fade usually in 3 to 4 weeks with mild desquamation, and relapse is exceptional. Inguinal and axillary lymphadenopathy is common.

In cases associated with HBV, the hepatitis begins at the same time as, or 1 to 2 weeks after the onset of, GCS. The liver is usually enlarged but not tender; jaundice is exceptional. There are high levels of liver enzymes, and the viral markers become detectable depending on the duration of infection. Complications are rare, although some patients developed chronic hepatitis. Abnormalities in the peripheral blood are inconsistent; the erythrocyte sedimentation rate is not raised.

In HBV-negative cases, hepatomegaly and liver function abnormalities, if present, are mild, probably because some viruses that are able to provoke GCS are considered minor hepatitic viruses.

There is no specific recommended treatment for GCS. However, when itching is disturbing, oral antihistamines or topical antipruritics can be used. Although corticosteroids are sometimes used, their benefit is not established, because corticosteroids could prolong or

delay the recovery of the disease.

In cases associated with HBV, the hepatitis can be treated with interferon- α_{2b} or pegylated interferon, with or without nucleoside analogs such as adefovir, entecavir, telbivudine, tenofovir, and lamivudine, with the last having been approved for children. It is important to investigate and treat other members of the family who may be carriers of HBV or may benefit from vaccination.

Specific Investigations

- Liver enzymes
- Viral serology for EBV, hepatitis B, hepatitis A, cytomegalovirus (CMV)
- Total IgE (paper radioimmunosorbent test [PRIST]) and specific IgE (radioallergosorbent test [RAST] or immuno solid-phase allergen chip [ISAC])

Other possible causes include coxsackievirus, adenovirus, enterovirus, human herpesvirus 6, reovirus, varicella, roseola, rotavirus, respiratory syncytial virus, Lyme borreliosis, *Mycoplasma pneumoniae*, meningococcal infection, etc., and immunization.

Gianotti–Crosti syndrome associated with transfusion acquired hepatitis B virus infection in a patient of sickle cell anemia

Pise GA, Vetrichevvel TP, Agarwal KK, Thappa DM. Indian J Dermatol Venereol Leprol 2007; 73: 123–4.

A 9-year-old boy presented with GCS. Liver function tests showed indirect hyperbilirubinemia and mildly elevated liver enzymes. HBsAg was detected. The patient was managed with antihistamines, and skin lesions cleared in 2 weeks.

Gianotti–Crosti syndrome in a child following hepatitis B virus vaccination

Karakas M, Durdu M, Tuncer I, Cevlik F. J Dermatol 2007; 34: 117–20.

A 5-year-old boy presented with a 1-month history of GCS. The lesions had appeared 3 weeks after a first dose of HBV recombinant vaccine.

Gianotti–Crosti syndrome and erythema nodosum: two distinct entities or two manifestations of the same infection?

Bassi A, Venturini E, Montagnani C, de Martino M, Galli L. *J Pediatr* 2016; 172: 217.

An 18-month-old boy was referred for evaluation of a widespread “itchy” rash consistent with GCS. In addition, nodules characteristic for erythema nodosum appeared 3 days after the skin eruption and increased in size over the subsequent days.

Gianotti-Crosti syndrome as presenting sign of cytomegalovirus infection: a case report and a critical appraisal of its possible cytomegalovirus etiology

Drago F, Javor S, Ciccarese G, Parodi A. *J Clin Virol* 2016; 78: 120–2.

In this case of a 3-year-old girl, GCS was related to CMV primary infection and may be considered the presenting sign of the infection.

Gianotti-Crosti syndrome following immunization in an 18 months old child

Babu TA, Arivazhahan A. *Indian Dermatol Online J* 2015; 6: 413–5.

A rare case of GCS following diphtheria, pertussis, and tetanus (DPT) and oral polio immunization in an 18-month-old child is reported along with a review of similar vaccine-induced GCS cases reported in the literature.

Gianotti–Crosti syndrome

Brandt O, Abeck D, Gianotti R, Burgdorf W. *J Am Acad Dermatol* 2006; 54: 136–45.

EBV is now the most common cause of GCS. Other viruses have been connected with GCS, including Hepatitis A Virus (HVA); CMV; HHV6; coxsackie A16, B4, and B5; rotavirus; Parvovirus B19 (parvo B19); respiratory syncytial virus; mumps virus; and parainfluenza virus types 1 and 2. Human Immunodeficiency Virus (HIV) also appears capable of triggering GCS. The association between various immunizations and GCS has long been known. Despite the proven connection between HBV and GCS, immunization against HBV only rarely causes GCS.

Atypical Gianotti-Crosti syndrome in two HIV and hepatitis B coinfecting adults

Cocciolone R, Morey A, Panasiuk P, Whitfield MJ. *Australas J Dermatol* 2011; 52: 32–6.

Atypical GCS in two unrelated adult male patients with coexistent

hepatitis B and HIV infection are described. Immunoperoxidase studies suggested the presence of HBsAg within the vessels of both lesional and perilesional skin, providing further support for the proposed immune-mediated pathogenesis.

Gianotti–Crosti syndrome and allergic background

Ricci G, Patrizi A, Neri I, Specchia F, Tosti G, Masi M. *Acta Dermatol Venereol* 2003; 83: 202–5.

In 29 children affected by GCS and 59 age- and sex-matched controls, the presence of atopic dermatitis (24.1%) was significantly higher ($p < 0.005$) than in the control group (6.8%).

First-Line Therapies

• Systemic antihistamines	E
• Systemic corticosteroids	E
• Topical corticosteroids	E
• Topical antiseptics	E
• Topical antipruritics	E
• Zinc shake lotions	E
• Systemic steroids	E
• Systemic antibiotics	E
• Ribavirin	E
• Emollients	E
• Vitamin C	E
• Interferon- α	B
• Nucleoside analogs	B
• Hepatitis B vaccine	B

Acute disseminated erythematous papulovesicular skin lesions in a 7-year-old child: a quiz. Diagnosis: vesicular Gianotti-Crosti syndrome

Linke M, Géraud C, Schneider SW, Goerdts S, Utikal J. *Acta Derm Venereol* 2011; 91: 491–4.

A 7-year-old girl presented with cutaneous lesions consistent with GCS in addition to tense blisters on the hands and feet. Oral corticosteroids and antihistamines were administered, and an antiseptic cream was applied topically. The skin lesions subsided within a week without relapse.

Recurrent Gianotti-Crosti syndrome

Metelitsa AI, Fiorillo L. *J Am Acad Dermatol* 2011; 65: 876–7.

A 2-year-old boy presented with GCS. Two weeks after onset of the eruption, he was immunized with influenza vaccination and new lesions appeared at the immunization site. Investigations revealed a positive urine culture for CMV and positive IgM for EBV. He was treated with hydrocortisone cream, and the eruption resolved. Twelve months later, he presented with a similar eruption at the site of influenza vaccination. Because GCS is a mild and self-limiting disease, further vaccinations are not contraindicated.

Efficacy of ribavirin in a case of long lasting and disabling Gianotti-Crosti syndrome

Zawar V, Chuh A. *J Dermatol Case Rep* 2008; 2: 63–6.

A 6-year-old girl presented with a history of a pruritic rash consistent with GCS after a febrile illness with common cold symptoms. Remission was not achieved despite several medications: topical emollients, topical and systemic corticosteroids, topical and systemic antibiotics, and oral histamines. A course of oral ribavirin at a dose of 300 mg daily for 5 days led to dramatic remission 5 days later.

Gonorrhea

Ted Rosen

Gonorrhea is a common and potentially severe sexually transmitted disease caused by the gram-negative aerobic diplococcus *Neisseria gonorrhoeae*. This organism primarily infects the mucous membranes of the urethra, endocervix, rectum, and pharynx. The disease can also become disseminated, causing petechial or acral pustular skin lesions, tenosynovitis, arthralgia, true septic arthritis, perihepatitis, and less commonly endocarditis or meningitis.

Management Strategy

Individuals with gonorrhea should be treated as promptly as possible (1) to prevent regional infection such as epididymitis or pelvic inflammatory disease leading to infertility or ectopic pregnancy; (2) to prevent disseminated gonococcal infection, which occurs in about 1% to 3% of cases; and (3) to stop transmission to sexual partners. Prompt management has become especially important due to a resurgence in incidence of gonococcal disease in the United States and increasing multidrug antimicrobial resistance worldwide.

Gonococcal urethritis is typically characterized by mucopurulent to frankly purulent discharge along with a burning sensation during urination. Dysuria may be the only symptom.

Gonococcal cervicitis is characterized by a mucopurulent or purulent endocervical exudate. However, a cervical discharge is not specific for a gonococcal infection, and gonococcal infection of the cervix is often asymptomatic.

Pharyngeal infection is asymptomatic in more than 90% of cases, but when symptomatic it presents as a pharyngitis of variable severity.

Rectal infection is prevalent in homosexual men, causing anal discharge and pain. In women, rectal infection results from spread through vaginal secretions and does not necessarily imply anal intercourse.

Patients infected with *N. gonorrhoeae* are often coinfecting with *Chlamydia trachomatis* and should be treated with *azithromycin* to cover this organism, with or without diagnostic evidence of chlamydial disease. Patients with gonorrhea have engaged in unprotected intercourse and, therefore, always should be tested for both syphilis and HIV.

Patients should be instructed to return for evaluation if symptoms persist or recur after therapy and to abstain from sexual intercourse until they and their sexual partners are cured. Because reinfection is so common, the Centers for Disease Control (CDC) recommends that all patients with known gonorrhea return for retesting 3 months posttreatment. A test of cure 3 to 4 weeks posttreatment is no longer recommended.

Antimicrobial resistance is a real threat, and treatment options for gonococcal disease are increasingly limited. To abate further spread of resistant strains of *N. gonorrhoeae*, physicians should strongly encourage patient referral of any sexual partner within the preceding 60 days for evaluation and treatment and obtain culture(s) to evaluate

individual antimicrobial susceptibility in any patient whose symptoms do not resolve with initial treatment.

Specific Investigations

Men

- Microscopic examination of gram-stained urethral secretions
- Culture on Thayer–Martin medium
- Nonculture test based upon immunodiagnostics, as available

Women

- Culture on Thayer–Martin medium
- Nonculture test based upon immunodiagnostics, as available

Male urethritis with and without discharge. A clinical and microbiological study

Janier M, Lassau F, Casin I, Grillot P, Scieux C, Zavaro A, et al. Sex Transm Dis 1995; 22: 244–52.

N. gonorrhoeae was found in 21% of patients with urethral discharge and in no patient without discharge. Treatment for *N. gonorrhoeae* in patients without discharge in the absence of proven contact with an infected patient is not recommended.

Sexually transmitted diseases treatment guidelines, 2015

Workowski KA, Bolan GA; Centers for Disease Control and Prevention. MMWR Recomm Rep 2015; 64: 1–137.

Because of its high specificity (>99%) and sensitivity (>95%), a Gram stain of a male urethral specimen that demonstrates polymorphonuclear leukocytes with intracellular gram-negative diplococci can be considered diagnostic for infection with *N. gonorrhoeae* in symptomatic men. Culture is the most widely available option for diagnosis in asymptomatic men, in women, and in nongenital sites (rectum and pharynx). Nonculture tests cannot provide antimicrobial susceptibility results, but can rapidly and accurately confirm a clinical diagnosis.

Screening tests to detect *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections – 2002

Johnson RE, Newhall WJ, Papp JR, Knapp JS, Black CM, Gift TL, et al. MMWR Recomm Rep 2002; 51: 1–38.

Nonculture tests called *nucleic acid hybridization tests* and *nucleic acid amplification tests* (NAATs) have been developed. Commercial NAATs differ in their amplification methods and their target nucleic acid sequences. The majority of commercial NAATs have been cleared by the Food and Drug Administration (FDA) to detect *C. trachomatis* and *N. gonorrhoeae* in endocervical swabs and urethral swabs from men. The sensitivity of NAATs might be less when using urine than when using an endocervical swab. Testing of rectal and oropharyngeal specimens with NAATs is not recommended.

First-Line Therapies for Uncomplicated Gonorrhea of the Cervix, Urethra, Rectum, Pharynx, and Conjunctiva

• Ceftriaxone 250 mg intramuscularly in a single dose + azithromycin 1 g orally	B
• Only if ceftriaxone is NOT immediately available: cefixime 400 mg orally in a single dose + azithromycin 1 g orally	B

Oral cefixime versus intramuscular ceftriaxone in patients with uncomplicated gonococcal infections

Portilla I, Lutz B, Montalvo M, Mogabgab J. Sex Transm Dis 1992; 19: 94–8.

The only current CDC-recommended options for treating *N. gonorrhoeae* infections are cephalosporins. The 400-mg dose of cefixime cured 97% of uncomplicated urogenital and anorectal gonococcal infections. The advantage of cefixime is that it can be administered orally. However, cefixime is no longer a reliable first-line therapy (see next citation).

Sexually transmitted diseases treatment guidelines, 2015

Workowski KA, Bolan GA; Centers for Disease Control and Prevention. MMWR Recomm Rep 2015; 64: 1–137.

The minimum concentrations of cefixime needed to inhibit in vitro growth of the *N. gonorrhoeae* strains circulating in the United States and many other countries have progressively increased since 2006. This suggests that the effectiveness of cefixime might be waning. In

addition, treatment failures with cefixime (or other similar oral cephalosporins) have been reported in Asia, Europe, South Africa, and Canada. As a result, the CDC no longer recommends the routine use of cefixime as a first-line regimen for treatment of gonorrhea at any anatomic site in the United States. Ceftriaxone in a single injection of 250 mg is a safe, effective dose for uncomplicated gonococcal infection at all anatomic sites. However, ceftriaxone failures have also been rarely reported. Consequently, only one regimen, dual treatment with ceftriaxone and azithromycin, is currently recommended for gonorrhea treatment at all anatomic sites in adults. *All patients with gonorrhea should also be treated with azithromycin to (1) treat possible coinfection with Chlamydia trachomatis and (2) gain additive microcidal effects for N. gonorrhoeae.*

First *Neisseria gonorrhoeae* strain with resistance to cefixime causing gonorrhoea treatment failure in Austria, 2011

Unemo M, Golparian D, Stry A, Eigentler A. Euro Surveill 2011; 16: 1–3.

Globally the susceptibility of *N. gonorrhoeae* to antimicrobial therapy, including first-line treatment options ceftriaxone and cefixime, is decreasing.

UK national guideline for the management of gonorrhoea in adults, 2011

Bignell C, Fitzgerald M, Guideline Development Group, British Association for Sexual Health and HIV UK. Int J STD AIDS 2011; 22: 541–7.

Three cases of cefixime failure were reported in the UK in 2011. First-line treatment for gonococcal infection in the UK is now ceftriaxone 500 mg intramuscularly plus azithromycin 1 g orally with test of cure recommended in all cases. Cefixime is only advised when intramuscular injection is contraindicated, refused by the patient, or immediately unavailable.

Second-Line Therapies (No Advantage over First-Line Therapies)

• Ceftrizoxime 500 mg intramuscularly as a single dose + azithromycin 1 g orally	B
• Cefoxitin 2 g intramuscularly with probenecid 1 g orally + azithromycin 1 g orally	B
• Cefotaxime 500 mg intramuscularly as a single dose + azithromycin 1 g orally	B

***Neisseria gonorrhoeae* with high-level resistance to azithromycin: case report of the first isolate identified in the United States**

Katz AR, Komeya AY, Soge OO, Kiaha MI, Lee MV, Wasserman GM, et al. CID 2012; 54: 841–3.

Eight isolates with reduced susceptibility to azithromycin were identified in Hawaii followed by laboratory documentation of the first isolate with high-level azithromycin resistance in California.

Previously, strains with high-level resistance had been documented in Argentina, Scotland, England, Wales, and Ireland.

Spectinomycin resistance in *Neisseria* spp. due to mutations in IGSrRNA

Galimand M, Gerbaud G, Courvalin P. Antimicrob Agents Chemother 2000; 44: 1365–6.

It is rare for a patient to be infected with a spectinomycin-resistant strain, but spectinomycin is expensive and must be injected.

Spectinomycin is useful for patients who cannot tolerate cephalosporins and quinolones.

Pfizer discontinued U.S.-based distribution of spectinomycin in November 2005.

Update to CDC's sexually transmitted diseases treatment guidelines 2006: fluoroquinolones no longer recommended for treatment of gonococcal infections

Centers for Disease Control and Prevention MMWR Morb Mortal Wkly Rep 2007; 56: 332–6.

Due to the increasing resistance, the CDC no longer recommends the use of fluoroquinolones for patients who acquired their infection in the United States, Asia, or the Pacific Islands. Recent data suggest that resistant strains comprise about 13% of all American-acquired isolates. Fluoroquinolones remain off the recommended treatment list for gonorrhea 10 years later.

Surveillance of antibiotic resistance in *Neisseria gonorrhoeae* in the WHO Western Pacific and South East Asian Regions, 2009

WHO Western Pacific and South East Asian Gonococcal Antimicrobial Surveillance Programmes. Commun Dis Intell 2011; 35: 2–7.

Recent data from China, Hong Kong, Japan, and elsewhere in Asia also demonstrate a very high rate of fluoroquinolone resistance. Australia and New Zealand are experiencing 35% to 45% of isolates being quinolone resistant.

Annual report of the Australian Gonococcal Surveillance Programme, 2010

Australian Gonococcal Surveillance Programme. Commun Dis Intell 2011; 35: 229–36.

Penicillin has been removed from the standard treatment regimen in Australia because of nationwide isolate resistance (up to 44% in some regions). However, in remote areas of Australia with extremely high disease rates, treatment with penicillin often remains effective. The same is also true in other industrialized countries.

Cephalosporin resistant *Neisseria gonorrhoeae*: time to consider gentamicin?

Ross JD, Lewis DA. Sex Transm Infect 2012; 88: 6–8.

Studies of efficacy of gentamicin from the 1970s and 1980s demonstrated cure rates of 65% to 100% with no report of adverse reactions.

***Neisseria gonorrhoeae* antimicrobial susceptibility surveillance—The Gonococcal Isolate Surveillance Project, 27 sites, United States, 2014**

Kirkcaldy RD, Harvey A, Papp JR, Del Rio C, Soge OO, Holmes KK, et al. MMWR Surveill Summ 2016; 65: 1–19.

This is the first report to present comprehensive surveillance data from the U.S. Gonococcal Isolate Surveillance Project (GISP) and summarize gonococcal susceptibility over time, as well as underscore the public health implications of emerging cephalosporin resistance. Antimicrobial susceptibility patterns vary by geographic region within the United States and by sex of sex partner. For example, the percentage of isolates resistant to tetracycline, ciprofloxacin, penicillin, or all three antimicrobials was greater in isolates from men

who have sex with men than from men who exclusively have sex with women. Because dual therapy with ceftriaxone plus azithromycin is the only recommended gonorrhea treatment, increases in azithromycin and cephalosporin minimal inhibitory concentrations are cause for concern that resistance to these antimicrobial agents might be emerging. Reduced azithromycin susceptibility (defined as minimum inhibitory concentration ≥ 2.0 $\mu\text{g/mL}$) increased from 0.6% in 2013 to 2.5% in 2014. It is unclear whether increases in the percentage of isolates with reduced susceptibility to azithromycin mark the beginning of an adverse trend.

Special Considerations

Pharyngeal infection

Treating uncomplicated *Neisseria gonorrhoeae* infections: is the anatomic site of infection important?

Moran JS. Sex Transm Dis 1995; 22: 39–47.

Pharyngeal infection is more difficult to cure. A cephalosporin regimen is the best choice, as it is likely to cure at least 80% of pharyngeal infections. Spectinomycin is unreliable (i.e., only 52% effective).

Azithromycin may increase efficacy for pharyngeal infection when using oral cephalosporins.

Disseminated gonococcal infection

Hospitalization is recommended for initial therapy. The experts recommend ceftriaxone 1 g intramuscularly or intravenously every 24 hours as the initial regimen, plus azithromycin 1 g orally as a single dose. The provider can switch to an oral agent guided by antimicrobial susceptibility testing 24 to 48 hours after substantial clinical improvement, for a total treatment course of at least 7 days. Acceptable alternative therapies include cefotaxime or ceftizoxime, with both drugs given in a dosage of 1 g intravenously every 8 hours, along with a single dose of azithromycin (1 g).

Pregnancy

Treatment of gonorrhoea in pregnancy

Cavenee MR, Farris JR, Spalding TR, Barnes DL, Castaneda YS, Wendel GD Jr. *Obstet Gynecol* 1993; 81: 33–8.

A randomized study on 250 cases comparing ceftriaxone 250 mg intramuscularly, spectinomycin 2 g intramuscularly, and amoxicillin 3 g orally with probenecid 1 g showed efficacy was 95%, 95%, and 89%, respectively. There was no increase in congenital malformations. Ceftriaxone and spectinomycin are the best choices. Pregnant women should not be treated with quinolones or tetracyclines. (Comment: Because spectinomycin is no longer available in the United States, ceftriaxone is the default drug of choice and is recommended, along with azithromycin, at standard doses enumerated earlier.)

Pregnant women who cannot tolerate a cephalosporin should receive azithromycin 2 g in a single dose.

Ophthalmia neonatorum

To prevent gonococcal ophthalmia neonatorum, a prophylactic agent should be instilled into both eyes of all newborn infants; this procedure is, in fact, required by law in most states. Prophylaxis consists of erythromycin (0.5%) ophthalmic ointment in each eye in a single application at birth. Ocular prophylaxis is warranted because it can prevent sight-threatening gonococcal ophthalmia, has an excellent safety record, is easy to administer, and is inexpensive. Gonococcal ophthalmia is strongly suggested when typical gram-negative diplococci are identified in conjunctival exudate, justifying presumptive treatment after appropriate cultures have been obtained. The recommended regimen is ceftriaxone 25 to 50 mg/kg IV or IM in a single dose, not to exceed 125 mg. Local treatment, with or without systemic antibiotics, is inappropriate.

Men who have sex with men

Gonorrhea screening among men who have sex with men: value of multiple anatomic site testing, San Diego, California, 1997–2003

Gunn RA, O'Brien CJ, Lee MA, Gilchick RA. *Sex Transm Dis* 2008; 35: 845–8.

This population should be screened annually for gonorrhea

infection at the urethral, pharyngeal, and rectal sites.

(Comment: The CDC also now recommends annual screening for N. gonorrhoeae infection for all sexually active women aged <25 years and for older women at increased risk for infection (e.g., those who have a new sex partner, more than one sex partner, a sex partner with concurrent partners, or a sex partner who has an STI). Additional risk factors for gonorrhea include inconsistent condom use among persons who are not in mutually monogamous relationships, previous or coexisting sexually transmitted infections, and exchanging sex for money or drugs. Individuals who fall into those categories should also be screened annually.)

Treatment failure

Patients with suspected treatment failure or persons infected with a strain found to demonstrate in vitro resistance should consult an infectious disease specialist, where the use of gentamicin or gemifloxacin may be entertained. Patients should be retreated with at least 250 mg of ceftriaxone IM or IV and ensure partner treatment. The situation should be promptly reported to public health agencies.

Graft-versus-host disease

Robert G. Micheletti

Graft-versus-host disease (GVHD) is the most significant source of morbidity and mortality among survivors of allogeneic hematopoietic stem cell transplantation, occurring in 30% to 70% of transplant recipients. Affecting the skin, liver, gastrointestinal tract, and other organs, it occurs when donor immune cells (the graft) recognize the transplant recipient (host) as foreign, resulting in inflammation and end organ damage. Of the organs involved, the skin is the most

common and most severely affected.

Management Strategy

The risk, timing, presentation, and treatment of GVHD depend on many factors, including the type of transplant, the degree of HLA mismatch, donor and recipient sex, the intensity of pretransplant conditioning, and the GVHD prophylactic regimen used. Evolution of transplant strategies, such as reduced-intensity conditioning, increasing age of some transplant recipients, novel prophylaxis and treatment regimens, and donor lymphocyte infusion, together with improved recognition of overlap phenomena and late-onset acute GVHD, have blurred the classic understanding of a temporally defined disease. Acute and chronic GVHD are best differentiated on the basis of clinical manifestations, because features of either may occur at any time posttransplant. Atypical manifestations, particularly of chronic GVHD, can mimic other dermatologic diseases and present a diagnostic dilemma; input of a dermatologist and skin biopsy, when appropriate, can help shape diagnosis and management.

Initial management of GVHD includes adjustment of GVHD prophylaxis. Optimization of organ-specific supportive care and *topical therapies* may be sufficient for mild cutaneous GVHD, whereas in more severe disease, maximizing topical care can minimize the need for systemic immunosuppression and related side effects. For moderate or severe GVHD, *systemic corticosteroids* are first-line therapy, but in many cases GVHD becomes steroid refractory or dependent. Evidence for second- and third-line therapies is derived from small trials or series and is frequently contradictory. The optimal approach in patients with steroid-refractory acute or chronic GVHD is therefore not known. Commonly used agents with reported activity and adequate safety profiles include *calcineurin inhibitors*, *extracorporeal photopheresis*, *mycophenolate mofetil*, *mTOR inhibitors*, *ruxolitinib* (increasingly), and several others. Additional skin-directed therapies such as *narrowband UVB* and *PUVA phototherapy* can benefit some patients.

Future work to identify effective therapies, using standardized criteria, is needed. In addition to aiding diagnosis and optimizing skin-directed therapies, dermatologists can play an important role in assessment of response, severity scoring, and research.

Acute GVHD

Specific Investigations

- Skin biopsy
- Medication history
- Liver function tests
- Complete blood count
- Serum chemistry
- Biomarker panel (investigational)
- Consider viral testing (e.g., cytomegalovirus)
- Consider colonoscopy/endoscopy

Clinical differentiation of acute cutaneous graft-versus-host disease from drug hypersensitivity reactions

Byun HJ, Yang JI, Kim BK, Cho KH. J Am Acad Dermatol 2011; 65:726–32.

Cutaneous manifestations of acute GVHD are generally nonspecific. However, a morbilliform eruption involving the face (including pinnae), palms, and soles is suggestive of acute GVHD (aGVHD), as is the presence of diarrhea or hyperbilirubinemia, typically developing within 2 to 3 days of rash onset. Absence of these findings favors a diagnosis of drug hypersensitivity reaction but does not rule out GVHD.

Quantitative analysis of eosinophils in acute graft-versus-host disease compared with drug hypersensitivity reactions

Weaver J, Bergfeld WF. Am J Dermatopathol 2010; 32: 31–4.

Interface dermatitis with basilar vacuolization and dyskeratotic keratinocytes with satellite cell necrosis are characteristic but nonspecific histologic findings of GVHD. Only significant tissue eosinophilia (≥ 16 eosinophils per 10 high-powered fields) safely excludes aGVHD in favor of drug hypersensitivity reaction. Therefore the decision to diagnose and treat aGVHD should not depend on skin biopsy findings.

ST2 as a marker for risk of therapy-resistant graft-versus-host disease and death

Vander Lugt MT, Braun TM, Hanash S, Ritz J, Ho VT, Antin JH, et al. N Engl J Med 2013; 369: 529–39.

Serum biomarkers to help diagnose and predict the severity and outcome of GVHD are under investigation but are not yet available for clinical use. Suppression of tumorigenicity 2 (ST2), a member of the interleukin-1 receptor family, is one such marker, which predicts the risk for treatment-refractory GVHD and nonrelapse mortality after bone marrow transplantation.

First-Line Therapies

• Topical corticosteroids	D
• Systemic corticosteroids (methylprednisolone 1–2 mg/kg/day)	A

Topical corticosteroids, along with sensitive skin care measures and optimization of prophylactic medications (e.g., ciclosporin, tacrolimus, methotrexate), may be sufficient therapy for mild cutaneous grade I aGVHD (defined as cutaneous GVHD involving ≤50% body surface area [BSA] without liver or gastrointestinal [GI] involvement).

Effectiveness and safety of lower dose prednisone for initial treatment of acute graft-versus-host disease: a randomized controlled trial

Mielcarek M, Furlong T, Storer BE, Green ML, McDonald GB, Carpenter PA, et al. Haematologica 2015; 10: 842–8.

For patients with grade II or higher aGVHD (skin involvement >50% BSA or with any liver or GI involvement), systemic corticosteroids are the mainstay of initial therapy, typically 2 mg/kg/day prednisone equivalent in divided doses, followed by gradual taper. A randomized controlled trial comparing standard vs. lower dose (0.5–1 mg/kg/day) glucocorticoids showed that initial treatment of aGVHD with lower-dose prednisone may be sufficient.

Second-Line Therapies

• Mycophenolate mofetil	B
• Extracorporeal photopheresis	B
• Etanercept	B
• Calcineurin inhibitors (tacrolimus, ciclosporin)â	B
• mTOR inhibitors (sirolimus)	B

First- and second-line systemic treatment of acute graft-versus-host disease: recommendations of the American Society of Blood and Marrow Transplantation

Martin PJ, Rizzo JD, Wingard JR, Ballen K, Curtin PT, Cutler C, et al. Biol Blood Marrow Transpl 2012; 18: 1150–63.

In this review of primary and secondary treatments for aGVHD, evidence for second-line therapies is derived from small trials or series and is frequently contradictory. The optimal approach in patients with steroid-refractory aGVHD is not known.

Etanercept, mycophenolate, denileukin, or pentostatin plus corticosteroids for acute graft-versus-host disease: a randomized phase 2 trial from the Blood and Marrow Transplant Clinical Trials Network

Alousi AM, Weisdorf DJ, Logan BR, Bolaños-Meade J, Carter S, Difrongo N, et al. Blood 2009; 114: 511–7.

In this randomized phase II trial, the addition of mycophenolate to systemic corticosteroids resulted in higher complete response and overall survival rates and fewer infectious complications than did prednisone combined with etanercept, pentostatin, or denileukin diftitox.

Phase 3 clinical trial of steroids/mycophenolate mofetil vs. steroids/placebo as therapy for acute GVHD: BMT CTN 0802

Bolaños-Meade J, Logan BR, Alousi AM, Antin JH, Barowski K, Carter SL, et al. Blood 2014; 124: 3221–7.

Although mycophenolate mofetil appears to be more effective than other second-line agents for aGVHD and is commonly used for this purpose, its actual efficacy appears to be limited. This phase III

randomized, double-blind trial was ended early for futility after showing no benefit to therapy with glucocorticoids plus mycophenolate versus glucocorticoids alone.

Etanercept plus methylprednisolone as initial therapy for acute graft-versus-host disease

Levine JE, Paczesny S, Mineishi S, Braun T, Choi SW, Hutchinson RJ, et al. Blood 2008; 111: 2470–5.

A regimen of etanercept plus corticosteroids was more likely to achieve complete response (69% vs. 33%) and 100-day survival (82% vs. 66%) than were steroids alone.

Sirolimus for treatment of steroid-refractory acute graft-versus-host disease

Hoda D, Pidala J, Salgado-Vila N, Kim J, Perkins J, Bookout R, et al. Bone Marrow Transplant 2010; 45: 1347–51.

Sirolimus was initiated in 34 patients with steroid-refractory aGVHD. The overall response rate was 76%, with 44% achieving complete response. Complications included myelosuppression and hemolytic uremic syndrome.

Extracorporeal photopheresis versus anticytokine therapy as a second-line treatment for steroid-refractory acute GVHD: a multicenter comparative analysis

Jagasia M, Greinix H, Robin M, Das-Gupta E, Jacobs R, Savani BN. Biol Blood Marrow Transplant 2013; 19: 1129–33.

A retrospective analysis of 98 patients with steroid-refractory aGVHD receiving photopheresis revealed superior complete response rates (54% vs. 20%) and survival compared with those receiving anticytokine therapy (etanercept or inolimomab). The safety profile of extracorporeal photopheresis was excellent.

Third-Line Therapies

• Pentostatin	B
• Anti-CD52 antibody (alemtuzumab)	B
• Ruxolitinib	C
• Infliximab	B
• Interleukin-2 receptor antibodies (basiliximab)	B
• Mesenchymal stem cells	A
• Methotrexate	B
• Tocilizumab	C
• Antithymocyte globulin	B
• Denileukin diftitox	B
• PUVA	B
• Narrowband UVB	C

Diagnosis and management of acute graft-versus-host disease

Dignan FL, Clark A, Amrolia P, Cornish J, Jackson G, Mahendra P, et al. *Br J Haematol* 2012; 158: 30–45.

Evidence-based guidelines for aGVHD are reviewed. Pentostatin, alemtuzumab, mesenchymal stem cells, and MTX are among third-line therapies used after second-line agents have failed or in the context of clinical trials. Most such drugs have limited or negative/conflicting data.

Other agents with a possible therapeutic role in steroid-refractory aGVHD include ruxolitinib, tocilizumab, antithymocyte globulin, and others.

Ruxolitinib in corticosteroid-refractory graft-versus-host disease after allogeneic stem cell transplantation: a multicenter survey

Zeiser R, Burchert A, Lengerke C, Verbeek M, Maas-Bauer K, Metzelder SK, et al. *Leukemia* 2015; 29: 2062–8.

Treatment with the Jak 1/2 inhibitor ruxolitinib resulted in an 82%

response rate, including 25 complete responses, among 54 patients with steroid-refractory aGVHD. This class of medication is the subject of growing interest for treatment of both acute and chronic GVHD.

A phase III study of infliximab and corticosteroids for the initial treatment of acute graft-versus-host disease

Couriel DR, Saliba R, de Lima M, Giral S, Andersson B, Khouri I, et al. Biol Blood Marrow Transplant 2009; 15: 1555–62.

Although several case series demonstrated benefit from infliximab, this trial's 63 patients with grade II to IV aGVHD had no benefit from initial therapy with combination steroids and infliximab compared with methylprednisolone alone.

Basiliximab for the treatment of steroid-refractory acute graft-versus-host disease after unmanipulated HLA-mismatched/haploidentical hematopoietic stem cell transplantation

Wang JZ, Liu KY, Xu LP, Liu DH, Han W, Chen H, et al. Transplant Proc 2011; 43: 1928–33.

The chimeric IL-2 receptor antagonist basiliximab yielded a therapeutic response in 46/53 patients with steroid-refractory aGVHD.

The mesenchymal stromal cells dilemma—does a negative phase III trial of random donor mesenchymal stromal cells in steroid-resistant graft-versus-host disease represent a death knell or a bump in the road?

Galipeau J. Cytotherapy 2013; 15: 2–8.

Despite promising results of a phase II study, a phase III trial of mesenchymal stromal cells failed to meet its primary end points for treatment of both new-onset and steroid-refractory aGVHD.

Narrowband ultraviolet B phototherapy for treatment of steroid-refractory and steroid-dependent acute graft-versus-host disease

Feldstein JV, Bolaños-Meade J, Anders VL, Abuav R. J Am Acad Dermatol 2011; 65: 733–8.

Of 14 patients with skin-predominant steroid-refractory or dependent aGVHD, 11 had a complete or partial response, suggesting narrowband ultraviolet B phototherapy is a potentially effective and low-risk skin-directed therapy for selected patients with aGVHD.

Chronic GVHD

Specific Investigations

- Skin biopsy
- Liver function tests
- Complete blood count
- Quality-of-life assessment
- Range of motion/physical therapy evaluation
- Pulmonary function tests
- Schirmer test
- Evaluation of other organs (ocular, oral, genital, gastrointestinal, musculoskeletal)

National Institutes of Health consensus development project on criteria for clinical trials in chronic graft-versus-host disease: I. Diagnosis and staging working group report

Filipovich AH, Weisdorf D, Pavletic S, Socie G, Wingard JR, Lee SJ, et al. Biol Blood Marrow Transplant 2005; 11: 945–56.

Cutaneous signs that are considered diagnostic of chronic GVHD (cGVHD) include poikiloderma; lichen planus–like lesions; and lichen sclerosis–like, morphea-like, and sclerotic features. Standardization of response criteria, staging, and grading are detailed.

Atypical manifestations of graft-versus-host disease

Cornejo CM, Kim EJ, Rosenbach M, Micheletti RG. J Am Acad Dermatol 2015; 72: 690–5.

Numerous common and atypical manifestations of GVHD may be seen. Biopsy or additional investigations may help confirm a diagnosis of cGVHD in patients without diagnostic features.

First-Line Therapies

• Systemic corticosteroids	A
• Systemic corticosteroid and calcineurin inhibitor	C

Organ-specific management and supportive care in chronic graft-versus-host disease

Dignan FL, Scarisbrick JJ, Cornish J, Clark A, Amrolia P, Jackson G, et al. *Br J Haematol* 2012; 158: 62–78.

The choice of initial therapy depends on disease severity, organ involvement, and other factors. Organ-specific supportive care (e.g., emollients, sun protection) and a multidisciplinary approach can be beneficial.

Diagnosis and management of chronic graft-versus-host disease

Dignan FL, Amrolia P, Clark A, Cornish J, Jackson G, Mahendra P, et al. *Br J Haematol* 2012; 158: 46–61.

For those with moderate or severe cGVHD, corticosteroids are first-line systemic therapy, usually beginning at a daily dose of 1 mg/kg prednisone tapered slowly based on clinical response. There are no randomized studies comparing standard to higher or lower steroid doses. Optimization of topical steroids and other skin-directed therapies may enable dose reduction in those with skin-limited cGVHD.

Therapy for chronic graft-versus-host disease: a randomized trial comparing cyclosporine plus prednisone versus prednisone alone

Koc S, Leisenring W, Flowers ME, Anasetti C, Deeg HJ, Nash RA, et al. *Blood* 2002; 100: 48–51.

Initial treatment with prednisone plus ciclosporin may reduce some steroid-related toxicities compared with treatment with prednisone alone, but there is no difference in mortality or time at which therapy can be discontinued. Randomized trials of other agents for the initial treatment of cGVHD have failed to show benefit compared with prednisone alone.

Second-Line Therapies

• Calcineurin inhibitors (tacrolimus, ciclosporin)	C
• Extracorporeal photopheresis	B
• Mycophenolate mofetil	C
• mTOR inhibitors (sirolimus, everolimus)	C
• Rituximab	B
• Imatinib	C
• UVB, narrowband UVB	C
• PUVA, UVA1	C

Consensus conference on clinical practice in chronic GVHD: second-line treatment of chronic graft-versus-host disease

Wolff D, Schleuning M, von Harsdorf S, Bacher U, Gerbitz A, Stadler M, et al. Biol Blood Marrow Transplant 2011; 17: 1–17.

Additional therapy is warranted for those with cGVHD that progresses despite 1 mg/kg/day prednisone for 2 weeks, fails to respond after 4 to 6 weeks of therapy, or flares with attempts to taper below 0.5 mg/kg/day. Initial second-line therapy should include agents with documented activity and adequate safety profiles, such as calcineurin inhibitors, extracorporeal photopheresis, mycophenolate mofetil, mTOR inhibitors, imatinib, or rituximab. Unfortunately, without available predictors of response, “trial and error” is the only way to determine efficacy of a particular agent or combination regimen for a given patient.

Extracorporeal photopheresis for the treatment of acute and chronic graft-versus-host disease in adults and children: best practice recommendations from an Italian Society of Hemapheresis and Cell Manipulation (SIdEM) and Italian Group for Bone Marrow Transplantation (GITMO) consensus process

Pierelli L, Perseghin P, Marchetti M, Messina C, Perotti C, Mazzoni A, et al. Transfusion 2013; 53: 2340–52.

Among 735 patients with steroid-resistant or dependent cGVHD included for review, photopheresis resulted in a response rate of 50%

to 65% (complete response 30%–35%). Approximately 25% to 35% of patients were able to taper steroid use significantly.

Efficacy of mycophenolate mofetil in the treatment of chronic graft-versus-host disease

Lopez F, Parker P, Nademanee A, Rodriguez R, Al-Kadhimi Z, Bhatia R, et al. *Biol Blood Marrow Transplant* 2005; 11: 307–13.

Eighteen of 24 (75%) patients receiving mycophenolate mofetil as second-line therapy responded to treatment, and 14 of 22 (64%) patients on prednisone were able to taper the dose of steroids. Complications included gastrointestinal side effects, hematologic toxicities, and infectious episodes.

Therapy of sclerodermatous chronic graft-versus-host disease with mammalian target of rapamycin inhibitors

Jedlickova Z, Burlakova I, Bug G, Baurmann H, Schwerdtfeger R, Schleuning M. *Biol Blood Marrow Transplant* 2011; 17: 657–63.

Thirty-four patients with severe scleroderma-like cGVHD had an overall response rate of 76% to sirolimus or everolimus. Hyperlipidemia, poor wound healing, cytopenias, infections, and thrombotic microangiopathy were seen in a minority.

A randomized phase II crossover study of imatinib or rituximab for cutaneous sclerosis after hematopoietic cell transplantation

Arai S, Pidala J, Pusic I, Chai X, Jaglowski S, Khera N, et al. *Clin Cancer Res* 2016; 22: 319–27.

In a randomized phase II study of patients with steroid-refractory sclerotic cGVHD, 9 of 35 (26%) patients receiving imatinib and 10 of 37 (27%) patients receiving rituximab had quantitative improvements in skin sclerosis or joint range of motion. The response rates in this study were somewhat lower than reported previously for these agents and likely reflect increased stringency of response criteria, as well as the refractory nature of sclerotic cGVHD in general.

Graft-versus-host disease: part II. Management of cutaneous graft-versus-host disease

Hymes SR, Alousi AM, Cowen EW. *J Am Acad Dermatol* 2012; 66: 535.

PUVA, PUVA bath, UVB, narrowband (NB)-UVB, and UVA1 have all shown efficacy for cGVHD in small series. UVB and NB-UVB may

work best for lichen planus–like manifestations, whereas PUVA and UVA1 penetrate more deeply and are better suited for scleroderma-like disease.

Third-Line Therapies

Systemic

• Ruxolitinib	C
• Pulse corticosteroids	C
• Interleukin-2	C
• Pentostatin	B
• Low-dose methotrexate	C
• Thalidomide	B
• Hydroxychloroquine	C
• Infliximab	C
• Etanercept	C
• Alefacept	C
• Alemtuzumab	C
• Cyclophosphamide	C
• Etrexinate / isotretinoin / acitretin	C
• Clofazimine	C
• Thoracoabdominal irradiation	C
• Mesenchymal stromal cell therapy	C

Oral GVHD

• Topical corticosteroids	C
• Topical calcineurin inhibitors	C
• Intraoral PUVA	C
• Oral UVB	C

Ruxolitinib in corticosteroid-refractory graft-versus-host disease after allogeneic stem cell transplantation: a multicenter survey

Zeiser R, Burchert A, Lengerke C, Verbeek M, Maas-Bauer K, Metzelder SK, et al. *Leukemia* 2015; 29:2062–8.

In a multicenter retrospective study, 35 of 41 (85%) patients with steroid-refractory cGVHD responded to the JAK1/2 inhibitor ruxolitinib. Complications included cytopenias and cytomegalovirus reactivation.

Interleukin-2 and regulatory T cells in graft-versus-host disease

Koreth J, Matsuoka K, Kim HT, McDonough SM, Bindra B, Alyea EP 3rd, et al. *N Engl J Med* 2011; 365: 2055–66.

Low-dose IL-2 stimulates T-regulatory cell expansion. Of 23 patients in this phase I study, 12 had a partial response and 11 had stable disease.

Phase II study of pentostatin in patients with corticosteroid-refractory chronic graft-versus-host disease

Jacobsohn DA, Chen AR, Zahurak M, Piantadosi S, Anders V, Bolaños-Meade J, et al. *J Clin Oncol* 2007; 25: 4255–61.

Fifty-eight heavily pretreated patients (median four prior regimens) with cGVHD were given pentostatin 4 mg/m² every 2 weeks for 12 doses. The overall response rate was 32 of 58 (55%), with major improvements seen in 31 patients. Survival was 70% at 2 years, with infectious complications predominant.

Granuloma annulare

Andrew Ilchyshyn, and Ajoy Bardhan

Granuloma annulare (GA) is a self-limiting inflammatory skin disease. Most commonly, it is characterized by smooth, skin-colored to pink or violaceous arciform and annular beaded plaques localized to the distal extremities. Other variants include generalized, perforating, and subcutaneous forms of GA. Histology shows palisading granulomas with a central core of necrobiotic collagen surrounded by a lymphohistiocytic infiltrate.

The etiology and pathogenesis are unclear. An association with diabetes mellitus is controversial, with conflicting evidence in the literature. Concomitant dyslipidemias, autoimmune thyroiditis, viral infection (hepatitis B and C and human immunodeficiency virus (HIV)), and malignancies (lymphoma and solid organ neoplasms) have also rarely been reported.

Management Strategy

The localized variety of GA is often diagnosed clinically, but a skin biopsy may be required to confirm the diagnosis of less common varieties. Once the diagnosis is made, it is prudent to exclude diabetes mellitus. Other disease associations, mentioned earlier, are rare.

The majority of cases of GA are asymptomatic and self-limiting; therefore the need for treatment should be considered carefully. In many cases reassurance that the disease is benign and will resolve spontaneously is sufficient. Painful or unsightly lesions may justify active treatment, but the evidence to support the efficacy of reported treatments is poor.

Localized GA may be treated with topical or intralesional steroids. Clobetasol propionate (Dermovate) lotion under occlusion with a hydrocolloid dressing, changed weekly, can be used for up to 6 weeks. Alternatively, intralesional triamcinolone injections may be used at intervals of 6 to 8 weeks. Cryotherapy using liquid nitrogen can be repeated every 3 to 4 weeks as required. Treatment of refractory lesions includes photodynamic therapy, ultraviolet A1 phototherapy (UVA1), intralesional interferon, and laser therapy; large, tumid lesions may require excision.

Generalized GA may be persistent, and its unsightly appearance causes patients to seek active treatment. Both UVA and psoralen and ultraviolet A (PUVA) may be used, but relapses can occur. Isotretinoin and dapsone have been associated with improvement or clearance of generalized GA. Topical tacrolimus and pimecrolimus have been used, with greater success in generalized disease than in the localized variety. Other reported treatments for this condition include laser, fumaric acid esters, hydroxychloroquine, methotrexate, chlorambucil, ciclosporin, hydroxyurea, doxycycline, pulsed triple-antibiotic therapy, systemic steroids, adalimumab, infliximab, anthralin, vitamin E, allopurinol, nicotinamide, pentoxifylline, and defibrotide.

Specific Investigation

- Check glycated hemoglobin (HbA1c)

Unlike necrobiosis lipoidica, in which there is a strong association with diabetes mellitus, the relationship between GA and diabetes is unclear. However, a simple check of HbA1c to exclude undiagnosed diabetes may be sensible.

Carbohydrate tolerance in patients with granuloma annulare. Study of fifty-two cases

Haim S, Friedman-Birnbaum R, Haimn Shafrir A, Ravina A. Br J Dermatol 1973; 88: 447–51.

In a study of 39 patients with localized GA the incidence of abnormal carbohydrate tolerance was 23% and similar to that of a control population, compared with an incidence of 77% in 13 patients with generalized disease.

Absence of carbohydrate intolerance in patients with granuloma annulare

Gannon TF, Lynch PJ. J Am Acad Dermatol 1994; 30: 662–3.

In a study of 23 patients in which 13 patients had localized lesions and 10 patients had generalized disease, glycosylated hemoglobin levels were found to be normal.

Localised granuloma annulare is associated with insulin-dependent diabetes mellitus

Muhlemann MF, Williams DR. Br J Dermatol 1984; 111: 325–9.

This retrospective study looked at 557 insulin-dependent diabetics and found that 16 patients had GA, significantly more than the 0.9 cases that might have been expected.

Localized Granuloma Annulare

First-Line Therapies

• Intralesional corticosteroids	B
• Cryotherapy	B
• Topical corticosteroid	E

Granuloma annulare and necrobiosis lipoidica treated by jet injector

Sparrow G, Abell E. Br J Dermatol 1975; 93: 85–9.

In this study of 45 patients with GA, intralesional triamcinolone produced a complete response in 68% of patients after three treatments carried out at 6- and 8-week intervals. About half of the patients suffered recurrences, which responded to retreatment.

Successful outcome of cryosurgery in patients with granuloma annulare

Blume-Peytavi U, Zouboulis CH, Jacobi H, Scholz A, Bisson S, Orfanos CE. Br J Dermatol 1994; 130: 494–7.

In a study of 31 patients with GA, 22 patients were treated with liquid nitrogen and 9 with nitrous oxide. After a single freeze – thaw cycle 81% of lesions were cleared. Four cases had persistent atrophic scars where large lesions had been treated with liquid nitrogen.

It should be possible to prevent cryoatrophy by avoiding freeze–thaw cycles of more than 10 seconds and taking care not to overlap treatment areas.

Granuloma annulare of childhood successfully treated with potent topical corticosteroids previously unresponsive to tacrolimus ointment 0.1%: report of three cases

Rallis E, Stavropoulou E, Korfitis C. Clin Exp Dermatol 2009; 34: e475–6.

Twice-daily application of clobetasol propionate 0.05% or mometasone furoate 0.1% without occlusion for 2 to 3 weeks led to complete remission of localized GA in three children aged between 7 and 10.

Successful treatment of chronic skin diseases with clobetasol propionate and a hydrocolloid occlusive dressing

Volden G. *Acta Derm Venereol* 1992; 72: 69–71.

One of three cases of GA showed a complete response after 4 weeks of treatment with clobetasol propionate under occlusion.

This treatment has the advantage of being painless, but evidence for its efficacy is not strong.

Second-Line Therapies

• Pulsed dye laser	C
• 308-nm excimer laser	E
• Topical photodynamic therapy	D
• Topical imiquimod	E
• Topical dapsone	E
• Topical tacrolimus	E
• Topical pimecrolimus	E
• Scarification	E
• Surgery	E
• UVA1	E
• Intralesional Interferon	E
• Pulsed monthly rifampicin, ofloxacin, and minocycline	D

Treatment of granuloma annulare with the 595 nm pulsed dye laser (PDL), a multicenter retrospective study with long-term follow-up

Passeron T, Fusade T, Vabres P, Bousquet-Rouaud R, Collet-Vilette A-M, Dahan S, et al. *J Eur Acad Dermatol Venereol* 2013; 27: 785–8.

In this study, five patients with localized and eight with generalized GA were treated with three sessions of pulsed-dye laser. A significant response was seen only in the localized forms.

Granuloma annulare treated with excimer laser

Bronfenbrener R, Ragi J, Milgraum S. J Clin Aesthet Dermatol 2012; 5: 43–5.

A 73-year-old woman with a greater than 40-year history of generalized GA underwent treatment with excimer laser therapy on the dorsum of her hands. The regimen comprised fluence of 300 mJ/cm² with five doses per treatment session. After 15 treatment sessions, there was complete resolution, with no recurrence at treated sites at 6 months' follow-up.

Photodynamic therapy for granuloma annulare: more than a shot in the dark

Weisenseel P, Kuznetsov AV, Molin S, Ruzicka T, Berking C, Prinz JC. Dermatology 2008; 217: 329–32.

Seven patients with GA were treated with three sessions of photodynamic therapy with topical aminolevulinic acid (ALA-PDT) with an interval of 2 to 4 weeks between each session. In two patients, GA cleared completely, in two the skin lesions improved markedly, and in three no response was observed.

A retrospective analysis of real-life practice of off-label photodynamic therapy using methyl aminolevulinate (MAL-PDT) in 20 Italian dermatology departments. Part 1: inflammatory and esthetic indications

Calzavara-Pinton PG, Rossi MT, Aronson E, Sala R, Arpaia N, Burtica EC. J Photochem Photobiol Sci 2013; 12: 148–57.

Nine out of 13 patients with GA showed improvement.

Successful treatment of granuloma annulare with imiquimod cream 5%: a report of four cases

Badavanis G, Monastirli A, Pasmatzis E, Tsambaos D. Acta Derm Venereol 2005; 85: 547–8.

Four patients with multiple lesions of GA treated with imiquimod cream once daily. The majority of lesions cleared within 12 weeks of treatment with no recurrence observed at 18 months' follow-up.

Granuloma annulare: dramatically altered appearance after application of 5% imiquimod cream

Stephenson S, Nedorost S. Pediatr Dermatol 2008; 25: 138–9.

GA *worsened* in a child after accidental application of imiquimod

used to treat adjacent plane warts.

Management of periocular granuloma annulare using topical dapsone

Kassardjian M, Patel M, Shitabata P, Horowitz D. *J Clin Aesthet Dermatol* 2015; 8: 48–51.

A 41-year-old male with arciform GA of the right upper eyelid and lateral canthus was treated with dapsone 5% gel applied twice daily, with significant improvement seen at 3 weeks.

Periorbital granuloma annulare successfully treated with tacrolimus 0.1% ointment

Gomez-Moyano E, Vera-Casaño A, Martinez S, Sanz A. *Int J Dermatol* 2014; 53: e156–7.

Scarification treatment of granuloma annulare

Wilkin JK, DuComb D, Castrow FF. *Arch Dermatol* 1982; 118: 68–9.

Two patients successfully treated by scarification once weekly for 8 weeks and at 3-weekly intervals thereafter, using the point of a 19G injection needle drawn across the lesions to produce capillary bleeding.

Surgical pearl: surgical treatment of tumour sized granuloma annulare of the fingers

Shelley WB, Shelley ED. *J Am Acad Dermatol* 1997; 37: 473–4.

A case report of nodular GA treated with shave excision, allowing the wound to heal by secondary intention.

Multiple localized granuloma annulare: ultraviolet A1 phototherapy

Frigerio E, Franchi C, Garutti C, Spadino S, Altomare GF. *Clin Exp Dermatol* 2007; 32: 762–4.

Four patients responded to high-dose UVA1, starting with 60 J/cm² on day 1, followed by fixed daily doses of 100 J/cm², five times weekly for 3 weeks.

Treatment of granuloma annulare by local injections with low dose recombinant human interferon gamma

Weiss JM, Muchenberger S, Schöpf E, Simon JC. *J Am Acad Dermatol* 1998; 39: 117–9.

Three patients achieved clearance of localized GA treated with intralesional interferon- γ 2.5×10^5 IU on 7 consecutive days and continued three times weekly for a further 2 weeks.

Granuloma annulare treated with rifampin, ofloxacin, and minocycline combination therapy

Marcus DV, Mahmoud BH, Hamzavi IH. Arch Dermatol 2009; 145: 787–9.

Six patients with localized GA achieved complete clearance after 3 to 5 months' combination therapy with rifampin 600 mg, ofloxacin 400 mg, and minocycline 100 mg administered monthly.

Generalized (Disseminated) Granuloma Annulare

First-Line Therapies

• UVA1	B
• PUVA	C
• Narrowband-ultraviolet B (NB-UVB)	D
• Isotretinoin	C
• Oral dapsone	C
• Topical tacrolimus	E
• Topical photodynamic therapy	E

UVA1 phototherapy for disseminated granuloma annulare

Schnopp C, Tzaneva S, Mempel M, Schulmeister K, Abeck D, Tanew A. Photodermatol Photoimmunol Photomed 2005; 21: 68–71.

Twenty patients with disseminated GA underwent phototherapy

with UVA1 340 to 400 nm, which provided good or excellent results in half of them and satisfactory responses in the majority. Discontinuation of treatment was followed by early recurrence.

Psoralen and ultraviolet A in the treatment of granuloma annulare

Browne F, Turner D, Goulden V. Photodermatol Photoimmunol Photomed 2011; 27: 81–4.

A retrospective study of 33 patients treated with twice-weekly PUVA, showing clearance in 50% of patients, a further 16% with good improvement, 25% with moderate benefit, and 9% with poor outcome. Seventy-nine percent remained in remission at 6 months, but only 32% remained in remission at 12 months.

Clearance of generalized papular umbilicated granuloma annulare in a child with bath PUVA therapy

Batchelor R, Clark S. Pediatr Dermatol 2006; 23: 72–4.

GA cleared with bath PUVA.

NB-UVB phototherapy for generalized granuloma annulare

Pavlovsky M, Samuelov L, Sprecher E, Matz H. Dermatol Ther 2016; 29: 152–4.

A retrospective study of 13 patients with generalized GA treated with NB-UVB phototherapy showed 54% of patients had a complete or partial response to treatment.

Generalized granuloma annulare in a patient with type 2 diabetes mellitus: successful treatment with isotretinoin

Sahin M, Türel-Ermertcan A, Oztürkcan S, Türkdogan P. J Eur Acad Dermatol Venereol 2006; 20: 111–4.

A case of generalized granuloma annulare with myelodysplastic syndrome: successful treatment with systemic isotretinoin and topical pimecrolimus 1% cream combination

Baskan EB, Turan A, Tunalı S. J Eur Acad Dermatol Venereol 2007; 21: 693–5.

A man with generalized GA achieved full remission after 4 months of treatment with isotretinoin 0.5 mg/kg/day and topical pimecrolimus 1% cream twice daily.

There are several case reports in which isotretinoin has been

successfully employed at doses of 0.5 to 1 mg/kg/day for generalized disease.

The response of generalised granuloma annulare to dapsone

Czarnecki DB, Gin D. *Acta Derm Venereol* 1986; 66: 82–4.

Six patients with generalized GA treated with dapsone 100 mg daily showed a complete response, with five clearing within 8 weeks and four remaining clear for 20 months after stopping treatment.

Efficacy of dapsone on disseminated granuloma annulare: a case report and review of the literature

Martín-Sáez E, Fernández-Guarino M, Carrillo-Gijón R, Muñoz-Zato E, Jaén-Olasolo P. *Actas Dermosifilogr* 2008; 99: 64–8.

A patient showed improvement taking 100 mg dapsone daily, with improvement noted at 2 months and clearance at 15 months. No recurrence was noted several months after discontinuation of treatment.

Successful treatment of disseminated granuloma annulare with topical tacrolimus

Jain S, Stephens CJM. *Br J Dermatol* 2004; 150: 1042–3.

Four patients were treated with twice- daily application of 0.1% tacrolimus ointment. At 6 weeks, two patients showed clearance, and the remaining two patients showed significant improvement. There was no recurrence or deterioration noted 6 weeks after discontinuation of treatment.

Generalized granuloma annulare treated with methylaminolevulinate photodynamic therapy

Piaserico S, Zattra E, Linder D, Peserico A. *Dermatology* 2009; 218: 282–4.

Three patients with persistent generalized GA responded to MAL-PDT.

Second-Line Therapies

• Topical corticosteroids	E
• Systemic corticosteroids	E
• Topical pimecrolimus	E
• Hydroxychloroquine	D
• Fumaric acid esters	C
• Chlorambucil	D
• Doxycycline	E
• Allopurinol	E
• Nicotinamide	E
• Pentoxifylline	E
• Oral calcitriol	E
• Monthly rifampicin, ofloxacin, and minocycline	D
• Ciclosporin	E
• Methotrexate	E
• Hydroxyurea	E
• Defibrotide	E
• Anthralin	E
• Adalimumab	D
• Infliximab	E
• Etanercept	E
• Laser (Neodymium-doped Yttrium Aluminium Garnet, Nd:YAG)	E
• Oral vitamin E and leukotriene inhibitor	E
• Topical vitamin E	E

A contact dermatitis reaction to clobetasol propionate cream associated with resolution of recalcitrant, generalised granuloma annulare

Agarwal S, Berth-Jones J. *J Dermatol Treat* 2000; 11: 279–82.

A patient cleared of disseminated GA by topical clobetasol; however, the patient developed contact sensitization to the medication, raising the possibility that this reaction may also have played a therapeutic role.

Granuloma annulare, generalised

Larralde J. Arch Dermatol 1963; 87: 777–8.

A case report describing the use of systemic steroids in generalized GA.

Systemic corticosteroids may exacerbate preexisting diabetes.

Pimecrolimus 1% cream in the treatment of disseminated granuloma annulare

Rigopoulos D, Prantsidis A, Christofidou E, Ioannides D, Gregoriou S, Katsambas A. Br J Dermatol 2005; 152: 1364–5.

An adult improved with twice-daily treatment for 3 months.

Antimalarials for control of disseminated granuloma annulare in children

Simon M, Van Den Driesch P. J Am Acad Dermatol 1994; 31: 1064–5.

Six children achieved complete clearance within 6 weeks of treatment with 3 to 6 mg/kg/day hydroxychloroquine and remained clear for 2.5 years of follow-up.

Treatment of generalized granuloma annulare with hydroxychloroquine

Cannistraci C, Lesnoni La Parola I, Falchi M, Picardo M. Dermatology 2005; 211: 167–8.

Four patients out of nine achieved complete remission when treated with hydroxychloroquine for 4 months with the following reducing regimen: 9 mg/kg/day for 2 months, 6 mg/kg/day for month 3, and 2 mg/kg/day for month 4. One child was treated with 50% of the dose delineated.

Therapy of noninfectious granulomatous skin diseases with fumaric acid esters

Breuer K, Gutzmer R, Völker B, Kapp A, Werfel T. Br J Dermatol 2005; 152: 1290–5.

Thirteen patients with generalized GA were treated with Fumaderm, with gradual uptitration of dose, as tolerated. Eight patients experienced improvement of disease. Treatment courses were between 3 and greater than 14 months.

Treatment of disseminated granuloma annulare recalcitrant to topical therapy: a retrospective 10 year analysis with comparison

of photochemotherapy alone versus photochemotherapy plus oral fumaric acid esters

Wollina U, Langner D. *J Eur Acad Dermatol Venereol* 2011; 26: 1319–21.

A retrospective study comparing PUVA alone with oral PUVA plus fumaric acid esters showed a better complete or almost complete clearance rate with a combination of PUVA and fumaric acid esters. In addition these patients needed a lower total UVA dosage to achieve this effect.

There are a number of small series of patients demonstrating the efficacy of fumaric acid esters in the management of disseminated GA using the dose regimen used in psoriasis.

Low dose chlorambucil in the treatment of generalised granuloma annulare

Kossard S, Winkelmann RK. *Dermatologica* 1979; 158: 443–50.

Six patients were treated with chlorambucil 2 mg twice daily. Five showed a marked improvement by 12 weeks.

Chlorambucil should only be considered in refractory cases of GA and only for a maximum of 12 weeks.

Generalized granuloma annulare: response to doxycycline

Duarte AF, Mota A, Pereira MA, Baudrier T, Azevedo F. *J Eur Acad Dermatol Venereol* 2009; 23: 84–5.

A woman with GA achieved almost complete resolution after treatment with doxycycline 100 mg/day for 10 weeks.

Treatment of disseminated granuloma annulare with allopurinol: case report

Mazzatenta C, Ghilardi A, Grazzini M. *Dermatol Ther* 2010; 23(Suppl 1): S24–7.

Allopurinol 300 mg twice daily is an alternative treatment in therapy-resistant patients with disseminated GA.

Response of generalized granuloma annulare to high dose niacinamide

Ma A, Medenica M. *Arch Dermatol* 1983; 119: 836–9.

A patient with generalized GA experienced resolution of her lesions after 6 months of treatment with niacinamide 1500 mg/ day.

Generalised granuloma annulare successfully treated with pentoxifylline

Rubel DM, Wood G, Rosen R, Jopp-McKay A. *Australas J Dermatol* 1993; 34: 103–8.

A man with generalized GA showed dramatic clearing of papules after 4 weeks of treatment with pentoxifylline 400 mg three times a day.

Granuloma annulare responsive to oral calcitriol

Boyd AS. *Int J Dermatol* 2012; 51: 120–2.

One patient described improvement in pruritus at 1 month, and improvement in appearance was noted at 3 months with 0.25 µg oral calcitriol daily.

Monthly rifampicin, ofloxacin, and minocycline therapy for generalized and localized granuloma annulare

Garg S, Baveja S. *Indian J Dermatol Venereol Leprol* 2015; 81: 35–9.

Five patients with generalized disease and one patient with localized disease were treated with monthly pulses of rifampicin 600 mg, ofloxacin 400 mg, and minocycline 100 mg until clearance of lesions was achieved. Courses lasted between 4 and 8 months, with no recurrence seen in follow-up of between 9 and 18 months.

Disseminated granuloma annulare: efficacy of cyclosporine therapy

Spadino S, Altomare A, Cainelli C, Franchi C, Frigerio E, Garutti C, et al. *Int J Immunopathol Pharmacol* 2006; 19: 433–8.

Four patients treated with ciclosporin 4 mg/kg/day achieved complete clearance within 3 weeks, with no relapses during the following 12 months.

Cyclosporine for the treatment of granuloma annulare

Fiallo P. *Br J Dermatol* 1998; 138: 369–70.

Two patients treated with ciclosporin 3 mg/kg/day showed flattening and clearance of lesions within a month. Treatment was tapered and discontinued after 2 further months, with no recurrence noted at 12 months.

Successful treatment of disseminated granuloma annulare with methotrexate

Plotner AN, Mutasim DF. Br J Dermatol 2010; 163: 1123–4.

A patient experienced a resolution of the majority of lesions with methotrexate 15 mg weekly and daily folic acid supplementation for 6 weeks. Discontinuation of methotrexate upon two occasions for surgical procedures resulted in a recurrence of disease within 1 month.

Treatment of recalcitrant disseminated granuloma annulare with hydroxyurea

Hall CS, Zone JJ, Hull CM. J Am Acad Dermatol 2008; 58: 525.

Two patients with recalcitrant disseminated GA responded to hydroxyurea 500 mg three times per week for up to 2 months. Subsequently the dose was decreased to 500 mg two times a day.

There would need to be a strong indication for the use of hydroxyurea given the potential risk of toxicity.

A case of disseminated granuloma annulare treated with defibrotide: complete clinical remission and progressive hair darkening

Rubegni P, Sbrano R, Fimiani M. Br J Dermatol 2003; 149: 437–8.

A man with generalized GA and deep vein thrombosis showed improvement in his skin disease within 30 days of starting treatment with defibrotide. His generalized GA subsequently cleared completely after 90 days.

Treatment of disseminated granuloma annulare with anthralin

Jantke ME, Bertsch H-P, Schön MP, Fuchs T. Hautarzt 2011; 62: 935–9.

Two cases demonstrated significant improvement after treatment with anthralin.

Treatment of recalcitrant granuloma annulare (GA) with adalimumab: a single-center, observational study

Min MS, Lebwohl M. J Am Acad Dermatol 2016; 74: 127–33.

Seven patients with generalized granuloma annulare were administered adalimumab 80 mg subcutaneously, followed by 40 mg every other week, 1 week after initiation. Patients were asked to return in 1 and 3 months. Adalimumab was either discontinued with disease clearance or patient wish or escalated to weekly injections if minimal improvement was noted after 3 months. In cases in which lesions recurred after discontinuing adalimumab, patients were

permitted to restart therapy. All seven patients experienced clearance, with two requiring weekly injections. Three patients maintained remission at 40 months after discontinuation of treatment.

Disseminated granuloma annulare: a cutaneous adverse effect of anti-TNF agents

Ratnarathorn M, Raychaudhuri S, Naguwa S. Indian J Dermatol 2011; 56: 752–4.

A woman developed GA after receiving adalimumab for rheumatoid arthritis. There was clearance of the GA on stopping adalimumab, but this recurred when treatment was switched to etanercept.

Antitumor necrosis factor- α treatment with infliximab for disseminated granuloma annulare

Murdaca G, Colombo BM, Barabino G, Caiti M, Cagnati P, Puppo F. Am J Clin Dermatol 2010; 11: 437–9.

A 62-year-old female patient was administered infliximab intravenously at a dosage of 5mg/kg at weeks 0, 2, and 6 and thereafter at monthly intervals for 10 additional months. Most of the GA lesions improved within 8 weeks and slowly resolved within 10 months of treatment.

Rapid improvement of recalcitrant disseminated granuloma annulare upon treatment with the tumor necrosis factor- α inhibitor, infliximab

Hertl MS, Haendle I, Schuler G, Hertl M. Br J Dermatol 2005; 152: 552–5.

A 59-year-old woman with type 1 diabetes and a 4-year history of recalcitrant generalized granuloma annulare was administered infliximab at 5 mg/kg/day at weeks 0, 2, and 6 and thereafter at a monthly interval for an additional 4 months. The majority of disease cleared within 4 to 6 weeks. New lesions were not seen in follow-up to 16 months.

Conflicting evidence emerges with reports of inefficacy as well as efficacy with regard to etanercept.

Resolving granuloma annulare with etanercept

Shupack J, Siu K. Arch Dermatol 2006; 142: 394–5.

A case report of improvement in generalized granuloma annulare

after 12 weeks of treatment.

Failure of etanercept therapy in disseminated granuloma annulare

Kreuter A, Altmeyer P, Gambichler T. Arch Dermatol 2006; 142: 1236–7.

A case series of four patients in which two patients showed no improvement and two patients displayed more extensive disease after 12 weeks of treatment. Administered dosing was either 25 mg twice weekly or 50 mg twice weekly.

Fractional photothermolysis for the treatment of granuloma annulare: a case report

Karsai S, Hammes S, Rütten A, Raulin C. Lasers Surg Med 2008; 40: 319–22.

Remission of four lesions after two to three treatment sessions with a 1440 nm Nd:YAG laser.

Treatment of disseminated granuloma annulare with a 5-lipoxygenase inhibitor and vitamin E

Smith KJ, Norwood C, Skelton H. Br J Dermatol 2002; 146: 667–70.

Three patients were treated with vitamin E 400 IU daily and zileuton 2400 mg daily. All responded within 3 months with complete clinical clearing.

Disseminated granuloma annulare: therapy with vitamin E topically

Burg G. Dermatology 1992; 184: 308–9.

A patient with disseminated GA was successfully treated with topical vitamin E twice daily for 2 weeks.

Treatment of co-existing viral infection or malignancy

GA manifesting as a paraneoplastic phenomenon or associated with diabetes and viral infection has been reported to improve or clear with treatment of the coexisting pathology.

Disseminated granuloma annulare as a presentation of acquired immunodeficiency syndrome (AIDS)

McGregor JM, McGibbon DH. Clin Exp Dermatol 1992; 17: 60–2.

Treatment with zidovudine was associated with resolution of cutaneous lesions.

Generalized granuloma annulare associated with chronic hepatitis B virus infection

Ma H, Zhu W, Yue X. J Eur Acad Dermatol Venereol 2006; 20: 186–9.

Generalized GA resolved after 3 months of treatment with interferon- α .

Generalized granuloma annulare associated with gastrointestinal stromal tumour: case report and review of clinical features and management

Chiu MLS, Tang MBY. Clin Exp Dermatol 2008; 33: 469–71.

Extensive generalized GA cleared 1 month after surgical excision of gastrointestinal stromal tumor.

Generalized granuloma annulare with open comedones in photoexposed areas

Bhushan P, Aggarwal A, Yadav R, Baliyan V. Clin Exp Dermatol 2011; 36: 495–8.

Patient with a background of diabetes mellitus was commenced upon metformin and glimepiride, resulting in a rapid improvement of granuloma annulare.

Granuloma faciale

Nevianna Bordet

Courtesy of University Hospitals of Leicester NHS Trust, Department of Medical Illustration.

Granuloma faciale is a rare, benign, chronic inflammatory dermatosis caused by a localized form of cutaneous vasculitis. It presents primarily in middle-aged Caucasian males, usually as a single lesion on the face. Multiple lesions occur in up to a third of patients, and there are isolated reports of similar conditions affecting the eye and upper airways. Extensive involvement of the nose can

mimic rhinophyma.

Lesions are red-brown, violaceous, or flesh-colored plaques or nodules with accentuation of follicular openings. Clinical diagnosis is difficult. Differential diagnosis includes sarcoid, lupus, lymphocytoma cutis, persistent insect bite reactions, and lymphoma. The histologic differential diagnosis includes erythema elevatum diutinum and angiolymphoid hyperplasia with eosinophilia.

Management Strategy

Granuloma faciale is a chronic condition, and spontaneous remission is unusual. Lesions are usually asymptomatic, but treatment is needed to reduce disfigurement. It is notoriously resistant to treatment and, because of the rarity of the condition, there are no formal trials of therapy. Treatment modalities can be divided into destructive techniques and antiinflammatory approaches. The optimal treatment depends on the size, site, and thickness of the lesions. For isolated or small numbers of lesions *intralesional steroid* or destructive treatments such as *cryotherapy*, *laser*, or surgical *excision* can be used. For multiple or widespread lesions systemic treatment, such as *dapsone* or *clofazimine*, can be considered. In the last few years, there have been increasing numbers of case reports of successful treatment with topical calcineurin inhibitors for isolated or multiple lesions.

Cosmetic camouflage can be helpful for some patients with flatter lesions.

Specific Investigations

- Skin biopsy
- Hematology (full blood count)
- Dermoscopy

Histologic findings include a dense eosinophilic and neutrophilic infiltrate, often perivascular, affecting the upper and sometimes deep dermis. The epidermis is spared, and there is a Grenz zone. Telangiectasia is common. Vasculitis with leukocytoclasia is reported. Dermal fibrosis is often seen.

Granuloma faciale: a clinicopathologic study of 66 patients

Ortonne N, Wechsler J, Bagot M, Grosshans E, Cribier B. J Am Acad Dermatol 2005; 53: 1002–9.

Peripheral blood eosinophilia is sometimes found.

Dermoscopic patterns of common facial inflammatory skin disease

Lallas A, Argenziano G, Apalla Z, Gourhant JY, Zaballos P, Di Lernia V, et al. J Eur Acad Dermatol Venereol 2014; 28: 609–14.

Dermoscopy is increasingly used to aid diagnosis in granuloma faciale. Follicle abnormalities such as dilated follicular openings, perifollicular whitish halo, follicular keratotic plugs, and linear slightly arborizing vessels in a parallel arrangement are the most commonly described dermoscopic criteria.

First-Line Therapies

• Corticosteroids	D
• Calcineurin inhibitors	D
• Cryotherapy	D
• Laser therapy	D
• 5-Fluorouracil	E

Granuloma faciale treated with intradermal dexamethasone

Arundell FD, Burdick KH. Arch Dermatol 1960; 82: 437–8.

This paper reports response to dexamethasone, but triamcinolone acetonide and triamcinolone hexacetonide have also been used. Patients should be warned of the risk of skin atrophy and pigment

change.

Granuloma faciale: is it a new indication for pimecrolimus? A case report

Eetam I, Ertekin B, Unal I, Alper S. *J Dermatol Treat* 2006; 17: 238–40.

A case report of a lesion on the central face showing “dramatic recovery” after pimecrolimus cream 1% twice daily for 2 months.

Granuloma faciale: treatment with topical tacrolimus

Marcoval J, Moreno A, Bordas X, Peyri J. *J Am Acad Dermatol* 2006; 55: S110–1.

This and other papers describe response to topical tacrolimus, sometimes within a few months. In some patients lesions had previously failed to respond to other therapies. Remission for up to 2 years is described.

Assessment of the efficacy of cryosurgery in the treatment of granuloma faciale

Panagiotopoulos A, Anyfantakis V, Rallis E, Chasapi V, Stavropoulos P, Boubouka C, et al. *Br J Dermatol* 2006; 154: 357–60.

Nine patients were treated with either spray or closed probe cryotherapy. The open-spray technique was given as one or two freeze–thaw cycles of 20 to 30 seconds. The cryoprobe was given as one to three freeze–thaw cycles of 15 to 20 seconds. Patients were retreated after 1 and 3 months. All were clear of disease activity at 6 months. One patient developed severe inflammatory reaction with blistering. Two had hypopigmentation, but this resolved in 4 months. There was no recurrence within 2 to 4 years’ follow-up.

Granuloma faciale: successful treatment of nine cases with a combination of cryotherapy and intralesional corticosteroid injection

Dowlati B, Firooz A, Dowlati Y. *Int J Dermatol* 1997; 36: 548–51.

Cryotherapy for 20 to 30 seconds was followed by triamcinolone acetonide 5 mg/mL intralesionally. Lesions cleared completely in all nine cases.

Granuloma faciale treated with pulsed-dye laser: a case series

Cheung S-T, Lanigan SW. *Clin Exp Dermatol* 2005; 30: 373–5.

Four patients who had all failed with cryotherapy were treated

with pulsed-dye laser at 595 nm. In two patients the lesions resolved. Nasal lesions, especially flatter ones, seem to respond better to treatment.

Reports of granuloma faciale responding to argon laser and KTP laser are described in the literature, but the pulsed-dye laser is the type most frequently reported as achieving improvement.

Carbon dioxide laser treatment of granuloma faciale

Wheeland RG, Ashley JR, Smith DA, Ellis DL, Wheeland DN. J Dermatol Surg Oncol 1984; 10: 730–3.

A single treatment resulted in healing with no discernible scar. There was no recurrence at 1 year.

Rhinophyma-like granuloma faciale successfully treated with carbon dioxide laser

Bakkour W, Madan V. Br J Dermatol 2014; 170: 474–5.

A patient who failed to respond to topical and intralesional steroids as well as 150 mg dapsone showed an excellent response with no recurrence at 18 months.

A handful of other case reports show benefit with carbon dioxide laser.

Treatment of laser resistant granuloma faciale with intralesional triamcinolone acetonide and 5-fluorouracil combination therapy

Norris DL, Apikian M, Goodman GJ. J Cutan Aesthet Surg 2015; 8: 111–3.

Case report of one patient who failed to respond to topical tacrolimus and pulsed-dye laser achieving “an excellent response” with intralesional 0.8 mL 5-fluorouracil 50 mg/1 mL combined with 0.2 mL triamcinolone acetonide 10 mg/mL. No more than 2 mL per treatment should be used according to the authors.

Second-Line Therapies

• Dapsone	E
• Surgery	E

On the efficacy of dapsone in granuloma faciale

Van de Kerkhof PCM. Acta Derm Venereol 1994; 74: 61–2.

A 4-cm plaque showed “impressive improvement” with dapsone 200 mg daily. Dapsone needs careful monitoring, and many patients would not tolerate 200 mg daily.

Many authors mention dapsone as a treatment that has been tried but failed.

Granuloma faciale treated with topical dapsone: a case report

Babalola O, Zhang J, Kristjansson A, Whitaker-Worth D, McCusker M. Dermtol Online J 2014; 20: 25148282.

Twice-daily topical dapsone 5% gel was used successfully to treat a single patient who had failed with intralesional steroid injections, potent topical steroids, and a 6-month trial of doxycycline 20 mg twice daily. Near-complete resolution was achieved at 9 months with no recurrence at 18 months.

Recurrent facial plaques following full-thickness grafting

Phillips DK, Hymes SR. Arch Dermatol 1994; 130: 1436–7.

Although surgery is mentioned in many papers, recurrence can occur even after full-thickness excision and grafting.

Third-Line Therapies

• Clofazimine	E
• Topical PUVA	E

Granuloma faciale mimicking rhinophyma: response to clofazimine

Gomez-de la Fuente E, del Rio R, Guerra A, Rodriguez-Peralto JL, Iglesias L. Acta Derm Venereol 2000; 80: 144.

A patient with a 10-year history of histologically proven disease on the nose was treated with 300 mg clofazimine once daily for 5 months, with “remarkable improvement.” Two similar reports are cited.

Granuloma faciale: treatment with topical psoralen and UVA

Hudson LD. J Am Acad Dermatol 1983; 8: 559.

A 62-year-old man with a 1-month history of biopsy-proven granuloma faciale affecting the nasal alae responded to 24 J UVA given over 10 weeks, showing a very marked improvement with no evidence of residual lesion at 6 months.

There are old reports of treatment with intralesional gold and bismuth, radiotherapy, oral colchicine, isoniazid, potassium arsenite, testosterone, and antimalarials, but within the past 30 years there have been no reports of successful response to these agents.

Acknowledgments

With thanks to Dr. Susan E. Handfield-Jones as a previous contributor to this chapter.

Granuloma inguinale

Ted Rosen

Granuloma inguinale, or donovanosis, is an infection causing granulomatous and destructive ulceration of genital, inguinal, and perineal skin. Cervical lesions are rare, but may clinically mimic carcinoma. Extragenital lesions occur in about 6% of cases. This disorder is extremely rare in Western Europe and the United States, but is still endemic or epidemic in India, South Africa, Brazil, Papua New Guinea, and rarely among aborigines in Australia. The causative organism is *Klebsiella granulomatis*, an intracellular gram-negative bacillus.

The disease presents with a subcutaneous granuloma or nodule that develops into characteristically painless, progressive ulcerative lesions without regional lymphadenopathy. Most often lesions are ulcerogranulomatous, highly vascular (i.e., a beefy red appearance), and friable (bleed easily on contact).

Management Strategy

Patients with donovanosis should be treated to prevent the gradual worsening of the disease leading to genital deformity or (very rarely) life-threatening disseminated infection, to prevent transmission, and to prevent the risk of concomitant transmission of human immunodeficiency virus (HIV) infection.

In the absence of evidence from randomized placebo-controlled trials, antibiotic treatment of donovanosis is based on the results of local clinical experience and individual case reports, typically involving relatively small numbers of patients.

The U.S. Centers for Disease Control and Prevention (CDC) (2015) currently recommends *azithromycin*, with many alternative regimens (e.g., *doxycycline*, *ciprofloxacin*, *erythromycin*, *trimethoprim-sulfamethoxazole*). Azithromycin is also recommended in the 2016 European Guideline on donovanosis. The addition of an aminoglycoside, such as *gentamicin*, is recommended by the CDC if lesions do not respond within the first few days.

Therapy should be continued until all lesions have healed completely. This typically starts at the outside margins and progresses inward. Despite seemingly effective initial therapy, a relapse can occur 6 to 18 months later. *Surgical excision* may be necessary for extensive disease that is unresponsive to antibiotic therapy. It should be noted that squamous cell carcinoma has been reported concurrent with active donovanosis, complicating long-standing cases, and even developing at sites of healed lesions.

Sexual partners of patients who have granuloma inguinale should be examined and treated if they had sexual contact with the patient during the 60 days preceding the onset of symptoms in the patient or have clinical signs and symptoms of the disease.

Specific Investigations

- Tissue smear or biopsy with Wright or Giemsa stains
- Screen for other sexually transmitted infections (e.g., HIV, syphilis)
- Culture (not readily available)
- Polymerase chain reaction (PCR) (not readily available)

Genital ulcer disease: accuracy of clinical diagnosis and strategies to improve control in Durban, South Africa

O'Farrell N, Hoosen AA, Coetzee KD, Van den Ende J. Genitourin Med 1994; 70: 7–11.

The clinical diagnostic accuracy for donovanosis was relatively high (63% in men, 83% in women). Donovanosis ulcers bled on touch and were not usually associated with inguinal lymphadenopathy.

Donovanosis

Hart G. Clin Infect Dis 1997; 25: 24–32.

Confirmation involves demonstration of typical intracellular Donovan bodies within large mononuclear cells visualized in smears prepared from lesions or biopsy specimens. The large mononuclear cells are 25 to 90 µm in diameter with a vesicular or pyknotic nucleus.

Sexually transmitted disease surveillance 2010

Centers for Disease Control and Prevention. U.S. Department of Health and Human Services, Atlanta; 2011.

Cases are confirmed by demonstration of intracytoplasmic Donovan bodies in Wright- or Giemsa-stained smears or biopsies of granulation tissue in a clinically compatible case (one or more painless or minimally painful granulomatous lesions in the anogenital area).

A colorimetric detection system for *Calymmatobacterium granulomatis*

Carter JS, Kemp DJ. Sex Transm Infect 2000; 76: 134–6.

A PCR test that could be used by well-equipped laboratories; largely a research tool.

Squamous cell carcinoma complicating donovanosis not a thing of the past!

Sethi S, Sarkar R, Garg V, Agarwal S. Int J STD AIDS 2014; 25: 894–7.

A reminder that squamous cell carcinoma has been associated with active and even with healed donovanosis.

First-Line Therapy

• Azithromycin	B
-----------------------	----------

Donovanosis: treatment with azithromycin

Bowden FJ, Savage J. Int J STD AIDS 1998; 9: 61.

An Australian report of over 100 patients treated with azithromycin with no primary treatment failures. Regimens employed were 500 mg orally daily for 7 days or 1 g orally weekly for 4 weeks. The 1996 to 1997 edition of the Australian Antibiotic Guidelines lists azithromycin as the first-line agent for donovanosis. The drug is listed as a B1 agent in pregnancy, meaning that it can be used for the treatment of antenatal patients with the disease.

2016 European guideline on donovanosis

O'Farrell N, Moi H. Int J STD AIDS 2016; 27: 605–7.

Azithromycin 1 g orally weekly or 500 mg orally daily until complete healing is achieved is recommended as first-line therapy. Second-line therapeutic recommendations parallel those enumerated by the CDC (see the next citation).

Centers for Disease Control and Prevention Sexually Transmitted Diseases Treatment Guidelines, 2015

Workowski KA. Clin Infect Dis 2015; 61(Suppl 8): S759–62.

The treatment of choice is azithromycin 1 g orally once per week or 500 mg daily for at least 3 weeks and until all lesions have completely healed. Alternative (second-line) therapies include doxycycline 100 mg orally twice a day for at least 3 weeks and until all lesions have completely healed, ciprofloxacin 750 mg orally twice a day for at least 3 weeks and until all lesions have completely healed, erythromycin base 500 mg orally four times a day for at least 3 weeks and until all

lesions have completely healed, and trimethoprim–sulfamethoxazole one double-strength (160 mg/800 mg) tablet orally twice a day for at least 3 weeks and until all lesions have completely healed.

Second-Line Therapies

• Doxycycline	C
• Erythromycin	C
• Trimethoprim–sulfamethoxazole	B
• Ciprofloxacin	C

Clinico-epidemiologic features of granuloma inguinale in the era of acquired immune deficiency syndrome

Jamkhedkar PP, Hira SK, Shroff HJ, Lanjewar DN. Sex Transm Dis 1998; 25: 196–200.

Fifty patients (21 HIV positive and 29 HIV negative) treated with erythromycin 2 g orally daily. Healing took longer in the seropositive group (mean 25.7 vs. 16.8 days).

Granuloma inguinale

Rosen T, Tschen JA, Ramsdell W, Moore J, Markham B. J Am Acad Dermatol 1984; 11: 433–7.

Twenty patients were safely and effectively treated with trimethoprim–sulfamethoxazole. It has been used extensively in India with consistently good results.

Third-Line Therapies

• Ceftriaxone	C
• Gentamicin	C
• Surgical treatment	E
• Norfloxacin	C
• Trovafloxacin	C
• Ampicillin	C
• Chloramphenicol	C
• Thiamphenicol	C

Ceftriaxone in the treatment of chronic donovanosis in Central Australia

Merianos A, Gilles M, Chuah J. Genitourin Med 1994; 70: 84–9.

Eight women and four men treated with daily injections of 1 g ceftriaxone diluted in 2 mL of 1% lidocaine. Clinical improvement was dramatic in most lesions, and four patients healed completely without recurrence after a total 7 to 10 g of ceftriaxone.

1998 guidelines for treatment of sexually transmitted diseases

Centers for Disease Control and Prevention. MMWR Recomm Rep 1998; 47: 1–116.

The CDC recommends the addition of gentamicin (1 mg/kg IV

every 8 hours) if lesions do not respond within the first few days of therapy.

Surgical treatment of granuloma inguinale

Bozbor A, Erbil Y, Berber E, Ozarmagan S. Br J Dermatol 1998; 138: 1079–81.

Fistulas and abscesses unresponsive to antibiotics may require surgical treatment.

Treatment of donovanosis with norfloxacin

Ramanan CR, Sarma PSA, Ghorpade A, Das M. Int J Dermatol 1990; 29: 298–9.

Ten patients treated with oral norfloxacin 400 mg twice daily showed complete healing in 2 to 11 days.

Trovafloxacin for the treatment of chronic granuloma inguinale

Hsu SL, Chia JK. Sex Transm Infect 2001; 77: 137.

One patient had complete resolution of lesions after 2 months of trovafloxacin 200 mg daily after previously failing doxycycline, ampicillin, erythromycin, trimethoprim–sulfamethoxazole, ceftriaxone, gentamicin, and chloramphenicol.

The diagnosis and treatment of donovanosis (granuloma inguinale)

Richens J. Genitourin Med 1991; 67: 441–52.

Ampicillin is unreliable and not recommended as first-line therapy.

Donovanosis in Papua New Guinea

Maddocks I, Anders EM, Dennis E. Br J Vener Dis 1976; 52: 190–6.

Fifty cases treated with chloramphenicol 500 mg four times daily. Forty-three had complete or near-complete clinical and bacteriologic healing.

Chloramphenicol is effective, but risk of aplastic anemia limits its use to life-threatening disease.

Donovanosis treated with thiamphenicol

Belda W, Velho PE, Arnone M, Romitti R. Braz J Infect Dis 2007; 11: 388–9.

Ten patients with donovanosis of the penis treated with thiamphenicol 2.5 g orally on day 1 followed by 1 g daily for the next

14 days. Eight, including two HIV-positive patients, had healing of their lesions without recurrence.

Thiamphenicol is advantageous over chloramphenicol because of its once-daily administration and lack of reports of serious marrow toxicity.

Special considerations

Pregnancy: Pregnant and lactating women should be treated with erythromycin with consideration for the addition of a parenteral aminoglycoside. Azithromycin may also be safe and effective. Doxycycline should be avoided in the second and third trimester of pregnancy because of the risk for discoloration of teeth and bones, but is compatible with breastfeeding. Ciprofloxacin presents a low risk to the fetus during pregnancy, but sulfonamides are associated with rare but serious kernicterus in those with G6PD deficiency and should be avoided in the third trimester and during breastfeeding.

HIV infection: Patients often require prolonged antibiotic treatment after the regimens cited earlier. The addition of gentamicin should be strongly considered.

Children: Children should be treated with a short course of azithromycin dosed at 20 mg/kg. Infants born to mothers with donovanosis should be treated prophylactically with 3 days of azithromycin dosed at 20 mg/kg once daily.

Granulomatous cheilitis

Charlene Lam, and Bryan E. Anderson

Granulomatous cheilitis is characterized by painless swelling of one or both lips, with histologic evidence of noncaseating granulomatous inflammation. Granulomatous cheilitis exists along the spectrum of orofacial granulomatosis, which encompasses localized disease (granulomatous cheilitis, Miescher cheilitis) to multisystem disease (Melkersson–Rosenthal syndrome). Melkersson–Rosenthal syndrome describes the triad of recurrent orofacial edema, recurrent facial nerve palsy, and lingua plicata (fissured tongue). Many investigators consider isolated granulomatous cheilitis to be a monosymptomatic form of Melkersson–Rosenthal syndrome.

Management Strategy

The treatment of granulomatous cheilitis is very challenging. Because the etiology is unknown, a variety of therapeutic strategies with varying degrees of success have been attempted. No randomized clinical trials or comparative studies have been performed. Given the waxing-and-waning nature of the condition, treatment outcomes are difficult to assess. Spontaneous remissions of granulomatous cheilitis rarely occur, further confounding assessment of therapies. Furthermore, a recent retrospective study demonstrated long-term treatment with topical medications and/or combination therapy may be required.

The aim of treatment is to prevent permanent labial deformity. Conservative measures for acute granulomatous cheilitis involve symptomatic relief, including *cold compresses* and *oral antihistamines* to reduce erythema and *ointments* to protect against fissuring of the lips. Initial therapy frequently includes *corticosteroids*, either topical, intralesional, or systemic. Initial topical therapy may include either triamcinolone or clobetasol (compounded into Orabase). Intralesional steroids may be used in doses ranging from 10 to 40 mg/kg. Nerve blocks may reduce patient discomfort in cases where large volumes at low concentrations are needed. Although short courses of prednisone will frequently improve tissue swelling, flares are often noted on cessation.

Clofazimine has been reported to treat granulomatous cheilitis successfully. Response to therapy has been variable. Possible side effects include transient orange-pink discoloration of the skin, nausea, and vomiting. Fatal enteropathy may occur but only at higher doses than those recommended for granulomatous cheilitis treatment.

Thalidomide can also be considered, especially in refractory cases. Patients must be monitored for the development of peripheral neuropathy and warned of its teratogenicity. Monotherapy with *metronidazole*, *tetracyclines*, *azithromycin*, *hydroxychloroquine*, or *sulfasalazine*, although less well substantiated, may be attempted. These medications may be used with corticosteroids. The addition of *minocycline* 100 mg twice daily or *tetracycline* 500 mg daily may prevent rebound after prednisone discontinuation. The value of *dapsone* and topical *tacrolimus* in the treatment of granulomatous cheilitis is unclear. Biologics, including *infliximab* and *adalimumab*, have also been successful treatments.

Granulomatous cheilitis may become persistent. Patients who suffer from permanent esthetic deformity or functional impairment may benefit from cheiloplasty. Surgical intervention should be performed only when more conservative approaches have failed and when inflammation is quiescent. An important consideration for Melkersson–Rosenthal syndrome patients undergoing anesthesia for surgical intervention or any surgical procedures is the risk of urticarial reaction due to anesthetic triggers during the procedure. In the past, remission was maintained with the use of postoperative corticosteroid injections. More recent reports, however, have described long remissions after surgery, with no additional treatment needed.

Granulomatous cheilitis has characteristics that are associated with several conditions that may require evaluation, including Crohn disease, sarcoidosis, infections (tuberculosis, leprosy, deep fungal, Human Immunodeficiency Virus (HIV), and syphilis), acquired or hereditary angioedema, cheilitis glandularis, and leukemic infiltrates. It is also important to rule out any provocative cause such as odontogenic infections or allergenic sensitizers. Orofacial granulomatosis is associated with Crohn disease, especially in children, and may precede gastrointestinal symptoms. The signs and symptoms of Crohn disease may be minimal, necessitating a complete physical examination and continued observation and surveillance of the patient.

Initial biopsies of granulomatous cheilitis may reveal dilated lymphatic channels, nonspecific inflammatory infiltrates, and edema. In the later stages, the classic noncaseating granulomas are found. Absence of granulomata on biopsy does *not* exclude the diagnosis of granulomatous cheilitis. Granulomatous cheilitis is primarily a

clinical diagnosis.

Specific Investigations

- Biopsy for histopathologic examination: polarization and stains/cultures for fungi and acid-fast bacilli
- Complete blood count and chemistry profile, including serum calcium
- Angiotensin-converting enzyme level
- Chest radiograph
- C1-esterase inhibitor; C1-esterase inhibitor functional assays; C1, C2, and C4 levels
- Consultation with dental professional if odontogenic infection suspected
- Consultation with gastroenterologist if there are any gastrointestinal complaints
- Standard patch testing (metal, bakery, dental, and other specialized patch series may be required) and food allergy testing to determine whether an allergen is causative

Orofacial granulomatosis

Miest R, Bruce A, Rogers RS. Clin Dermatol 2016; 34: 505–13.

This article reviews orofacial granulomatosis and provocative factors and discusses possible etiologies and differential diagnoses.

A comprehensive review of current treatments for granulomatous cheilitis

Banks T, Gada S. Br J Dermatol 2012; 166: 934–7.

Characteristics of patients with orofacial granulomatosis

McCartan BE, Healy CM, McCreary CE, Flint SR, Rogers S, Toner ME. Oral Dis 2011; 17: 696–704.

The largest review of clinical and laboratory findings in 119 patients with orofacial granulomatosis. Mean age of 28, with an equal male-to-female ratio. Almost all patients had clinical evidence of lip and/or facial swelling. Over 50% of biopsies showed granulomatous inflammation.

Melkersson–Rosenthal syndrome: a review of 36 patients

Greene RM, Rogers RS III. J Am Acad Dermatol 1989; 21: 1263–70.

Cheilitis granulomatosa

van der Waal RIF, Schulten EAJM, van de Scheur MR, Wauters IM, Starink TM, van der Waal I. J Eur Acad Dermatol Venereol 2001; 15: 519–23.

Cheilitis granulomatosa: overview of 13 patients with long-term follow-up: results of management

van der Waal RIF, Schulten EAJM, van der Meij E, van de Scheur MR, Starink TM, van der Waal I. Int J Dermatol 2002; 41: 225–9.

Orofacial granulomatosis: clinical features and long-term outcome of therapy

Al Johani KA, Moles DR, Hodgson TA, Porter SR, Fedele S. J Am Acad Dermatol 2010; 62: 611–20.

Anesthetic management of patients with Melkersson–Rosenthal syndrome

Tekin M, Kati I. J Anesth 2008; 22: 294–6.

Is orofacial granulomatosis in children a feature of Crohn's disease?

Khouri JM, Bohane TD, Say AS. Acta Paediatr 2005; 94: 501–4.

Re: Melkersson–Rosenthal syndrome as an early manifestation of Crohn's disease

Narbutt P, Dziki A. Colorectal Dis 2005; 7: 420–1.

Orofacial granulomatosis in a patient with Crohn's disease

van der Scheur MR, van der Waal RI, Völker-Dieben JH, Klinkeberg-Knol ED, Starink TM, van der Waal I. J Am Acad Dermatol 2003; 49: 952.

Cheilitis granulomatosa and Melkersson–Rosenthal syndrome: evaluation of gastrointestinal involvement and therapeutic regimens in 14 patients

Ratzinger G, Sepp N, Voetseder W, Tilg H. J Eur Acad Dermatol Venereol 2007; 21: 1065–70.

Orofacial granulomatosis as the initial presentation of Crohn's disease in an adolescent

Bogenrieder T, Lehn N, Landthaler M, Stolz W. *Dermatology* 2003; 206: 273–8.

Cutaneous Crohn's disease mimicking Melkersson–Rosenthal syndrome: treatment with methotrexate

Tonkovic-Capin V, Galbraith SS, Rogers III RS, Binion DG, Yancey K. *J Eur Acad Dermatol Venereol* 2006; 20: 449–52.

Asymptomatic granulomatous vulvitis and granulomatous cheilitis in childhood: the need for Crohn disease workup

Nabatian AS, Shah KN, Iofel E, Rosenberg S, Javidian P, Pappert A, et al. *J Pediatr Gastroenterol Nutr* 2011; 53: 100–1.

Orofacial granulomatosis: three case reports illustrating the spectrum of disease and overlap with Crohn's disease

Smith VM, Murphy R. *Clin Exp Dermatol* 2013; 38: 33–5.

These articles highlight the possibility of Crohn disease presenting with, or subsequent to, the diagnosis of granulomatous cheilitis. Narbutt et al. notes that although the treatment of granulomatous cheilitis can be mostly cosmetic, Crohn disease is a systemic illness with multiple potential complications.

Though there are many similar clinical and histologic features between oral Crohn disease and orofacial granulomatosis, its relationship is controversial. Some contend that adolescent granulomatous cheilitis is a predictor of future Crohn disease. It is unknown what percentage of patients with granulomatous cheilitis will develop Crohn disease, but it may be prudent to discuss this issue with granulomatous cheilitis patients.

Melkersson–Rosenthal syndrome and cheilitis granulomatosa. A clinicopathologic study of thirty-three patients with special reference to their oral lesions

Worsaae N, Christensen KC, Schiødt M, Reibel J. *Oral Surg Oral Med Oral Pathol* 1982; 54: 404–13.

The elimination of odontogenic infections led to inactivity of orofacial edema in 11 of 18 patients.

The Melkersson–Rosenthal syndrome and food additive hypersensitivity

McKenna KE, Welsh MY, Burrows D. Br J Dermatol 1994; 131: 921–2.

Contact hypersensitivity in patients with orofacial granulomatosis

Armstrong DKB, Biagonia P, Lamey PJ, Burrows D. Am J Contact Dermatol 1997; 1: 35–8.

Ten of 48 patients showed positive reactions to an oral battery on standard patch testing. Of these 10, 7 showed an improvement on an elimination diet. In most cases this was not a complete result.

Patch testing for food-associated allergies in orofacial granulomatosis

Fitzpatrick L, Healy CM, McCartan BE, Flint SR, McCreary CE, Rogers S. J Oral Pathol Med 2011; 40: 10–3.

Orofacial granulomatosis associated with hypersensitivity to dental amalgam

Tomka M, Machovcova A, Pelclova D, Petanova J, Arenbergerova M, Prochazkova J. Oral Surg Oral Med Oral Pathol 2011; 112: 335–41.

First-Line Therapies

• Intralesional corticosteroids ± topical immunomodulators	C
• Oral corticosteroids	C

Long-term effectiveness of intralesional triamcinolone acetonide therapy in orofacial granulomatosis: an observational cohort study

Fedele S, Fung PPL, Bamashmous N, Petrie A, Porter S. Brit J Dermatol 2014; 170: 794–801.

This is the first retrospective observational cohort ($n = 22$) study demonstrating the long-term effectiveness of intralesional triamcinolone acetonide 40 mg/mL. Doses of 0.1 mL were injected into four equally distanced sites (left labial corner and next to median line, right corner and next to median line) per lip once a week for 3 weeks (one treatment course). The majority (14/22) of the patients were

treated with one course and did not experience recurrence. There were no adverse effects.

Clinical behavior and long-term therapeutic response in orofacial granulomatosis patients treated with intralesional triamcinolone acetonide injections alone or in combination with topical pimecrolimus 1%

Mignogna MD, Pollio A, Leuci S, Ruoppo E, Fortuna G. J Oral Pathol Med 2013; 42: 763–81.

Triamcinolone acetonide 40 mg/mL diluted to 2:1 with saline (25 mg/mL) weekly was injected every 2 weeks for a maximum of 3 months (six sessions). The majority (11/19) responded. The eight partial responders who were then administered topical pimecrolimus 1% twice daily achieved clinical remission.

Effectiveness of small-volume, intralesional, delayed-release triamcinolone injections in orofacial granulomatosis: a pilot study

Mignogna MD, Fedele S, Lo Russo L, Adamo D, Satriano RA. J Am Acad Dermatol; 2004; 51: 265–8.

In this pilot study, triamcinolone 40 mg/mL, with each injection amounting to 0.1 mL, was used weekly for two to three sessions. The needle was injected between the prolabium and labia mucosa and directed to the oral mucosa to avoid atrophy and hypopigmentation of the labial skin.

With the growing evidence demonstrating the safety and efficacy of high-concentration, low volumes of intralesional steroids, the necessity of nerve blocks for low-concentration, large volumes of intralesional steroids is limited.

Melkersson–Rosenthal syndrome and orofacial granulomatosis

Rogers RS III. Dermatol Clin 1996; 14: 371–9.

Oral prednisone 1 to 1.5 mg/kg daily tapered over 3 to 6 weeks may be effective for more severe and symptomatic episodes of granulomatous cheilitis.

Second-Line Therapies

• Clofazimine	C
• Biologics, including infliximab, adalimumab	C
• Azithromycin/roxithromycin	D
• Minocycline/tetracycline ± oral corticosteroids	E
• Metronidazole ± intralesional corticosteroids	E
• Mycophenolate mofetil ± topical corticosteroids	E

Clofazimine as elective treatment for granulomatous cheilitis

Fernandez-Freire LF, Gotarredona AS, Wittel JB, Ruis AP, Cabrera R, Ortoga MN, et al. J Drugs Dermatol 2005; 4: 374–7.

Three patients with granulomatous cheilitis treated with clofazimine 200 to 300 mg daily for 3 to 6 months obtained regression. Side effects included hyperpigmentation of the skin and elevation of liver enzymes.

Cheilitis granulomatosa Miescher: treatment with clofazimine and review of the literature

Ridder GJ, Fradis M, Löhle E. Ann Otol Rhinol Laryngol 2001; 110: 964–7.

A 15-year-old girl's granulomatous cheilitis was treated with clofazimine 100 mg daily. Regression was noted after 30 days of treatment. Thereafter, 100 mg of clofazimine three times a week was given for 3 months. Her lip eventually returned to normal size. Follow-up for 6 years revealed no recurrence.

This article reviews several case reports and a case series of clofazimine therapy and discusses the great variability in response to therapy.

Melkersson–Rosenthal syndrome: clinical, pathologic, and therapeutic considerations

Sussman GL, Yang WH, Steinberg S. Ann Allergy 1992; 69: 187–94.

Clofazimine 100 mg four times weekly for 3 to 11 months was used to treat 10 patients with granulomatous cheilitis/Melkersson–Rosenthal syndrome. Complete remission occurred in 5, partial

clinical responses occurred in 3, and 2 patients had no clinical response.

Other studies have reported efficacy with a regimen consisting of clofazimine 100 mg daily for 10 days, followed by 200 to 400 mg weekly for 3 to 6 months.

Experience with anti-TNF- α therapy for orofacial granulomatosis

Elliot T, Campbell H, Esudier M, Poate T, Nunes C, Lomer M, et al. *J Oral Pathol Med* 2011; 40: 14–9.

A retrospective review of 14 patients treated with infliximab and adalimumab for orofacial granulomatosis with and without Crohn disease. Short-term remission was achieved with infliximab in 10 of the patients. Of those patients, 8 and 4 of them remained responsive at 1 and 2 years, respectively. Two of the patients who failed infliximab responded to adalimumab.

Treatment of granulomatous cheilitis with infliximab

Barry O, Barry J, Langan S, Murphy M, Fitzgibbon J. *Arch Dermatol* 2005; 141: 1081–3.

A 24-year-old woman with recalcitrant granulomatous cheilitis was treated with infliximab. In order to reduce the risk of infusion reactions, hydrocortisone (200 mg) was administered intravenously before treatment. The patient had restoration of normal lip architecture. Infliximab infusions were continued to maintain remission.

Melkersson–Rosenthal syndrome: a form of pseudoangioedema

Kakimoto C, Sparks C, White AA. *Ann Allergy Asthma Immunol* 2007; 99: 185–9.

A 19-year-old woman with recalcitrant granulomatous cheilitis was treated with infliximab infusions. The patient improved after the second infusion and had complete resolution after the third. Because adverse effects developed, therapy was changed to adalimumab (40 mg subcutaneously weekly), with no evidence of relapse noted.

Successful treatment of granulomatous cheilitis with adalimumab

Ruiz Villaverde R, Sanchez Cano D. *Int J Dermatol* 2012; 51: 118–20.

A 46-year-old woman with recalcitrant granulomatous cheilitis was treated with adalimumab at 80 mg SC for the first week, 40 mg the

second week, and then every 2 weeks. After the third dose, clinical improvement was noticed, and no relapse occurred after completing 6 months of treatment.

Orofacial granulomatosis responding to weekly azithromycin pulse therapy

Yadav S, Dogra S, De D, Saikia UN. JAMA Dermatol 2015; 151: 219–20.

A case series of five patients with idiopathic orofacial granulomatosis on azithromycin 500 mg PO daily for 3 consecutive days weekly demonstrated improvement after 1 month and significant improvement in 3 months.

Granulomatous cheilitis successfully treated with roxithromycin

Inui S, Itami S, Katayama I. J Dermatol 2008; 35: 244–5.

A 37-year-old man with granulomatous cheilitis was treated with 300 mg/day of roxithromycin. Swelling resolved in 6 weeks. Roxithromycin was tapered, and remission was achieved at 1 year of follow-up.

Successful treatment of granulomatous cheilitis with roxithromycin

Ishiguro E, Hatamochi A, Hamasaki Y, Ishikawa S, Yamazaki S. J Dermatol 2008; 35: 598–600.

A 13-year-old male with granulomatous cheilitis treated with roxithromycin 150 mg/day. No relapse was noticed after 6 months of follow-up.

Melkersson–Rosenthal syndrome in childhood: successful management with combination steroid and minocycline therapy

Stein SL, Mancini AJ. J Am Acad Dermatol 1999; 41: 746–8.

Two children with Melkersson–Rosenthal syndrome were treated successfully with minocycline and prednisone.

Tetracyclines would usually be contraindicated until the permanent dentition has erupted.

Minocycline in granulomatous cheilitis: experience with 6 cases

Veller Fornasa C, Catalano P, Peserico A. Dermatology 1992; 185: 220.

Six case reports of patients with granulomatous cheilitis treated with minocycline after failing other oral therapies (steroids,

clofazimine, hydroxychloroquine, and surgery). Only one of the six patients responded to minocycline. The sole responder was later found to have chronic granulomatous disease.

Treatment and follow-up of persistent granulomatous cheilitis with intralesional steroid and metronidazole

Coskun B, Saral Y, Cicek D, Akpolat N. J Dermatol Treat 2004; 15: 333–5.

Cheilitis granulomatosa treated with metronidazole

Miralles J, Barnadas MA, de Moragas JM. Dermatology 1995; 191: 252–3.

A 30-year-old woman with monosymptomatic Melkersson–Rosenthal syndrome was successfully treated with metronidazole 750 to 1000 mg daily for an 8-month tapering course.

Metronidazole has also been useful in two patients with granulomatous cheilitis associated with Crohn disease. Treatment failures are also reported.

Orofacial granulomatosis successfully treated with mycophenolate mofetil

Antonyan AS, Pena-Robichaux V, McHargue CA. J Am Acad Dermatol 2014; 70: 137–9.

A 59-year-old woman with orofacial granulomatosis was successfully treated with mycophenolate mofetil 500 mg twice a day (BID) with significant improvement after 1 month and near-complete remission after 6 months of therapy.

Third-Line Therapies

• Cheiloplasty ± postoperative intralesional corticosteroids	C
• Thalidomide	E
• Hydroxychloroquine	E

Plastic surgical solutions for Melkersson–Rosenthal syndrome: facial liposuction and cheiloplasty procedures

Tan O, Atik B, Calka O. Ann Plast Surg 2006; 56: 268–73.

This article discusses surgical procedures in four patients, including reduction cheiloplasty consisting of mucosa, submucosa, and tangential muscle resection; crescent-shaped commissuroplasty; and facial liposuction. Mean follow-up duration was 13.7 months. No postoperative steroids were given, and there was no evidence of relapse in the follow-up period.

Cheilitis granulomatosa: successful treatment with combined local triamcinolone injections and surgery

Krutchkoff D, James R. Arch Dermatol 1978; 114: 1203–6.

A man with granulomatous cheilitis was treated with triamcinolone injections, followed by upper and lower cheiloplasty. Four months later, repeat cheiloplasty of the upper lip revealed granulomas were more numerous and larger than those observed initially. Postoperative corticosteroid injections maintained remission. The authors recommend postoperative corticosteroid injections to prevent exaggerated recurrences.

Long-term results after surgical reduction cheiloplasty in patients with Melkersson–Rosenthal syndrome and cheilitis granulomatosa

Ellitsgaard N, Andersson AP, Worsaae N, Medgyesi S. Ann Plast Surg 1993; 31: 413–20.

A reduction cheiloplasty was performed on 13 patients. All were satisfied with their results, despite postoperative disease activity in six patients.

Lip reduction cheiloplasty for Miescher's granulomatous macrocheilitis (cheilitis granulomatosa) in childhood

Oliver DW, Scott MJL. Clin Exp Dermatol 2002; 27: 129–31.

Lip reduction cheiloplasty provided successful treatment of granulomatous cheilitis in an 11-year-old boy, suggesting surgery can be safely undertaken in young children.

Treatment of Miescher's cheilitis granulomatosa in Melkersson–Rosenthal syndrome

Camacho F, Garcia-Bravo B, Carrizosa A. J Eur Acad Dermatol Venereol 2001; 15: 546–9.

The authors conclude the best treatment for resistant granulomatous cheilitis is surgery with immediate injection of

triamcinolone, followed by a course of oral tetracycline.

Successful treatment of granulomatous cheilitis with thalidomide

Thomas P, Walchner M, Ghoreschi K, Rocken M. Arch Dermatol 2003; 139: 136–8.

A 39-year-old woman was treated with thalidomide 100 mg daily for 6 months. Lip swelling almost completely resolved. Thalidomide was reduced to 100 mg every other day for 2 months and then stopped. One year later, the patient's condition was stable with no signs of relapse.

Baseline and follow-up neurologic assessments need to be done with thalidomide.

Thalidomide in treatment of refractory orofacial granulomatosis

Eustace K, Clowry J, Kirby B, Lally A. Br J Dermatol 2014; 171: 423–5.

Cheilitis granulomatosa: report of six cases and review of the literature

Allen CM, Camisa C, Hamzeh S, Stephens L. J Am Acad Dermatol 1990; 23: 444–50.

Hydroxychloroquine 200 to 400 mg daily has been reported to be efficacious in granulomatous cheilitis. Chloroquine therapy has not been successful in Melkersson–Rosenthal syndrome.

Hailey–Hailey disease

Anthony J. Chiaravalloti, and Michael Payette

Hailey-Hailey affecting the axilla, pre and post treatment with CO₂ laser.

Hailey–Hailey disease (benign familial pemphigus) is a rare genodermatosis first described by two medical brothers in 1939. It is characterized by recurrent flares of vesicles, painful erosions, and

weeping plaques, particularly involving the flexural areas. Symptoms usually begin in the second to fourth decades. The disease is generally localized, although widespread and severe involvement can occur. The most commonly affected sites are intertriginous areas like the axillae, groin, neck, and inframammary folds. The disease can exhibit an isomorphic response and affect areas of trauma or sites of inflammation from other diseases.

Hailey–Hailey disease is a dominantly inherited condition with variable expressivity. The defective gene, ATPase secretory pathway Ca^{2+} transporting 1 (ATP2C1), encodes the protein Secretory-pathway Ca^{2+} -ATPases (SCPA1), which is an ATP-dependent calcium and manganese channel pump on the Golgi membrane in which downstream manifestations disrupt desmosome function between keratinocytes. The clinical and histopathologic picture can be similar to Darier disease and Grover disease (see relevant chapters).

Management Strategy

The management of Hailey–Hailey disease is accomplished through a combination of lifestyle modifications and medical and/or surgical therapy. Because the lesions of Hailey–Hailey disease are frequently precipitated by friction and aggravated by heat and moisture, lifestyle changes to minimize these can help reduce the frequency and severity of disease.

Polymicrobial infections with bacteria, yeasts, and viruses also appear to be exacerbating factors, and secondary infection with these organisms can significantly worsen the disease and cause a pungent odor. Thus simple antiinfective agents, topical or systemic, reduce the severity of exacerbations and remain the mainstay of treatment. Topical *clindamycin*, *fusidic acid*, and *imidazoles* have all been recommended. *Tetracyclines* and *semisynthetic penicillins* are the best systemic agents. If secondary infection with herpes simplex is suspected, *appropriate oral antiviral therapy* should be instituted.

Combining antiinfective therapy with *topical corticosteroids* seems to be particularly helpful, but corticosteroids alone may reduce the severity of lesions. Generally, moderate to potent agents are required, though some patients gain benefit from milder preparations. Caution should be exercised with long-term use because intertriginous skin is particularly prone to atrophy. Topical calcineurin inhibitors, like *tacrolimus* and *pimecrolimus*, may be effective as monotherapy or in

combination with topical corticosteroids, although some authors dispute this. Some success has also been recorded with *calcitriol*. If there is not an expected response to topical therapy, clinicians should consider patch testing, as these patients commonly develop allergic contact dermatitis.

Patients with major exacerbations may benefit from a short course of systemic corticosteroids; however, there may be a rebound of the disease on withdrawal. Systemic alternatives that have been tried include *dapsone*, *ciclosporin*, *methotrexate*, and *retinoids*, but there is little evidence for their effectiveness beyond anecdotal case reports. *Electron beam therapy* has been reported for recalcitrant disease. There are few reports of treatment with biologic agents with limited benefit.

Surgical modalities like *cryotherapy*, *excision with grafting*, *dermabrasion*, and *CO₂ and other lasers* may also be beneficial in some patients, specifically for localized disease. Injections of *botulinum toxin* appear to be efficacious in reducing the sweating in axillary Hailey–Hailey disease.

Specific Investigations

- Biopsy
- Microbiologic cultures for bacteria, yeast, and herpesvirus
- Consider patch testing to topical preparations

First-Line Therapies

• Topical antimicrobials and systemic antibiotics	C
• Topical corticosteroids	C

Hailey–Hailey disease: the clinical features, response to treatment and prognosis

Burge SM. Br J Dermatol 1992; 126: 275–82.

In this series 86% of patients found combinations of topical corticosteroids and antimicrobial agents helpful at the first sign of a flare.

Familial benign chronic pemphigus and doxycycline: a review of 6 cases

Le Saché-de Peufeilhoux L, Raynaud E, Bouchardeau A, Fraitag S, Bodemer C. J Eur Acad Dermatol Venereol 2014; 28: 370–3.

This is a review of six patients who received oral doxycycline 50 to 100 mg/day. Two patients had complete remission, and two patients had significant improvement with mild flares during 4 years of follow-up.

The first article remains a key review of clinical and therapeutic aspects of this disease. We recommend patients failing topical therapies be started on doxycycline as first-line systemic therapy.

Second-Line Therapies

• Topical calcineurin inhibitors	E
• Calcitriol	E
• Systemic corticosteroids	E
• Dapsone	E
• Ciclosporin	E
• Botulinum toxin	E
• Carbon dioxide laser	E

Topical tacrolimus ointment is an effective therapy for Hailey–Hailey disease

Sand C, Thomsen HK. Arch Dermatol 2003; 139: 1401–2.

A 67-year-old man was cleared with once-daily tacrolimus 0.1% within 1 month and was maintained with as-needed use.

Familial benign chronic pemphigus (Hailey–Hailey disease): use of topical immunomodulators as a modern treatment option

Tchernev G, Cardoso JC. Rev Med Chil 2011; 139: 633–7.

This is a report of a 51-year-old male responding well to pimecrolimus 1% cream twice daily.

Treatment of Hailey–Hailey disease with topical calcitriol

Bianchi L, Chimenti M, Giunta A. J Am Acad Dermatol 2004; 51: 475–6.

This report showed complete clearance of lesions for 3 months after completing 1 month of twice-daily calcitriol 3 mcg/g ointment.

Generalized Hailey–Hailey disease

Marsch WC, Stüttgen G. Br J Dermatol 1978; 99: 553.

The use of systemic corticosteroids was successful in controlling extensive disease, but cessation of therapy resulted in significant rebound.

Benign familial chronic pemphigus treated with dapsone

Sire DJ, Johnson BL. Arch Dermatol 1971; 103: 262.

Three 21- to 64-year-old patients were cleared with 100 to 200 mg of dapsone daily and one was maintained on 50 mg every other day.

Benign familial pemphigus (Hailey-Hailey disease) responsive to low dose ciclosporin

Nanda A, Khawaja F, Harbi R, Nanda M, Dvorak R, Alsaleh QA. Indian J Dermatol Venereol Leprol 2010; 76: 422–4.

The reported patient was treated with 2.5 mg/kg/day and achieved a lasting remission with topical tacrolimus for maintenance.

Remission of refractory benign familial chronic pemphigus (Hailey-Hailey disease) with the addition of systemic ciclosporin

Varada S, Ramirez-FORT MK, Argobi Y, Simkin AD. J Cutan Med Surg 2015; 19: 163–6.

This patient had improvement on 2.8 mg/kg/day but nearly cleared on 3.8 mg/kg/day and had significant improvement in pain and pruritus.

Botulinum toxin type A as an adjuvant treatment modality for extensive Hailey–Hailey disease

Koeyers WJ, Van Der Geer S, Krekels G. J Dermatolog Treat 2008; 19: 251–4.

Diminution of the hyperhidrosis that exacerbates Hailey–Hailey disease may also be accomplished by utilizing oral glycopyrrolate.

Carbon dioxide laser treatment for Hailey-Hailey disease: a retrospective chart review with patient-reported outcomes

Hochwalt PC, Christensen KN, Cantwell SR, Hocker TL, Otley CC, Brewer JD. Int J Dermatol 2015; 54: 1309–14.

Thirteen patients with refractory disease were treated with CO₂ laser, and all patients had no recurrence in the treated areas. Seventy percent had new disease outside of treated sites that responded to additional treatments.

Tacrolimus, pimecrolimus, and calcitriol are at least safe and a good option for steroid-sparing maintenance therapy. Dapsone is generally safe and may work in certain patients. Ciclosporin can be used safely if doses do not exceed 5 mg/kg and patients are properly monitored. There are now a number of reports suggesting that botulinum toxin and CO₂ laser may be less invasive and efficacious options for refractory local disease.

Third-Line Therapies

• Surgical excision (with healing by secondary intention or by grafting)	E
• Dermabrasion	E
• Laser therapy (excluding CO ₂ laser – see earlier)	E
• Superficial irradiation (Grenz rays or electron beam)	E
• Methotrexate	E
• Oral retinoids	E
• Topical 5-fluorouracil	E
• Biologics	E
• Photodynamic therapy	E
• Narrowband ultraviolet B therapy	E

Surgical treatment of familial benign chronic pemphigus

Crotty CP, Scheen SR, Masson JK, Winkelmann RK. Arch Dermatol

1981; 117: 540–2.

This is a report of five patients who had excision followed by split-thickness skin grafting. Three patients had no recurrence in treated areas, and one patient had mild recurrence after 8 years.

Refractory Hailey–Hailey disease successfully treated with sandpaper dermabrasion

LeBlanc KG Jr, Wharton JB, Sheehan DJ. *Skinmed* 2011; 9: 263–4.

A 53-year-old female had a lasting improvement on the neck and popliteal fossae after fine sandpaper dermabrasion down to the superficial dermis; however, she did have recurrence in the axillae.

Successful treatment of refractory Hailey-Hailey disease with a 595-nm pulsed dye laser: a series of 7 cases

Hunt KM, Jensen JD, Walsh SB, Helms ME, Soong VY, Jacobson ES. *J Am Acad Dermatol* 2015; 72: 735–7.

This report showed varying amounts of improvement of clinical lesions in six of seven patients treated with 595-nm pulsed-dye laser.

Effective treatment of Hailey-Hailey disease with a long-pulsed (5 ms) alexandrite laser

Awadalla F, Rosenbach A. *J Cosmet Laser Ther* 2011; 13: 191–2.

A 35-year-old male had complete clearance after 13 treatments with long pulsed alexandrite laser for 1 year with occasional short courses of topical hydrocortisone. The fluences ranged from 12 to 20 J/cm² with 10- to 15-mm spot sizes.

Persistent improvement of previously recalcitrant Hailey–Hailey disease with electron beam therapy

Narbutt J, Chrusciel A, Rychter A, Fijuth J, Lesiak A, Sysa-Jedrzejowska A. *Acta Derm Venereol* 2010; 90: 179–82.

Three patients had improvement of lesions after 20 Gy in 10 fractions to 90% isodose to each axilla without recurrence in 38 months of follow-up.

Methotrexate for refractory Hailey–Hailey disease

Vilarinho C, Ventura F, Brito C. *J Eur Acad Dermatol Venereol* 2010; 24: 106.

A 42-year-old woman showed near clearance after 3 months of oral methotrexate 15 mg weekly and had no recurrence in 2 years of

follow-up.

Vesiculobullous Hailey–Hailey disease: successful treatment with oral retinoids

Hunt MJ, Salisbury EL, Painter DM, Lee S. *Australas J Dermatol* 1996; 37: 196–8.

A 56-year-old male had significant improvement after 6 weeks of 25 mg of daily etretinate. The patient was recurrence free 2 months after completing a 6-month course.

Successful treatment of Hailey–Hailey disease with acitretin

Berger EM, Galadari HI, Gottlieb AB. *J Drugs Dermatol* 2007; 6: 734–6.

A 64-year-old male had significant improvement after 6 months of 25 mg of daily acitretin.

Successful treatment of Hailey–Hailey disease with topical 5-fluorouracil

Dammak A, Camus M, Anyfantakis V, Guillet G. *Br J Dermatol* 2009; 161: 967–8.

A 43-year-old male was treated with 5-fluorouracil 5% cream three times weekly for 3 months, followed by weekly applications for 3 months, and showed near clearance for 6 months after completion of therapy.

Case reports of etanercept in inflammatory dermatoses

Norman R, Greenberg RG, Jackson JM. *J Am Acad Dermatol* 2006; 54 (Suppl 2): S139–42.

A 47-year-old woman was treated with subcutaneous etanercept 25 mg weekly for 1 month, then increased to 50 mg for 6 months, and then to 75 mg weekly to improve response. She showed dramatic improvement in 10 months and continued to improve.

Experience with photodynamic therapy in Hailey–Hailey disease

Fernandez Guarino M, Ryan AM, Perez-Garcia B, Arrazola JM, Jaen P. *J Dermatol Treat* 2008; 19: 288.

Three patients were treated with methyl aminolevulinic acid for 3 hours and then exposed to 7.5 min of 630 nm red light. The patients had a lot of pain and did not have significant improvement.

Successful therapeutic use of targeted narrow-band ultraviolet B

therapy for refractory Hailey-Hailey disease

Hamada T, Umemura H, Aoyama Y, Iwatsuki K. Acta Derm Venereol 2013; 93: 110–1.

This report showed efficacy of narrow band ultraviolet B (NbUVB) therapy conflicting with previous reports of exacerbation with ultraviolet (UV) light.

Surgery can be definitive and should be considered for refractory localized disease. Many authors report some recurrences, either around the edges of the treated areas or on further friction or trauma. Treatment is invasive, and the trauma of dressings may exacerbate the disease, so proper patient selection is important. The rest of the modalities in this section have few reports demonstrating their efficacy. They should be reserved for very recalcitrant disease in appropriate patients.

Hand and foot eczema (endogenous, dyshidrotic eczema, pompholyx)

Ivan D. Camacho, and Anne E. Burdick

Endogenous hand and foot dermatitis occurs in two fairly distinct clinical patterns: pompholyx and hyperkeratotic dermatitis. There is considerable overlap, and both may occur in the same individual.

Pompholyx is usually episodic. Acute episodes of intense itching or burning are followed after a few hours by an eruption of vesicles, which expand and may coalesce to form large bullae. The sites most affected are the palms, soles, and the sides of hands, fingers, and toes. As the bullae rupture the dermatitis becomes highly exudative and very sore. The eruption tends to dry out after 2 weeks leading to painful fissuring of the skin in the subacute and chronic phase. The clinical course is highly variable, but in some cases recurrent attacks occur at 3- to 4-weekly intervals for months or years.

The hyperkeratotic pattern presents with pruritic, erythematous, scaly, fissured, hyperkeratotic patches on the palms and palmar surfaces of fingers and on the soles. The hyperkeratosis is variable but can cause distressing pain associated with deep fissures when pronounced.

Secondary infection of hand and foot dermatitis is common and may result in pustulation or lymphangitis.

Hand and foot dermatitis often occurs as a manifestation of atopy.

Management Strategy

Diagnosis of endogenous eczema requires exclusion of exogenous (irritant or allergic) dermatitis, hyperhidrosis, dermatophytosis, and other inflammatory skin diseases, notably psoriasis, which may be clinically indistinguishable. Although the pathogenesis is not completely understood, it is thought that overexpression of aquaporin 3 and aquaporin 10 proteins in the mid and upper epidermis with concomitant water exposure lead to skin dehydration and increased transepidermal water loss. Dyshidrotic eczema has also been reported to be induced by intravenous immunoglobulin (IVIG) therapy and during the immune reconstitution inflammatory syndrome.

Although endogenous eczema may resolve spontaneously, treatment is usually required to control pruritus, formation of vesicular lesions, and painful cracking and fissuring.

Topical corticosteroids are the mainstay of treatment. For mild localized disease, *mid- to-high-potency corticosteroid* creams or ointments are recommended. *Oral antihistamines* are useful for control of symptoms or as mild sedatives. *Emollients* are beneficial. The

chronic, hyperkeratotic forms are dry, requiring occlusive emollients and keratolytic agents. A course of *oral antibiotics* (*cephalosporins* or *doxycycline*) is recommended for secondary impetiginization.

Topical tacrolimus or *pimecrolimus* is useful, alone or in combination with a corticosteroid, which may be delivered under occlusion for increased penetration. For severe disease, *systemic corticosteroids* are indicated: daily *prednisone* 0.5 to 1.0 mg/kg/day tapered over 2 weeks, or intramuscular *triamcinolone acetonide* (40–60 mg). Hand and foot narrowband phototherapy and UVA, alone or with *oral* or *topical psoralen*, are also effective. Paradoxically, sunlight has been reported to induce pompholyx, with positive provocation on phototesting.

Refractory hand and foot eczema may respond to systemic retinoids such as *alitretinoin*; immunosuppressive agents including *azathioprine*, *methotrexate*, *ciclosporin*, *mycophenolate mofetil*, or *etanercept*; and *radiotherapy*.

Intradermal botulinum toxin A and *oxybutynin* may be helpful as adjuvant therapy in dyshidrotic cases. *Low-nickel and low-cobalt diets* are recommended in nickel-sensitive patients who demonstrate a positive provocation test.

Specific Investigations

- Potassium hydroxide preparation
- Bacterial culture
- Patch testing

Pompholyx eczema as a manifestation of HIV infection, response to antiretroviral therapy

MacConnachie AA, Smith CC. *Acta Derm Venereol* 2007; 87: 378–9.

Pompholyx may present as both a manifestation of symptomatic HIV infection and as part of the immune reconstitution inflammatory syndrome. Conventional treatment for pompholyx may fail, but improvement may be observed with highly active antiretroviral therapy.

Pompholyx and eczematous reactions associated with intravenous immunoglobulin therapy

Gerstenblith MR, Antony AK, Junkins-Hopkins JM, Abuav R. *J Am Acad Dermatol* 2012; 66: 312–6.

A 3-year causative study of pompholyx in 120 patients

Guillet MH, Wierzbicka E, Guillet S, Dagregorio G, Guillet G. Arch Dermatol 2007; 143: 1504–8.

A prospective survey reported allergic contact pompholyx in 67.5% of cases (31.7% to cosmetic and hygiene products and 16.7% to metals), 15% idiopathic, 10% secondary to dermatophytes, and 6.7% due to ingestion of drugs, food, or nickel.

Role of contact allergens in pompholyx

Jain V, Passi S, Gupta S. J Dermatol 2004; 31: 188–93.

Patch testing with the Indian Standard Patch Test Battery was performed on 50 subjects, and 40% reacted to one or more allergens. Nickel sulfate was the most common allergen, followed by potassium dichromate, phenylenediamine, nitrofurazone, fragrance mix, and cobalt.

Low-cobalt diet for dyshidrotic eczema patients

Stuckert J, Nedorost S. Contact Derm 2008; 59: 361–5.

Restriction of dietary cobalt and nickel reduces flares of dyshidrotic eczema, regardless of patch test results.

Photoaggravated pompholyx

Nalluri R, Rhodes LE. Photodermatol Photoimmunol Photomed 2016; 32: 168–70.

Photoaggravated pompholyx must be considered if pompholyx worsens in summer.

First-Line Therapies

• Topical corticosteroids	A
• Topical calcineurin inhibitors	C
• Oral antibiotics	D
• Oral antihistamines	D
• Oral corticosteroids	D
• Emollients	D
• Keratolytics	D

Pompholyx: a review of clinical features, differential diagnosis, and management

Wollina U. Am J Clin Dermatol 2010; 11: 305–14.

Acute and recurrent vesicular hand dermatitis

Veien NK. Dermatol Clin 2009; 27: 337–53.

Comprehensive review on chronic hand dermatitis.

Topical tacrolimus (FK 506) and mometasone furoate in treatment of dyshidrotic palmar eczema: a randomized, observer-blinded trial

Schnopp C, Remling R, Mohrenschlager M, Weigl L, Ring J, Abeck D. J Am Acad Dermatol 2002; 46: 73–7.

Topical tacrolimus 0.1% ointment was as effective as 0.1% mometasone furoate ointment after 4 weeks of twice-daily application, reducing the Dyshidrotic Area and Severity Index (DASI) to approximately 50% in 16 patients.

Efficacy and safety of pimecrolimus cream 1% in mild-to-moderate chronic hand dermatitis: a randomized, double-blind trial

Hordinsky M, Fleischer A, Rivers JK, Poulin Y, Belsito D, Hultsch T. *Dermatology* 2010; 221: 71–7.

Pimecrolimus 1% cream twice daily with overnight occlusion for 6 weeks improved pruritus and skin lesions in up to 30% of 652 treated patients.

Second-Line Therapies

• Alitretinoin (9- <i>cis</i> -retinoic acid)	A
• UVA, PUVA, and narrowband UVB	B
• Intradermal botulinum A toxin	C
• Oxybutynin	C

Oral alitretinoin in chronic refractory hand eczema: a “real life” case-series of 12 patients

Kubica E, Ezzedine K, Lalanne N, Dartial Y, Taieb A, Milpied B. *Eur J Dermatol* 2011; 21: 454–6.

Twelve patients were treated with alitretinoin 30 mg daily for 3 to 6 months. Seven out of 10 patients responded within 1 to 3 months. Three stayed in remission for 6 months, and four relapsed within 10 days to 3 months after stopping the medication.

Successful retreatment with alitretinoin in patients with relapsed chronic hand eczema

Bissonnette R, Worm M, Gerlach B, Guenther L, Cambazard F, Ruzicka T, et al. *Br J Dermatol* 2010; 162: 420–6.

Alitretinoin 30 mg daily for 12 to 24 weeks showed 80% efficacy in 117 patients who were responders but relapsed within 24 weeks after a previous 24-week course of alitretinoin 30 mg daily.

Efficacy and safety of oral alitretinoin (9-*cis* retinoic acid) in patients with severe chronic hand eczema refractory to topical corticosteroids: results of a randomized, double-blind, placebo-

controlled, multicentre trial

Ruzicka T, Lynde CW, Jemec GB, Diepgen T, Berth-Jones J, Coenraads PJ, et al. Br J Dermatol 2008; 158: 808–17.

Alitretinoin 30 mg daily monotherapy for 12 to 24 weeks improved symptoms and skin lesions in 48% of 409 patients with chronic hand eczema, regardless of clinical presentation.

Acitretin may also be of value in selected cases.

Local narrowband UVB phototherapy vs. local PUVA in the treatment of chronic hand eczema

Sezer E, Etikan I. Photodermatol Photoimmunol Photomed 2007; 23: 10–4.

Compared with PUVA, narrowband UVB was as effective in 12 patients treated three times a week, over a 9-week period. The initial dose of 150 mJ/cm² was increased by 20% until a final dose of 2000 mJ/cm² was reached.

Comparison of localized high-dose UVA1 irradiation versus topical cream psoralen–UVA for treatment of chronic vesicular dyshidrotic eczema

Petering H, Breuer C, Herbst R, Kapp A, Werfel T. J Am Acad Dermatol 2004; 50: 68–72.

Twenty-four of 27 patients treated with UVA1 irradiation to one hand and cream psoralen–UVA (PUVA) to the other showed a similar 50% improvement after a 3-week period of UV irradiation. One patient relapsed within the 3-week follow-up period.

Oral vs. bath PUVA using 8-methoxypsoralen for chronic palmoplantar eczema

Tzaneva S, Kittler H, Thallinger C, Hönigsmann H, Tanew A. Photodermatol Photoimmunol Photomed 2009; 25: 101–5.

Oral PUVA was as effective as bath PUVA in 29 patients with dyshidrotic eczema, who received treatment three times weekly for up to 20 weeks and were followed up for up to 40 months.

Regression of relapsing dyshidrotic eczema after treatment of concomitant hyperhidrosis with botulinum toxin-A

Kontochristopoulos G, Gregoriou S, Agiasofitou E, Nikolakis G, Rigopoulos D, Katsambas A. Dermatol Surg 2007; 33: 1289–90.

Two patients treated with 100 units of botulinum toxin A to each

hand showed significant improvement of their dyshidrosis 1 week later, with no relapse after 8 weeks.

Pompholyx: what's new?

Wollina U. Expert Opin Investig Drugs 2008; 17: 897–904.

Hyperhidrosis is an aggravating factor in approximately 40% of pompholyx patients. Botulinum toxin A, 100 units administered intradermally to each hand, resulted in improvement of pruritus, lesions, and the starch iodine test for hyperhidrosis. The major disadvantages are the cost and the need for recurrent injections.

Remarkable improvement of relapsing dyshidrotic eczema after treatment of coexistent hyperhidrosis with oxybutynin

Markantoni V, Kouris A, Armyra K, Vavouli C, Kontochristopoulos G. Dermatol Ther 2014; 27: 365–8.

Improvement was reported with oxybutynin 5 mg twice a day for the first month and once a day for the second month. Patients experienced dry mouth, constipation, headache, and mild urine retention.

Third-Line Therapies

• Ciclosporin	B
• Methotrexate	D
• Azathioprine	C
• Mycophenolate mofetil	D
• Etanercept	D
• Radiotherapy	D

Long-term follow-up of eczema patients treated with cyclosporine

Granlund H, Erkkö P, Reitamo S. *Acta Derm Venereol* 1998; 78: 40–3.

Twenty-seven patients with chronic hand eczema treated with ciclosporin 3 mg/kg/day for 6 weeks had reduced disease activity of 54% and sustained improvement for 1 year, without topical treatment.

Low-dose oral methotrexate treatment for recalcitrant palmoplantar pompholyx

Egan CA, Rallis TM, Meadows KP, Krueger GG. *J Am Acad Dermatol* 1999; 40: 612–4.

In five patients with severe pompholyx 12.5 to 22.5 mg of methotrexate weekly resulted in a reduced dose or discontinuation of prednisone. Superpotent corticosteroids were continued topically.

Azathioprine in dermatological practice. An overview with special emphasis of its use in non-bullous inflammatory dermatoses

Scerri L. *Adv Exp Med Biol* 1999; 455: 343–8.

Six patients with severe dyshidrotic eczema received azathioprine monotherapy 100 to 150 mg daily with a mean duration of treatment of 34 months; three had excellent, one had good, and two had fair responses.

Dyshidrotic eczema treated with mycophenolate mofetil

Pickenacker A, Luger TA, Schwarz T. *Arch Dermatol* 1998; 134: 378–9.

One patient with recurrent dyshidrotic eczema refractory to topical and systemic corticosteroids and UVA1 had complete resolution after 4 weeks of mycophenolate mofetil at a dose of 1.5 g twice daily and 12 months of 1 g daily.

Recalcitrant hand pompholyx: variable response to etanercept

Ogden S, Clayton TH, Goodfield MJ. *Clin Exp Dermatol* 2006; 31: 145–6.

One patient responded significantly to etanercept 25 mg twice weekly for 6 weeks. The remission lasted 4 months. A subsequent flare was unresponsive to etanercept 50 mg twice weekly.

Long-term results of radiotherapy in patients with chronic palmo-plantar eczema or psoriasis

Sumila M, Notter M, Itin P, Bodis S, Gruber G. Strahlenther Onkol 2008; 184: 218–23.

Twenty-eight patients irradiated with a single dose of either 1 Gy or 0.5 Gy twice weekly, up to a total dose of 4 to 5 Gy, demonstrated significant improvement that was maintained during the 20-month follow-up period.

Hemangiomas

Daniel A. Grabell, Adam V. Nguyen, and Adelaide A. Hebert

Hemangiomas are a neoplastic proliferation of endothelial cells that are generally benign but have been associated with local tissue damage, functional impact, and ulceration. The true incidence of the disease is unknown but is reported as 5% in Caucasian infants. Hemangiomas occur more frequently in Caucasian female infants with a predilection for premature infants, especially of low birth

weight or multiple gestations. Most hemangiomas arise spontaneously during infancy, but an autosomal-dominant pattern of inheritance has rarely been reported as well.

Management Strategy

Cutaneous hemangiomas appear in the first few weeks of life and reach 80% of size by 3 months, with spontaneous involution in most cases by age 10. Early evaluation and treatment, if necessary, are critical to limit the patient's functional impairment and disfigurement. About half of the children with hemangiomas will have normal skin after involution, but the rest may have residual changes, including telangiectasias, atrophy, fibrofatty residuum, and scarring.

Differentiating benign common hemangiomas from other vascular anomalies is essential, as the pathophysiology, treatment modalities, and prognoses are significantly different. Vascular malformations and tumors, such as the kaposiform hemangioendothelioma (KE) and tufted angioma (TA), differ from hemangioma in both clinical and histologic appearance as well as growth rate and involutional tendencies. In particular, KE and TA are associated with the Kasabach–Merritt syndrome and its accompanying coagulopathy, whereas common hemangiomas are not. The majority of common hemangiomas occur as solitary lesions but can be a sign of multisystem involvement such as diffuse neonatal hemangiomatosis, LUMBAR syndrome (lower body congenital infantile hemangiomas and other skin defects, urogenital anomalies and ulceration, myelopathy, bony deformities, anorectal malformations and arterial anomalies, and rectal anomalies), and PHACES syndrome (posterior fossa malformation, hemangiomas, cardiac anomalies, eye abnormalities, and sternal cleft/supraumbilical raphe).

Although the natural course of hemangiomas is self-limited and is often treated with active nonintervention, pharmaceutical intervention is indicated for hemangiomas that ulcerate, grow rapidly, compress, obstruct, or distort vital structures, such as the larynx, eyes, ears, and nose. In addition, hemangiomas associated with systemic involvement and large disfiguring facial hemangiomas should be treated. Medical management is generally centered on the administration of topical and systemic beta-blockers or corticosteroids. Surgical excision is a less frequently used management option.

Topical and systemic beta-blockers have become the preferred first-line therapy in hemangiomas that warrant treatment. The first case report of a hemangioma being successfully treated with propranolol was published in 2008. Oral propranolol hydrochloride solution was approved by the FDA for use in infants with an escalating starting dose of 1.2 mg/kg/day to a target dose of 3.4 mg/kg/day divided into two daily doses. Adverse events include the masking of hypoglycemia, hypotension, and bradycardia, which can be minimized by administering the medication after feeding and monitoring the heart rate and blood pressure after dose increases. Timolol, available as a solution or a gel, has been shown in small randomized clinical trials to be safe and effective for superficial infantile hemangiomas with twice-daily topical application.

Systemic corticosteroids may be used in patients who have contraindications to or do not respond to beta-blockers. Steroids are usually indicated during the growth phase. Prednisone or prednisolone can be given at doses from 2 to 4 mg/kg daily for 2 to 6 months and then gradually tapered over several months. Stopping treatment before adequate therapeutic response may result in rebound growth. Approximately one third of the patients will show an accelerated rate of involution, but another one third may have no response to this treatment modality. Reported risks include hypothalamopituitary–adrenal axis suppression, growth delays, pseudotumor cerebri, infections, and avascular bone necrosis. Surgical excision, either alone or in combination with corticosteroids, may also be employed in certain cases.

For the exceptional recalcitrant hemangioma, other treatments include cyclophosphamide, vincristine, bleomycin, and embolization.

Specific Investigations

- Ultrasound with Doppler
- Magnetic resonance imaging (MRI)
- Biopsy with immunohistochemistry

The diagnosis of a hemangioma is usually made clinically, and the previous investigations may only be needed in atypical cases to confirm the diagnosis, monitor the progress of treatment, establish the extent of the vascular lesion, or screen for other complications.

Soft-tissue vascular anomalies: utility of US for diagnosis

Paltiel HJ, Burrows PE, Kozakewich HPW, Zurakowski D, Mulliken JB. Radiology 2000; 214: 747–54.

Doppler ultrasonography is a low-cost, noninvasive method to confirm the diagnosis of a vascular anomaly, monitor therapeutic response, or preclude the involvement of visceral organs.

Hemangiomas can be differentiated from vascular malformations on ultrasonography by distinguishing features such as the presence of a solid tissue mass.

Although not specifically mentioned in this article, infants less than 3 months of age with a midline back or perineal hemangioma should be imaged with ultrasound of the spine to rule out LUMBAR syndrome and a tethered cord. A referral to a pediatric neurosurgeon and possible MRI may be needed as follow-up.

Hemangioma from head to toe: MR imaging with pathologic correlation

Vilanova JC, Barcelo J, Smirniotopoulos JG, Pérez-Andrés R, Villalón M, Miró J, et al. Radiographics 2004; 24: 367–85.

MRI is a useful noninvasive imaging technique to diagnose, characterize, and determine the extent of vascular lesions. On T₂-weighted images, hemangiomas have the characteristic appearance of multiple lobules, similar to a bunch of grapes.

Although not specifically mentioned in this article, infants with large, segmental, plaque-like facial hemangiomas should have an MRI of the head for possible posterior fossa brain abnormalities as a component of PHACES syndrome.

GLUT 1: a newly discovered immunohistochemical marker for juvenile hemangiomas

North PE, Waner M, Mizeracki A, Mihm MC Jr. Hum Pathol 2001; 31: 11–22.

Immunohistochemical staining can serve as a useful adjunct to distinguish between infantile hemangiomas and other common vascular malformations or vascular neoplasms that present during infancy. GLUT-1 (glucose transporter 1) stain is shown to be highly specific and uniformly positive in the endothelial vasculature of infantile hemangiomas.

Staining for placenta-associated vascular antigens Fc gamma RII, Lewis Y

antigen (LeY), and merosin in infantile hemangiomas has shown a high specificity and holds promise for the development of an infantile hemangioma-specific immunohistochemical panel.

First-Line Therapies

• Systemic beta-blockers	A
• Topical beta-blockers	B
• Topical corticosteroids	D
• Intralesional corticosteroids	B
• Systemic corticosteroids	B

Oral propranolol is the mainstay of therapy for life-threatening or endangering hemangiomas with active nonintervention or topical timolol reserved for relatively uncomplicated cases.

A randomized, controlled trial of oral propranolol in infantile hemangioma

Leaute-Labreze C, Hoeger P, Mazereeuw-Hautier J, Guibaud L, Baselga E, Posiunas G, et al. N Engl J Med 2015; 372: 735–46.

A randomized, double-blind, multicenter, two-stage adaptive trial of 460 infants to assess the efficacy of oral propranolol in treating infantile hemangiomas. In the first stage, the infants were randomized to receive either a placebo or one of four propranolol regimens of either 1 mg/kg/day or 3 mg/kg/day of propranolol for a duration of 3 or 6 months. After an interim analysis, new infants were treated with either a placebo or 3 mg/kg/day of propranolol for 6 months. Sixty percent of all infants receiving this regimen had complete or nearly complete resolution of the target hemangioma. Common adverse events include diarrhea, sleep disorder, and bronchitis.

Initiation and use of propranolol for infantile hemangioma: report of a consensus conference

Drolet BA, Frommelt PC, Chamlin SL, Haggstrom A, Bauman NM, Chiu YE, et al. *Pediatrics* 2013; 131: 128–40.

A multidisciplinary consensus conference reviewed the existing research on the use of oral propranolol for the treatment of infantile hemangiomas, with a primary goal of formulating a standardized set of guidelines that dermatologists could follow. Data compiled from 85 articles, including 1175 total patients, were reviewed. Based on the evidence, a starting dose of 1 mg/kg/day divided three times daily with a titration to a target dose of 2 mg/kg/day was recommended. Escalations should occur every 3 to 7 days as tolerated.

Propranolol treatment of infantile hemangiomas does not negatively affect psychomotor development

Movakine AV, Hermans DJ, Fuiikschot J, van der Vleuten CJ. *J Am Acad Dermatol* 2015; 73: 341–2.

A total of 103 patients previously started on oral propranolol between September 2008 and May 2013 were retrospectively assessed for possible psychomotor developmental delay caused by the medication. Data were collected from the Dutch Well Child Preventive Health Care Clinics and interpreted using the Van Wiechen scheme. Overall study results detected no evidence of psychomotor developmental delay in infants treated with propranolol for infantile hemangiomas.

Topical timolol maleate treatment of infantile hemangiomas

Puttgen K, Lucky A, Adams D, Pope E, McCuaig C, Powell J, et al. *Pediatrics* 2016; 138.

This multicenter retrospective cohort study of 731 patients evaluated the efficacy of topical timolol by scoring digital photographs of the infantile hemangioma utilizing a visual analog scale for color, size, extent, and volume. At 6 to 9 months of treatment 92.3% of patients had improved color and 76.6% had improvement in size, extent, and volume. The best response to therapy occurred in superficial hemangiomas <1 mm thick.

Timolol maleate 0.5% or 0.1% gel-forming solution for infantile hemangiomas: a retrospective, multicenter, cohort study

Chakkittakandiyil A, Phillips R, Frieden IJ, Siegfried E, Lara-Corrales

I, Lam J, et al. *Pediatr Dermatol* 2011; 29: 28–31.

This retrospective cohort study reviewed 73 patients with infantile hemangioma. The mean age at initiation of therapy was 8 months, with 85% of patients dosed at 0.5% strength and the remainder being treated with 0.1%. All patients were treated twice daily and without occlusion. Mean treatment period was 3.4 months, and photos were evaluated by investigators to correspond to a 0 to 100 visual analog scale. Mean visual analog scale improvement was 45 units at the last visit. Longer treatment period was associated with greater improvement. The incidence of adverse events was extremely low—only one patient. No skin-related adverse events were noted in any subjects. No rebound growth was observed after discontinuation at 3 to 6 months.

Ultrapotent topical corticosteroid treatment of hemangiomas of infancy

Garzon MC, Lucky AW, Hawrot A, Frieden IJ. *J Am Acad Dermatol* 2005; 52: 281–6.

A retrospective review of 34 patients with hemangiomas treated with class I topical steroids showed good response in 35%, partial response in 38%, and no response in 27%. Treatment protocols varied between patients.

Intralesional corticosteroid therapy in proliferating head and neck hemangiomas: a review of 155 cases

Chen MT, Yeong EK, Horng SY. *J Pediatr Surg* 2000; 35: 420–3.

In this retrospective study, 155 hemangiomas of the head and neck region treated with intralesional corticosteroid injections (three to six injections of triamcinolone acetonide 10 mg/mL at monthly intervals, with an average of four injections per lesion) were analyzed. At the 1-month visit, 85% of hemangiomas showed greater than 50% reduction, with superficial hemangiomas showing the most improvement. Perioral hemangiomas appeared the most recalcitrant to intralesional corticosteroid treatment.

Oral corticosteroid use is effective for cutaneous hemangiomas

Bennett ML, Fleischer AB, Chamlin SL, Frieden IJ. *Arch Dermatol* 2001; 137: 1208–13.

This meta-analysis of 10 case series with 184 patients analyzed the efficacy of systemic corticosteroids in the treatment of cutaneous

hemangiomas. The mean age of infants at the initiation of therapy was 4.5 months with an average prednisone dose equivalent to 2.9 mg/kg. The mean response rate was 84%, and the mean rate of rebound growth after treatment cessation was 36%. Treatment with higher doses of corticosteroids resulted in a higher response rate but greater adverse events. The average incidence of side effects was 35% (behavior changes, irritability, cushingoid appearance, and transient growth delay).

Second-Line Therapies

• Surgical excision	D
• Becaplermin gel for ulcerated lesions	D

Surgical treatment of facial infantile hemangiomas: an analysis based on tumor characteristics and outcomes

Goldenberg DC, Hiraki PY, Marques TM, Koga A, Gemperli R. *Plast Reconstr Surg* 2016; 137: 1221–31.

A retrospective case review of 74 patients treated surgically was analyzed to evaluate outcomes based on tumor-related clinical features. The best candidates for emergency surgery were nonresponders to pharmacologic therapy with segmental periorbital hemangiomas, whereas those undergoing elective surgery were patients with localized lip, nasal, or eyelid hemangiomas in the proliferative phase.

Although most patients with infantile hemangiomas should be managed with pharmacotherapy, surgery remains an important option. The exact algorithm of when to operate remains controversial.

Response of ulcerated perineal hemangiomas of infancy to becaplermin gel, a recombinant human platelet-derived growth factor

Metz BJ, Rubenstein MC, Levy ML, Metry DW. *Arch Dermatol* 2004; 140: 867–70.

Eight infants were treated with becaplermin gel 0.01% for ulcerated

perineal hemangiomas of infancy. Rapid ulcer healing occurred in all patients within 3 to 21 days (average, 10.25 days).

The rapid healing achieved with 0.01% becaplermin gel allows a reduction in the risk of secondary infection, pain, and the need for hospitalization, as well as in the costs that often accumulate from multiple follow-up visits and long-term therapy.

Third-Line Therapies

• Vincristine	E
• Imiquimod	C
• Bleomycin	B

Vincristine as a treatment for a large haemangioma threatening vital functions

Fawcett SL, Grant I, Hall PN, Kelsall AW, Nicholson JC. Br J Plast Surg 2004; 57: 168–71.

A 21-month-old infant with a large, deep hemangioma in the beard distribution, necessitating multiple hospital admissions for respiratory and feeding difficulties, was treated with vincristine after failing to respond to systemic corticosteroid therapy. Vincristine (1.5 mg), administered weekly for 1 month, improved the patient's feeding and speech, as well as the external appearance of the lesion with no adverse events.

Although there are literature reports of success achieved with vincristine, the data are anecdotal at best.

Topical imiquimod in the treatment of infantile hemangiomas: a

retrospective study

Ho NTC, Lansang P, Pope E. J Am Acad Dermatol 2007; 56: 63–8.

Eighteen children (median age of 18 weeks) treated with imiquimod 5% cream three or five times weekly for a mean of 17 weeks showed improvement in superficial hemangiomas and accelerated ulcer healing; no change was seen in deep hemangiomas. A 31% clearance rate was reported. Adverse events included crusting and inflammation.

Unfortunately, this study lacked a control arm, and the results may represent the natural course of untreated infantile hemangiomas.

Role of intralesional bleomycin in the treatment of complicated hemangiomas: prospective clinical study

Omidvari S, Nezakatgoo N, Ahmadloo N, Mohammadianpanah M, Mosalaei A. Dermatol Surg 2005; 31: 499–501.

Thirty-two patients with complicated hemangiomas (median age of 45 months) were treated with intralesional bleomycin (1–2 mg/cm² every 2 weeks for four to six courses). After the initial swelling and erythema, 56% of patients had 70% to 100% regression, whereas 21.9% had 50% to 70% regression. No severe adverse events were reported.

Hereditary angioedema

Tabi A. Leslie, and Malcolm W. Greaves

There are three types of hereditary angioedemas (HAEs). Types I and II HAEs—the most common forms—are autosomal dominantly inherited with a prevalence of 1:50,000 due to mutations in the C1-esterase inhibitor (C1INH) gene on chromosome 11q12-q13.1. However, de novo mutations of the gene controlling C1INH (*SERPINC1*) can occur, accounting for approximately 25% of C1INH-HAE cases. Type I (85%) is characterized by a quantitative

abnormality of the C1INH, and type II (15%) is due to a functional defect of the inhibitor of the first component of complement C1INH. These HAEs are mediated by the protease kallikrein and the nonapeptide bradykinin, acting on B₂ receptors, and are manifested by painless, nonpruritic swellings of subcutaneous (SC) and submucosal tissues, including abdominal organs and the upper airway. The third type of HAE, previously known as *HAE type III* (or the estrogen-dependent type), is now referred to as *HAE with normal C1INH*. This type is associated with a positive family history, occurring predominantly in women, with no detectable abnormality of C1INH or other complement components. A mutation in the gene encoding for factor 12 (*F12*), which encodes for the Hageman factor (HAE–FX11), has been identified in some of these families. Acute abdominal pain simulating an “acute abdomen” is an important presentation in any type of HAE, and fatalities are possible (due to laryngeal obstruction). Associations with autoimmune disorders, mainly lupus erythematosus, occur in type I HAE but are rare in type II.

Management Strategy

Therapy for HAE is dependent on three considerations:

- Relief of acute angioedema (AAE), especially preservation of the airway
- Long-term prophylaxis
- Prevention of relapse due to dental and surgical interventions (short-term prophylaxis)

Acute Angioedema

Acute presentations of HAE are treated optimally with intravenous (IV) *plasma-derived C1INH concentrate* at 20 units/kg body weight. This treatment is safe, and no proven cases of viral transmission have been reported. Reduction in swelling is usually significant within minutes and substantial within 2 to 3 hours. A recombinant C1INH preparation is now available. Patients can be taught to self-administer for a more rapid resolution of symptoms and to prevent further progression of the attack(s). *Fresh frozen plasma (FFP)*, which contains C1INH, can be used in an emergency if concentrate is unavailable.

However, FFP carries a higher risk of inadvertent viral transmission (HIV, hepatitis) and theoretically could exacerbate angioedema due to the presence of C1 esterase substrate. The kallikrein–bradykinin mediator pathway is the target of current approaches to treatment of acute HAE. The swellings of HAE are mediated by bradykinin, a product of the action of kallikrein on its substrate kininogen. Bradykinin acts on B2 receptors, and its specific antagonist *icatibant* 30 mg subcutaneously has been proven effective in acute attacks of HAE. Icatibant may be the preferred therapy because it is given subcutaneously and can be administered in a domiciliary setting by health care professionals or even by self-administration after appropriate training. *Ecallantide*, a kallikrein inhibitor given subcutaneously in a dose of 30 mg, has been proven to be safe and effective for acute attacks. Laryngeal edema may require *tracheostomy*, *intubation*, and/or other life-support measures. Patients are routinely admitted for 24 hours after acute episodes, as life-threatening relapses are common.

Long-Term Prophylaxis

Long-term prophylaxis is appropriate in those patients with at least one or more attacks of angioedema per month and in those with severe symptoms. However, patients could have infrequent attacks and still present with laryngeal edema. Even first-episode angioedema can be fatal. Prophylactic treatment with plasma-derived C1INH is now the first-line therapy if available. IV infusions of 1000 units administered twice weekly can lead to less severe symptoms and even attack prevention. Other treatments include the 17 α -alkylated (“attenuated”) androgens *danazol* (100–200 mg daily) or *stanozolol* (up to 5.0 mg once or twice daily), which are used as second-line prophylactic medications that may be effective in preventing angioedema in some patients with type I or II HAE. The lowest effective dose of androgen should be used to obtain clinical remission. Side effects include hirsutism, deepening of voice, and menorrhagia. These attenuated androgens are unsuitable for long-term treatment of HAE in children, pregnant women, or the treatment of acute attacks. However, they are safe and effective in adults, provided they are closely supervised with clinical biochemical and radiologic assessments. In some patients, less frequent dosage of danazol (100 mg) on weekdays only or stanozolol (2 mg) on alternate

days can be effective. Hepatocellular adenoma and hepatocellular carcinoma have been reported in patients on long-term danazol. Liver function tests and lipid levels should be monitored, with liver ultrasound scans performed every 2 years, although hepatic adenoma/carcinoma can occur in patients receiving attenuated androgens in the absence of any disturbance of liver function tests. Other less effective prophylactic therapies include *antifibrinolytics*, *tranexamic acid (TA)* (2.0–4.5 g daily), or *epsilon-aminocaproic acid (EACA)* (12–18 g daily) but should be avoided in patients with a history of thrombotic diseases. They are useful for short-term prophylaxis, especially for those where C1INH is not available or other therapies are contraindicated. In patients with mild infrequent attacks *avoidance of provoking factors*, including estrogens and angiotensin-converting enzyme (ACE) inhibitors, may be sufficient. For long-term management in selected cases, patients' caretakers can be trained to administer IV C1INH for occasional acute attacks if no medical facilities are at hand, thereby obviating the necessity for regular prophylaxis. Although not yet licensed for domiciliary administration, there is mounting evidence that C1INH concentrate can be safely and effectively self-administered by the SC route.

Prevention of Relapse Due to Dental and Surgical Interventions

In all patients, before elective surgical, dental, or other invasive procedures, *higher dose androgens can be used for 5 to 10 days*. Antifibrinolytics can be used 48 hours before and up to 2 to 5 days after the procedure. If an emergency procedure is necessary, C1INH concentrate or FFP can be administered. Patients with HAE should all wear a *MedicAlert disk* stating the diagnosis and emergency treatment.

Specific Investigations

- Complement levels (C4, C2, C1q)
- C1INH immunoreactive level
- Functional assay for C1INH

Angioedema

Kaplan AP, Greaves MW. J Am Acad Dermatol 2005; 53: 373–88.

Type I HAE is characterized by low antigenic and functional plasma levels of normal C1INH. Type II HAE is characterized by normal or elevated antigenic levels of a dysfunctional mutant C1INH together with functional C1INH. In those patients with a low C4 but normal C1INH levels, a functional assay should be obtained to identify type II disease. A depressed C1q level in addition to low C4 and C1INH levels is characteristic of acquired C1INH-deficient angioedema. Causes include B-cell lymphoma, cryoglobulinemia, and the presence of autoantibodies against C1INH itself.

Immunoregulatory disorders associated with hereditary angioedema. 1. Clinical manifestations of autoimmune disease

Brickman CN, Tsokos GC, James E. J Allergy Clin Immunol 1986; 77: 749–57.

One hundred fifty-seven HAE patients were systematically evaluated for manifestations of autoimmunity. Clinical immunoregulatory diseases were present in 19 of these (12%). Autoimmune diseases with a known human histocompatibility antigen association had developed in eight HAE patients, and all of these developed an associated disease. Four patients developed sicca syndrome or Sjögren's syndrome, and a further nine manifested part of the sicca complex. There were also HAE patients found with features (e.g., Raynaud disease, idiopathic pancreatitis) that suggested an immune-based abnormality.

An evaluation of tests used for the diagnosis and monitoring of C1 inhibitor deficiency: normal serum C4 does not exclude hereditary angioedema

Tarzi MD, Hickey A, Förster T, Mohammadi M, Longhurst HJ. Clin Exp Immunol 2007; 149: 513–6.

Although C4 is the single best screening test, it is not a definitive test. False-negative results may occur in patients, because normal C4 may occasionally present in HAE. Therefore assay of C1 inhibitor antigen and function should be performed, regardless of serum C4 levels, when clinical suspicion of HAE is high.

Genetic test indications and interpretations in patients with hereditary angioedema

Weiler CR, van Dellen RG. Mayo Clin Proc 2006; 81: 958–72.

Differentiating between HAE and AAE caused by C1INH

deficiency can be aided by C1q testing. Genetic testing would be especially helpful in patients with borderline C1q levels and no family history of angioedema. Many patients with acquired C1INH deficiency have autoantibodies against C1INH. Measuring these autoantibodies would be helpful; however, the test is only available in research laboratories.

Acute Angioedema

First-Line Therapy

- C1INH concentrate

Prospective study of rapid relief provided by C1 esterase inhibitor in emergency treatment of acute laryngeal attacks in hereditary angioedema

Craig TJ, Wasserman RL, Levy RJ, Bewtra AK, Schneider L, Packer F, et al. *J Clin Immunol* 2010; 30: 823–9.

Thirty-nine acute laryngeal attacks occurring in a prospective open-label study of 16 patients were treated with C1INH concentrate (Berinert). A single dose of 20 U/kg body weight was successful in treating all attacks with a median time to onset of relief of 15 minutes and a median time to complete resolution of all symptoms of 8.25 hours.

Nanofiltered C1 inhibitor concentrate for treatment of hereditary angioedema

Zuraw BL, Busse PJ, White M, Jacobs J, Lumry W, Baker J, et al. *N Engl J Med* 2010; 363: 513–22.

A placebo-controlled study of IV administration of nanofiltered pasteurized C1 inhibitor concentrate in 65 patients with HAE demonstrated that treatment shortened the acute attack from over 4 hours to 2 hours.

Pharmacokinetics of plasma-derived C1-esterase inhibitor after subcutaneous versus intravenous administration in subjects with mild or moderate hereditary angioedema: the PASSION study

Martinez-Saguer I, Cicardi M, Suffritti C, Rusicke E, Aygören-Pürsün E, Stoll H, et al. Transfusion 2014; 54: 1552–61.

Twenty-four subjects with mild or moderate HAE were randomly assigned to groups receiving 1000 units of C1INH concentrate by IV or SC administration. After SC administration, the mean relative bioavailability of functional C1INH was 39.7%, with maximum C1INH activity occurring within 48 hours and persisting for longer than IV administration. The mean half-life of functional C1INH was 120 hours after SC administration, compared with 62 hours after IV administration. The SC administration was well tolerated, with a higher incidence of mild injection site reactions than IV administration, as expected.

Subcutaneous self-injection of C1 inhibitor – an effective and safe treatment in a patient with hereditary angioedema

Weller K, Kruger R, Maurer M, Magerl M. Clin Exper Dermatol 2016; 41: 91–3.

A 25-year-old female patient diagnosed with HAE due to C1 inhibitor deficiency used an SC infusion kit to administer SC injections of C1 inhibitor 1000 U in 10 mL twice weekly. In the subsequent 2 years she has remained completely free of symptoms.

C1INH concentrate has also been effective as short-term prophylaxis in labor induction, tonsillectomy, and maxillofacial surgery. Long-term prophylaxis has not generally been advocated due to lack of availability, cost, and the potential for infectious transmission. However, this may be considered in children, pregnant women, and patients who do not respond to or tolerate androgens or antifibrinolytics, or if these drugs are contraindicated.

Suppliers of C1INH products include Berinert, Cinryze (human C1INH), and Ruconest (recombinant C1INH).

Second-Line Therapies

- FFP
- Icatibant
- Ecallantide

The safety of fresh frozen plasma for the treatment of hereditary angioedema

Prematta M, Thomas D, Scarupa M, Li C, Mende C, Rhoads C. J Allergy Clin Immunol 2008; 121: S99.

FFP was found to be effective in 76 of 82 acute attacks of HAE, and no patients developed significant adverse reactions.

FFP is effective and can be used if C1INH concentrate is unavailable. It is not virally inactivated and, being larger in volume, requires a longer infusion time. Apart from the risk of virus infection, using FFP carries the theoretical potential for exacerbation of attacks due to its content of complement substrates.

Treatment of acute edema attacks in hereditary angioedema with a bradykinin receptor-2 antagonist (icatibant)

Bork K, Frank J, Grundt B, Schlattmann P, Nussberger J, Kreuz W. J Allergy Clin Immunol 2007; 119: 1497–503.

Fifteen patients with 20 attacks were treated with icatibant, with significant improvement relative to previous episodes as assessed using visual analog scales. Symptom intensity decreased within 4 hours after administration.

Icatibant, a new bradykinin receptor antagonist in hereditary angioedema

Cicardi M, Banerji F, Bracho F, Malbrán A, Rosenkranz B, Riedl M, et al. N Engl J Med 2010; 363: 532–41.

In two randomized double-blind trials relief of symptoms occurred in 2.5 hours versus 4.6 hours with placebo and 2.0 hours versus 12.0 hours with TA.

Ecallantide for the treatment of acute attacks in hereditary angioedema

Cicardi M, Levy RJ, McNeil DL, Li HH, Sheffer AL, Campion M. N Engl J Med 2010; 363: 523–31.

In a randomized double-blind trial in 71 patients ecallantide caused relief of symptoms in 165 minutes compared with over 240 minutes with placebo

Icatibant, a synthetic decapeptide, is a bradykinin B2 receptor antagonist recently licensed in the European Union for treatment of acute episodes of HAE. The recommended dose is one subcutaneous injection of 30 mg, preferably in the abdominal area. Mild reactions at the injection site are common. Ecallantide, a kallikrein inhibitor recently licensed in the United States (but not Europe) for the same indication, is also administered

subcutaneously in a dosage of 30 mg.

Long-Term Prophylaxis of Hereditary Angioedema

First-Line Therapies

- Danazol
- Stanazolol

How do we treat patients with hereditary angioedema?

Cicardi M, Zingale L. Transfus Apheresis Sci 2003; 29: 221–7.

In a study of 141 patients, danazol and stanazolol proved equally effective; <10% of patients failed to obtain significant remission. Normalization of C1INH is not required. These authors start with a run-in period of 400 to 600 mg daily of danazol for 1 month, slowly tapering to 100 to 200 mg daily to determine the minimum dose that will maintain remission (C1INH level around 50% of normal; C4 within normal range; complete remission of angioedema).

Benefits and risks of danazol in hereditary angioedema: a long-term survey of 118 patients

Bork K, Bygum A, Hardt J. Ann Allergy Asthma Immunol 2008; 100: 153–61.

Data generated from patients who were treated with danazol for 2 months to 30 years showed that it was highly beneficial, with 111 out of 118 patients responding. Fifty-four (45.8%) patients had <1 attack per year or became symptom free. In the other patients during danazol treatment, the frequency of acute attacks decreased and became milder. Laryngeal edema decreased to 4.8%. Risk of adverse effects was high, with 93 patients suffering effects, including weight gain, menstrual irregularity, virilization, depression, headache, and liver adenomas, and 30 patients discontinuing the therapy.

Long-term prophylaxis of hereditary angioedema with androgen derivatives: a critical appraisal and potential alternatives

Maurer M, Magerl M. J Dtsch Dermatol Ges 2011; 9: 99–107.

The IV substitution of C1INH and SC administration of icatibant are both well tolerated and reliable in controlling swelling attacks of HAE. Therefore long-term prophylactic treatment of HAE patients with androgen derivatives such as danazol may be reconsidered. Patients might benefit from either the withdrawal or dose reduction of androgen prophylaxis and rely on demand-oriented acute treatment of attacks using C1INH or icatibant.

Side effects in female patients may be troublesome, including menstrual disturbance, deepening of the voice, and hirsutism. In males, prostate changes should be monitored. All patients should have regular liver function tests. Attenuated androgens are contraindicated in pregnancy.

Second-Line Therapies

- TA
- Epsilon aminocaproic acid

Hereditary and acquired C1-inhibitor deficiency: biological and clinical characteristics in 235 patients

Agostoni A, Cicardi M. Medicine (Baltimore) 1992; 71: OK206–15.

Twelve of 15 patients had initially effective prophylaxis with TA, but this agent was only effective long term in 28% of patients, whereas danazol was effective long term in 97% of patients.

Tranexamic acid therapy in hereditary angioneurotic edema

Sheffer AL, Austen KF, Rosen FS. N Engl J Med 1972; 287: 452–4.

A randomized, placebo-controlled, double-blind crossover trial over a 4- to 13-month period. Seven of 12 patients receiving TA 1 g three times daily achieved a complete or near-complete cessation of attacks. Four additional patients experienced a moderate response.

TA is more potent than EACA and has been reported to cause fewer side effects.

Epsilon aminocaproic acid therapy of hereditary angio-neurotic edema: a double blind study

Frank MM, Sargent JS, Kane MA, Alling DW. N Engl J Med 1972; 286: 808–12.

EACA (16 g daily) in a double-blind crossover trial prevented attacks of angioedema in four of five patients over a 2-year period.

Common side effects consisted of weakness and increased fatigability. A follow-up open trial led to control of symptoms on 7 to 10 g of EACA daily.

Higher dose therapy (24–30 g) has led to elevation of creatine phosphokinase and aldolase levels and muscle necrosis. EACA therapy can also be used as short-term prophylaxis for minor procedures, but because of its potential thrombotic effects it should be discontinued before major surgery.

Third-Line Therapy

- C1INH concentrate

Cinryze (C1-inhibitor) for the treatment of hereditary angioedema

Gompels MM, Lock RJ. Expert Rev Clin Immunol 2011; 7: 569–73.

In a double-blind, placebo-controlled crossover trial, a plasma-derived concentrate of C1INH (pdC1INH) was used to treat HAE patients as a prophylaxis, with the frequency of attacks reducing by half to 6.26 per 12 weeks (compared with 12.73 per 12 weeks in the placebo group). Attacks were milder and of shorter duration. Patients with acute attacks receiving pdC1INH, 1000 units, reported time to onset of relief was 2 hours, compared with >4 hours in the placebo group.

Prevention of Relapse Due to Dental and Surgical Interventions

First-Line Therapies

- FFP
- Danazol
- C1INH concentrate

Short-term prophylaxis in hereditary angioedema due to deficiency of the C1-inhibitor – a long-term survey

Farkas H, Zotter Z, Csuka D, Szabó E, Nébenfűhrer Z, Temesszentandrás G, et al. Allergy 2012; 67: 1586–93.

Retrospective analysis of 137 patients with HAE evaluated the efficacy of drugs administered for short-term prophylaxis. C1INH concentrate was found to be safe and effective in reducing edematous episodes after surgical procedures. Danazol may be used as an alternative to C1INH concentrate for prophylaxis before medical interventions.

WAO guideline for the management of hereditary angioedema

Craig T, Aygören-Pürsün E, Bork K, Bowen T, Boysen H, Farkas H, et. al. World Allergy Organ J 2012; 5: 182–99.

Androgens (danazol at 2.5–10 mg/kg/day, maximum 600 mg; stanozolol at 4–6 mg/d) may be used for 5 days before and 2 to 5 days postevent for preprocedural/short-term prophylaxis.

TA has been used in the past for preprocedural/short-term prophylaxis although with low efficacy in suppressing breakthrough attacks. The recommended oral dose is 25 mg/kg two to three times daily, maximum 3 to 6 g daily (not fully established).

Other preoperative options include 500 to 1000 units of C1INH concentrate or antifibrinolytic agents.

Treatment in Children

Pediatric hereditary angioedema due to C1-inhibitor deficiency

Farkas H. Allergy Asthma Clin Immunol 2010; 6:18.

C1INH replacement therapy, antifibrinolytics, and attenuated androgens are currently favored medicinal products for the treatment of HAE in children, with regular monitoring and follow-up being vital. C1INH replacement therapy is effective and a safe agent for use in children. Antifibrinolytics have a favorable long-term safety profile and are therefore recommended but may lack efficacy. Attenuated androgens are another option in children, to be administered in the lowest effective dose.

Hereditary Angioedema With Normal C1inh

Hereditary angioedema type 3, angioedema associated with

angiotensin II receptor antagonists and female sex

Bork K. Am J Med 2004; 116: 644.

Two unrelated female patients with normal C1INH and C4 levels experienced severe exacerbations of HAE after the administration of losartan and valsartan, respectively.

Acute attacks of HAE with normal C1INH do not respond to C1INH concentrate, and antihistamines or corticosteroids are ineffective. The value of antifibrinolytics is unproven. For prevention danazol is worth trying in nonpregnant patients, but substantiation of its value is awaited. All patients should avoid angiotensin-2-receptor antagonists (sartans) and estrogens because these are known to provoke attacks in affected women. Bradykinin antagonists, such as icatibant, or kallikrein inhibitors, such as ecallantide, may offer benefit to these patients, although their benefit is unproven.

Hereditary hemorrhagic telangiectasia

Mitchell S. Cappell, and Oscar Lebwohl

Patients with rosacea or lupus erythematosus may have telangiectasias solely on the face but lack other manifestations of HHT. Patients with sporadic GI angiodysplasia are differentiated

from patients with HHT by clinical presentation in old age, paucity of lesions, negative family history, and exclusive GI involvement without epistaxis or intranasal telangiectasia.

Hereditary hemorrhagic telangiectasia (HHT, or Osler–Weber–Rendu syndrome), an autosomal-dominant disease, produces a syndrome of multiple orocutaneous telangiectasias, especially on the face, lips, tongue, oral mucosa, and fingertips, together with multiple internal telangiectasias, especially on the mucosa of the nose and gastrointestinal (GI) tract. Individual telangiectasias typically are 3 to 10 mm wide, macular, bright red, nonpulsatile, and spidery or punctate in shape with a fine reticular internal structure. They tend to blanch under pressure (with diascopy) and refill immediately after releasing the pressure. They generally slowly increase in size and number with age. The basic lesion in HHT is a defect in the wall of small vessels that leads to direct arteriovenous communications without intervening capillaries. The prevalence of HHT is estimated at 1 per 6000 individuals. HHT is reliably diagnosed when three or more criteria are satisfied among a clinical tetrad (Curaçao criteria), listed later. HHT is possible or suspected when two criteria are satisfied. HHT is highly unlikely in adult patients satisfying only one or none of these criteria. About 85% of cases of HHT are due to underlying genetic mutations either in the gene encoding endoglin (ENG) that produces HHT1 or in the gene encoding activin receptor-like kinase (ACVRL1, previously called *ALK-1*) that produces HHT2. The remaining cases are caused by six other known families of mutations. Genetic mutations located on chromosome 5 cause HHT3, mutations located on chromosome 7 cause HHT4, and mutations located in the *MADH4* gene cause HHT associated with juvenile polyposis. The diagnosis can be confirmed by genetic tests for the individual mutations, but such tests are generally not necessary for diagnosis or clinical management.

Clinical (Curaçao) criteria for diagnosis of hereditary hemorrhagic telangiectasia

Organ or other parameter	Characteristic finding
Nose	Recurrent, spontaneous epistaxis
Mucocutaneous	Telangiectasias on lips, oral cavity, nasal mucosa, or fingers
Gastrointestinal	Mucosal telangiectasias (or visceral arteriovenous malformations)
Family history	One or more first-degree relatives with HHT

HHT, hereditary hemorrhagic telangiectasia.

Management Strategy

The two major clinical complications of HHT are significant epistaxis and GI bleeding from nasal and GI telangiectasias. The bleeding may be chronic because these telangiectasias have thin and fragile vessel walls. Chronic blood loss may cause iron-deficiency anemia, whereas acute blood loss may cause hypovolemia and systemic hypotension. Internal shunts created by direct arteriovenous communications in HHT uncommonly cause clinical manifestations, including hypoxia from pulmonary arteriovenous shunts; cerebral ischemia, hemorrhage, or abscesses from intracerebral shunts; and portal hypertension, biliary tract disease, or high-output cardiac failure from intrahepatic shunts. Dermatologic telangiectasias are usually only a minor, cosmetic problem.

Specific Investigations

For epistaxis or gastrointestinal bleeding

- Serial hematocrit determinations — to assess severity of bleeding
- Serum iron, total iron binding capacity (TIBC), and ferritin levels — to diagnose iron-deficiency anemia

For epistaxis

- Nasal examination using fine-caliber, rigid, nasal endoscope
- Flexible nasal endoscopy – alternative technique of examination

For gastrointestinal bleeding

- Esophagogastroduodenoscopy (EGD) – for suspected upper GI bleeding
- Colonoscopy – for suspected lower GI bleeding
- Capsule endoscopy or double-balloon enteroscopy – for GI bleeding after a nondiagnostic EGD and colonoscopy
- Angiography – for ongoing bleeding after nondiagnostic endoscopic examinations

For epistaxis, bleeding severity is determined by inspection, vital signs, and laboratory tests. The bleeding site is precisely localized by nasal examination with a fine-caliber rigid tube (endoscope), using spot suction, and bright, shadow-free illumination, with a headlight,

head mirror, or cold fiber-optic illumination. Flexible nasal endoscopy is a recent alternative examination technique. For GI bleeding, the bleeding severity is indicated by patient history, vital signs, physical findings, rectal examination, nasogastric aspiration, and transfusion requirements. The bleeding site and source are conclusively diagnosed by GI endoscopy.

Serial hematocrit determinations are important, particularly for acute bleeding, to determine need for transfusions of packed erythrocytes. Serum levels of iron, TIBC, and ferritin are important, particularly for chronic bleeding, to determine the need for iron replacement therapy.

Upper GI bleeding, usually manifested by hematemesis or melena, should be investigated by esophagogastroduodenoscopy (EGD). Lower GI bleeding, usually manifested by hematochezia or fecal occult blood, and occasionally by melena, should be investigated by colonoscopy. Small intestinal bleeding, usually manifested by hematochezia, melena, or fecal occult blood, can be investigated by capsule endoscopy after exclusion of upper and lower GI bleeding by EGD and colonoscopy, respectively. Double-balloon enteroscopy is often used at tertiary medical centers instead of capsule endoscopy to investigate small intestinal bleeding because of its greater diagnostic sensitivity and therapeutic capabilities despite its greater costs.

At endoscopy, telangiectasias appear as intensely red maculae due to the high oxygen content in erythrocytes within vessels supplied by arteries without intervening capillaries. The GI lesions resemble the cutaneous telangiectasias in size and shape. Telangiectasias are distinguished from lesions due to endoscopic trauma by identification during endoscopic intubation, as opposed to identification during endoscopic extubation with trauma; by a finely reticular (fernlike) internal structure due to a vascular tuft; by an irregular (fernlike) border as opposed to a round border with trauma; by an abrupt lesion margin as opposed to an indistinct margin with trauma; and by lesions lying flush (coplanar) with mucosa. Additionally, colonic lesions from endoscopic trauma usually occur at sharp colonic turns, during endoscopic looping, or after endoscopic suctioning.

Angiography is indicated for active GI bleeding if EGD and colonoscopy fails to diagnose the source of bleeding. The angiographic hallmarks of telangiectasias are a vascular tuft or tangle resulting from the local aggregation of irregular vessels; an early and intensely filling vein resulting from direct arteriovenous connection

without intervening capillaries; and persistent opacification beyond the normal venous phase (slowly emptying vein), attributed to vascular tortuosity. Telangiectasias bleed only intermittently, and extravasation of contrast material from telangiectasias is infrequently detected at angiography.

Hereditary hemorrhagic telangiectasia: from molecular biology to patient care

Dupuis-Girod S, Bailly S, Plauchu H. *J Thromb Haemostasis* 2010; 8:1447–56.

Clinically oriented review of the genetics, pathophysiology, clinical presentation, diagnosis, and therapy of HHT.

Liver disease in patients with hereditary hemorrhagic telangiectasia

Garcia-Tsao G, Korzenik JR, Young L, Henderson KJ, Jain D, Byrd B, et al. *N Engl J Med* 2000; 343: 931–6.

Review of clinical findings caused by intrahepatic shunts with HHT, including eight patients with high-output cardiac failure, six patients with portal hypertension, and five patients with biliary tract disease.

Evidence of small-bowel involvement in hereditary hemorrhagic telangiectasia: a capsule-endoscopic study

Ingrosso M, Sabba C, Pisani A, Principi M, Gallitelli M, Cirulli A, et al. *Endoscopy* 2004; 36: 1074–9.

Study demonstrates a high frequency of small intestinal telangiectasias in elderly patients with HHT as detected by capsule endoscopy. Chronic blood loss from these intestinal telangiectasias may contribute to iron-deficiency anemia from HHT.

Evaluation of patients with hereditary hemorrhagic telangiectasia with video capsule endoscopy: a single-center prospective study

Chamberlain SM, Patel J, Carter Balart J, Gossage JR Jr, Sridhar S. *Endoscopy* 2007; 39: 516–20.

Prospective study of 80 patients evaluated by capsule endoscopy for small intestinal bleeding. The 32 patients with known HHT had significantly more GI telangiectasias than did 48 control patients without HHT (75% vs. 8.3% of patients had five or more telangiectasias). This study demonstrates the high sensitivity of

capsule endoscopy in diagnosing small intestinal telangiectasias in patients who have HHT.

First-Line Therapies

For epistaxis or gastrointestinal bleeding

• Transfuse packed erythrocytes for significant, acute bleeding	A
• Oral iron therapy for iron-deficiency anemia from chronic blood loss	A
• Nonspecific therapy: avoid aspirin, other antiplatelet drugs, and anticoagulation	A
• Reverse severe coagulopathy if patient is actively bleeding (e.g., transfuse platelets for severe thrombocytopenia and transfuse fresh frozen plasma for elevated INR (international normalized ratio))	A
• Oral estrogen with progesterone	B

For epistaxis

• Nonspecific therapy: room humidification and nasal moisteners	A
• Nasal packing	A
• Septal dermoplasty	A
• Bevacizumab	B

For gastrointestinal bleeding

• Endoscopic therapy: argon plasma coagulation, thermocoagulation, electrocoagulation, or photocoagulation	B
• Angiographic embolization for bleeding refractory to endoscopic therapy	B
• Segmental bowel resection – for refractory bleeding	A

For cutaneous lesions

• Cosmetic therapy: laser or other focal ablation techniques for cutaneous lesions	A
--	---

The choice of therapy depends on bleeding site, severity, and chronicity as well as individual physician expertise. Severe bleeding requires hospitalization and insertion of two large-bore IV lines. Significant acute blood loss is treated with intravenous fluid resuscitation and transfusion of packed erythrocytes as needed. Chronic blood loss is treated with iron supplementation as needed.

Nonspecific therapy for bleeding from HHT includes *avoidance of aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), other antiplatelet drugs, and anticoagulants* and administration of iron for patients with significant iron-deficiency anemia.

Nasal moisteners and room humidification promote mucosal integrity and reduce nasal mucosal injury and epistaxis. Epistaxis is initially treated by nonspecific local therapy such as *nasal packing* to tamponade the bleeding. *Estrogen with progesterone* is used to prevent or arrest chronic epistaxis by promoting vascular integrity. Mutations in the different forms of HHT result in highly elevated levels of vascular endothelial growth factor (VEGF) that can cause an abnormal, immature vasculature with resultant telangiectasias. *Bevacizumab*, a recombinant humanized monoclonal antibody to VEGF, may reverse the telangiectasias occurring in HHT by inhibiting VEGF (antiangiogenesis). Preliminary clinical data, including one prospective open-label trial (described later), have shown IV bevacizumab may significantly reduce epistaxis in patients with HHT. Risks of IV bevacizumab include hypertension, bleeding in other organs, and bowel perforation. Submucosal or topical intranasal administration of bevacizumab may avoid much of the systemic toxicity of IV therapy with similar efficacy.

Several studies have reported a markedly reduced incidence of chronic epistaxis from telangiectasias after instituting estrogen therapy, either alone or with progesterone, due to the promotion of endothelial integrity. *Estrogen therapy* can be combined with other therapies, such as local endoscopic therapy, to increase efficacy. Despite controversy concerning efficacy, estrogen therapy should be considered before performing nasal surgery for chronic epistaxis because of its low risk and the risk of recurrent bleeding after surgery. Estrogen therapy is less desirable in males than in females because it can cause feminization.

Significant, refractory, chronic epistaxis is definitively treated by *septal dermoplasty*. Septal dermoplasty is indicated for severe, recurrent epistaxis, especially from anterior nasal mucosa. In this procedure, skin removed from the upper thigh is grafted on to the anterior nasal septum and floor to cover and protect the fragile mucosal telangiectasias from local trauma. The procedure is well tolerated using only local anesthesia, and complications, other than recurrent epistaxis, are rare. Septal dermoplasty is effective in >75% of cases. Failure results from inadequate graft coverage with bleeding from telangiectasias at or beyond the border of the grafted area. Focal laser therapy can be used to ablate discrete bleeding intranasal lesions.

Chronically bleeding GI telangiectasias may also be treated with

estrogen and progesterone. Multiple individual case reports have described cessation of GI bleeding from telangiectasia in HHT. At endoscopy, actively bleeding, individual GI telangiectasias are treated with endoscopic *argon plasma coagulation* (APC), *thermocoagulation*, *electrocoagulation*, or *photocoagulation*. Endoscopists increasingly prefer APC because of its easy application and its potentially greater safety due to more superficial tissue ablation. Nonetheless, all these endoscopic therapies are relatively safe and highly successful at achieving hemostasis when performed by an experienced endoscopist. Nonbleeding lesions are generally not treated at endoscopy unless the lesions are particularly large and thus likely to bleed. However, patients with HHT often rebleed from other, untreated GI telangiectasias after an initial session of endoscopic therapy and therefore require multiple sessions of endoscopic therapy to treat these other lesions.

Segmental bowel resection is reserved for severe active bleeding, localized to a single region and refractory to medical and endoscopic therapy. Where available, *angiographic embolization* can obviate the need for GI surgery. Surgery or angiographic embolization often provides only intermediate-term relief due to formation of telangiectasias at other GI sites.

Treatment of bleeding gastrointestinal vascular malformations with oestrogen-progesterone

van Custen E, Rutgeerts P, Vantrappen G. Lancet 1990; 335: 953–5.

In a double-blind, placebo-controlled crossover trial of 10 patients with frequent and severe GI bleeding from HHT, the number of transfusions decreased significantly from a mean of 10.9 units of packed erythrocytes in controls receiving placebo to a mean of 1.1 units in patients treated with estrogen-progesterone during a 6-month period.

Use of estrogen in treatment of familial hemorrhagic telangiectasia

Harrison DFN. Laryngoscope 1982; 92: 314–20.

Report of successful control of epistaxis with estrogen therapy in 67 patients with HHT, with few complications.

Treatment of hereditary hemorrhagic telangiectasia with submucosal and topical bevacizumab therapy

Karnezis TT, Davidson TM. *Laryngoscope* 2012; 122: 495–7.

In a prospective trial of 19 patients, the epistaxis severity score significantly decreased to 2.00 2 months after intranasal, submucosal injection of bevacizumab compared with the baseline, pretreatment severity score of 8.12 ($p < 0.0001$). Bevacizumab therapy statistically significantly protected against epistaxis for all 12 months of the clinical trial.

Bevacizumab in patients with hereditary hemorrhagic telangiectasia and severe hepatic vascular malformations and high cardiac output

Dupuis-Girod S, Ginon I, Saurin JC, Marion D, Guillot E, Decullier E, et al. *JAMA* 2012; 307: 948–55.

In a prospective, open-label study, 25 adult patients with severe HHT received bevacizumab intravenously for 2.5 months. The mean duration of epistaxis decreased from 221 min/mo at baseline to 43 min/mo at 6 mo ($p = 0.008$), and the mean number of episodes decreased from 26 episodes/mo at baseline to 11 episodes/mo at 6 mo. This study suggests that IV bevacizumab may decrease the frequency and duration of epistaxis in patients with HHT.

Outcome of septal dermoplasty in patients with hereditary hemorrhagic telangiectasia

Fiorella ML, Ross D, Henderson KJ, White RI Jr. *Laryngoscope* 2005; 115: 301–5.

Retrospective study reporting outcome of 32 consecutive patients undergoing septal dermoplasty in whom accurate records of transfusion requirements were available. Mean blood transfusion requirements declined significantly from a mean of 21 units of packed erythrocytes in the year before surgery to a mean of 1 unit in the year after surgery ($p < 0.001$). This study illustrates the fairly extensive literature supporting the efficacy of septal dermoplasty for treating recurrent, relatively severe epistaxis from HHT.

Diagnosis and management of gastrointestinal bleeding in patients with hereditary hemorrhagic telangiectasia

Longacre AV, Gross CP, Gallitelli M, Henderson KJ, White RI Jr, Proctor DD. *Am J Gastroenterol* 2003; 98: 59–65.

In a nonrandomized, long-term, observational study, the mean hemoglobin level increased and the chronic transfusion requirements

decreased in about three quarters of 17 patients after instituting chronic estrogen hormonal therapy, either alone or with other therapies, for GI bleeding from HHT.

Argon plasma coagulation is an effective treatment for hereditary hemorrhagic telangiectasia patients with severe nosebleeds

Pagella F, Matti E, Chu F, Pusateri A, Tinelli C, Olivieri C, et al. *Acta Otolaryngol* 2013; 133: 174–80.

In this retrospective study, 26 patients with HHT were followed by telephone calls one or more years after undergoing APC treatment of nasal mucosa for severe epistaxis requiring blood transfusions. The epistaxis severity score decreased significantly from 8.5 before APC therapy to 4.3 after therapy ($p < 0.005$), as did the number of patients requiring blood transfusions ($p < 0.02$). The frequency, intensity, and duration of epistaxis also decreased significantly after APC therapy compared with baseline ($p < 0.0001$). The beneficial effects of therapy lasted 22.9 months. This work demonstrates that APC is an effective therapy for severe epistaxis from HHT.

Long-term outcome of argon plasma ablation therapy for bleeding in 100 consecutive patients with colonic angiodysplasia

Olmos JA, Marcolongo M, Pogorelsky V, Herrera L, Tobal F, Davalos JR. *Dis Colon Rectum* 2006; 49: 1507–16.

In this prospective trial, 85 of 100 patients with moderate to severe bleeding from colonic angiodysplasia treated at colonoscopy with APC (mean 3.9 angiodysplasias treated per patient) had no further overt bleeding and had a stable hemoglobin level without further blood transfusions or iron therapy during a mean follow-up of 20 months. Only two minor procedure complications occurred. Although not specifically addressing APC for telangiectasias in HHT, this large prospective study demonstrated high efficacy of this therapy for preventing rebleeding from the similar lesions of sporadic colonic angiodysplasia.

Second-Line or Temporizing Therapies

For epistaxis

• Arterial ligation	B
• Topical vasoconstrictors	B
• Cryosurgery/electrical cautery/argon plasma coagulation	B
• Unilateral or bilateral surgical closure of nostrils	B
• Arterial embolization	B
• Tamoxifen	B
• Submucosal resection	C
• Topical aminocaproic acid	D

For gastrointestinal bleeding

• Bevacizumab	C
• Oral aminocaproic acid therapy	D
• α -Interferon	D

Some recent data support use of *tamoxifen*, an estrogen antagonist, to prevent bleeding from telangiectasia in HHT. A few patients have responded to therapy with α -interferon, which has known antiangiogenic properties, but this therapy is currently experimental because of insufficient data.

Local nonspecific therapy of *arterial ligation*, *cryosurgery*, *electrical cautery*, *APC*, or *submucosal resection* provides temporary relief of epistaxis from HHT. However, these treatments can cause mucosal scarring, which diminishes the efficacy of subsequent septal dermoplasty. Topical intranasal therapy with vasoconstrictors or aminocaproic acid rarely produces scarring. Nonspecific therapies are indicated only for temporary relief of acute bleeding. Life-threatening epistaxis refractory to septal dermoplasty is treated by surgical closure of one or both nostrils, depending on the bleeding source.

Bevacizumab is considered a second-line therapy for GI bleeding from telangiectasias because of limited data on efficacy for this

indication. *Aminocaproic acid* promotes thrombosis and retards bleeding by inhibiting fibrinolysis. Oral aminocaproic acid therapy has had mixed success with HHT. This therapy rarely causes hypotension or rhabdomyolysis. Aminocaproic acid is a temporary, second-line therapy.

Antiestrogen therapy for hereditary hemorrhagic telangiectasia: a double-blind placebo-controlled clinical trial

Yaniv E, Preis M, Hadar T, Shvero J, Haddad M. *Laryngoscope* 2009; 119: 284–8.

In a randomized, placebo-controlled trial of 21 patients with HHT, 9 of 10 patients (90%) treated with orally administered tamoxifen, an estrogen antagonist, had cessation of clinically significant epistaxis versus 3 of 11 patients receiving placebo ($p = 0.01$). This small, placebo-controlled trial suggests that tamoxifen may be effective in preventing epistaxis in HHT.

Herpes genitalis

Ramya Vangipuram, Laura Karas, Kevin Sharghi, Jarad Peranteau, and Stephen K. Tyring

Herpes genitalis, or genital herpes, is a recurrent vesicular eruption of the skin and mucosa in the region between the navel and the buttocks, usually preceded by prodromal symptoms including itching, burning, and tingling. It is a common sexually transmitted disease caused predominantly by herpes simplex virus type 2 (HSV-2) but can also be caused by HSV-1. First-episode genital herpes due to HSV-1 has become increasingly common in certain populations—namely, heterosexual women and men who have sex with men (MSM). Primary infection may have associated influenza-like systemic signs and symptoms, including fever, headache, malaise, and myalgias, which occur 2 to 20 days after exposure. Lesions of the

initial genital herpes infection typically last 2 to 3 weeks, during which time the lesions demonstrate a progression from grouped papules on an erythematous base, to vesicles, to ulcers with eventual crusting. Recurrences generally lack systemic symptoms and are less severe than the primary outbreak. Recurrent lesions occur in the same area but are fewer in number and heal more quickly, typically lasting 5 to 10 days. Genital herpes infection due to HSV-1 results in fewer symptomatic recurrences than infection caused by HSV-2. Residual hypopigmentation, hyperpigmentation, and scarring may occur with healing.

Management Strategy

Because no cure exists for herpes genitalis, treatment is aimed at reducing the number of recurrences using suppressive therapy and at promoting rapid healing when a recurrence is present. In addition, treatment aims to reduce infectivity by reducing viral shedding and to reduce complications such as urinary retention and aseptic meningitis. In the past, *acyclovir*, both topical and oral, was used as a first-line treatment for recurrences. Given acyclovir's low bioavailability, it requires frequent dosing. The standard dosing of oral acyclovir for a recurrence is 200 mg five times daily for 5 days. Alternative regimens have also been shown to be effective, including 400 mg three times daily for 5 days, 800 mg three times daily for 2 days, and 800 mg twice daily for 5 days. The frequent dosing of acyclovir led to the development of *valacyclovir* and *famciclovir* (the prodrugs of acyclovir and penciclovir, respectively) as alternative therapies with improved bioavailability. The use of topical acyclovir should be discouraged, as it is less effective than oral acyclovir. Valacyclovir has been shown to be effective when dosed 500 mg twice daily for 3 days or 1000 mg once daily for 5 days. A dosing regimen of oral valacyclovir, given 2000 mg twice daily for 1 day, has been studied and shown to be more convenient; however, further comparative studies are needed. Famciclovir is effective when prescribed as 1000 mg twice daily for 1 day. It may also be taken as 125 mg twice daily for 5 days. Acyclovir, valacyclovir, and famciclovir may all be used for suppressive therapy.

Immunocompromised individuals have more frequent recurrences and can develop more severe lesions, thus requiring longer treatment periods with higher doses than those used in the immunocompetent.

Severe cases may require intravenous therapy. Suppressive dosage regimens have been used in this population. Long-term therapy may lead to the selection of resistant strains of virus. In acyclovir-resistant cases, intravenous therapy with foscarnet may be required.

Addressing psychosocial issues is another important aspect of genital herpes management. The recurrent nature of genital HSV infection can have severe emotional and psychological impact on patients. Counseling serves to help them cope with the infection and to prevent sexual and perinatal transmission.

Specific Investigations

- Type-specific serologic testing
- Polymerase chain reaction (PCR)
- Viral culture
- Skin biopsy of atypical lesion

Type-specific laboratory testing should be performed to distinguish HSV-2 infections from HSV-1 infections, as this has implications for disease course and patient counseling. Patients with confirmed genital herpes should be offered testing for HIV and other sexually transmitted diseases. Severe or refractory cases may be due to underlying immunosuppression, which should be investigated further.

Precision of the Kalon herpes simplex virus type 2 IgG ELISA: an international interlaboratory assessment

Patel EU, Manucci J, Kahle EM, Lingappa JR, Morrow RA, Piwowar-Manning E, et al. BMC Infect Dis 2015; 15: 398.

Performance of the Focus HerpeSelect-2 EIA for the detection of herpes simplex virus type 2 antibodies in seven African countries

Using the evidence base on genital herpes: optimizing the use of diagnostic tests and information provision

Scoular A. Sex Transm Infect 2002; 78: 160–5.

Polymerase chain reaction for detection of herpes simplex virus (HSV) DNA on mucosal surfaces: comparison with HSV isolation in cell culture

Wald A, Huang M-L, Carrell D, Selke S, Corey L. J Infect Dis 2003; 188: 1345–51.

First-Line Therapies

• Valacyclovir (Valtrex)	A
• Acyclovir (Zovirax)	A
• Famciclovir (Famvir)	A

Primary Genital Infection

Antiviral treatment should be initiated promptly, ideally within 72 hours of the appearance of lesions, and should be continued for 7 to 10 days. Treatment duration may be extended if adequate healing has not occurred. The following regimens may be used: acyclovir 400 mg three times daily or 200 mg five times daily; valacyclovir 1000 mg twice daily; or famciclovir 250 mg three times daily. Acyclovir, valacyclovir, and famciclovir demonstrate similar efficacy. Therefore the initial drug choice may be influenced by factors such as provider preference, cost, and availability. Valacyclovir may be preferable due to the convenience of twice-daily dosing.

Genital herpes

Gnann JW Jr, Whitley RJ. *N Engl J Med* 2016; 375: 666–74.

Genital herpes

Gupta R, Warren T, Wald A. *Lancet* 2007; 370: 2127–37.

Acute Reactivation Episodes

Standard-dose and high-dose daily antiviral therapy for short episodes of genital HSV-2 reactivation: three randomised, open-label, crossover trials

Johnston C, Saracino M, Kuntz S, Magaret A, Selke S, Huang ML, et al. *Lancet* 2012; 379: 641–7. Erratum in: *Lancet* 2012; 379: 616.

Three separate complementary open-label crossover studies compared no medication with acyclovir 400 mg twice daily (standard dose), valacyclovir 500 mg daily (standard dose) with acyclovir 800 mg three times daily (high dose), and standard-dose valacyclovir with valacyclovir 1 g three times daily (high dose). High-dose acyclovir was associated with less viral shedding than standard-dose valacyclovir, but there was no significant difference in time to lesion healing between the groups. High-dose valacyclovir had less viral shedding and shorter lesion healing time compared with its standard dose. Viral shedding persisted even in high-dose regimens.

Single-day therapy for recurrent genital herpes

Tyring S, Berger T, Yen-Moore A, Tharp M, Hamed K. *Am J Clin Dermatol* 2006; 7: 209–11.

A multicenter, randomized, double-blind, placebo-controlled clinical trial found that famciclovir 1000 mg twice daily for 1 day, taken within 6 hours of prodrome onset, resulted in a significant reduction in lesion healing time and reduced the time of all symptom resolution compared with placebo. A greater proportion of subjects who took famciclovir did not progress to a full genital herpes outbreak compared with those taking placebo (23.3% vs. 12.7%, respectively).

Sexually transmitted diseases treatment guidelines 2015

Centers for Disease Control and Prevention. *MMWR Recomm Rep* 2015; 64: 27–32.

Antiviral therapy should be initiated during the prodrome or within 24 hours of the appearance of lesions. Therefore it is important that patients have a supply of drug on hand in order to initiate treatment promptly.

Single-day patient initiated famciclovir therapy for recurrent genital herpes: a randomized, double-blind, placebo-controlled trial

Aoki FY, Tyring S, Diaz-Mitoma F, Gross G, Gao J, Hamed K. Clin Infect Dis 2006; 42: 8–13.

This study proved that in addition to being convenient (potentially a boon for increased patient compliance), single-day therapy is safe and effective for the treatment of recurrent genital herpes. Subjects receiving 1000 mg famciclovir orally twice daily for 1 day healed approximately 2 days faster than those on placebo.

A randomized, placebo-controlled comparison of oral valacyclovir and acyclovir in immunocompetent patients with recurrent genital herpes infections

Tyring SK, Douglas JM, Corey LC, Spruance SL, Esmann J. Arch Dermatol 1998; 134: 185–91.

This multicenter, double-blind, placebo-controlled, randomized, parallel-design study showed that oral valacyclovir 1000 mg twice daily for 5 days was as effective and well tolerated as acyclovir five times daily for 5 days for the treatment of recurrent genital herpes.

Prophylactic Treatment

Prophylactic treatment for frequent reactivation, recurrent severe attacks, at bone marrow transplantation, or before delivery.

Effect of valacyclovir on viral shedding in immunocompetent patients with recurrent herpes simplex virus 2 genital herpes: a US-based randomized, double-blind, placebo-controlled clinical trial

Fife KH, Warren TJ, Ferrera RD, Young DG, Justus SE, Heitman CK, et al. Mayo Clin Proc 2006; 81: 1321–7.

Over a 60-day period 1 g of valacyclovir daily was well tolerated and effectively reduced clinical and subclinical HSV-2 shedding compared with placebo.

Once-daily valacyclovir to reduce the risk of transmission of genital herpes

Corey L, Wald A, Patel R, Sacks SL, Tyring SK, Warren T, et al. *N Engl J Med* 2004; 350: 11–20.

Among heterosexual HSV-2 discordant couples, once-daily valacyclovir (500 mg) significantly reduced the risk of transmission of genital herpes. Clinically symptomatic HSV-2 infection was reduced by 75%, and acquisition of HSV-2 was reduced by 48% in the valacyclovir group versus placebo.

Valacyclovir therapy to reduce recurrent genital herpes in pregnant women

Andrews WW, Kimberlin DF, Whitley R, Cliver S, Ramsey PS, Deeter R. *Am J Obstet Gynecol* 2006; 194: 774–81.

This double-blind, placebo-controlled, randomized trial showed that daily valacyclovir, initiated at 36 weeks' gestation in HSV-positive pregnant women with a history of recurrences, significantly reduced the number of women with subsequent clinical HSV recurrences. However, this suppressive regimen did not reduce shedding of HSV within 7 days of delivery compared with placebo. The number of women with clinical HSV lesions at delivery was similar for both the placebo and the treatment group.

Effect of serologic status and cesarean delivery on transmission rates of herpes simplex virus from mother to infant

Brown ZA, Wald A, Morrow RA, Selke S, Zeh J, Corey L. *JAMA* 2003; 289: 203–9.

Among women with HSV in genital secretions at the time of labor, the risk of neonatal HSV was significantly reduced in those who had a cesarean delivery.

Sexually transmitted diseases treatment guidelines 2015

Centers for Disease Control and Prevention. *MMWR Recomm Rep* 2015; 64: 27–32.

Severe HSV infection, or complications requiring hospitalization, such as disseminated infection, pneumonitis, hepatitis, meningitis, or encephalitis, requires intravenous antiviral therapy. A regimen of acyclovir 5 to 10 mg/kg intravenously every 8 hours for a minimum of 2 days until clinical improvement occurs is recommended. Transition to oral antiviral therapy is recommended to complete a 10-day course.

Frequent reactivation of herpes simplex virus among HIV-1-infected patients treated with highly active antiretroviral therapy

Posavad CM, Wald A, Kuntz S, Huang ML, Selke S, Krantz E, et al. J Infect Dis 2004; 190: 693–6.

In HIV-infected individuals, antiretroviral therapy reduced the frequency and severity of symptomatic genital herpes. However, frequent asymptomatic viral shedding occurred.

Sexually transmitted diseases treatment guidelines 2015

Centers for Disease Control and Prevention. MMWR Recomm Rep 2015; 64: 27–32.

Acyclovir, valacyclovir, and famciclovir are safe to use in immunocompromised patients. Treatment duration is generally for 5 to 10 days of the following: acyclovir 400 mg three times daily, famciclovir 500 mg twice daily, or valacyclovir 1 g twice daily. Intravenous therapy may be required in severe cases.

Valacyclovir prophylaxis for the prevention of herpes simplex virus reactivation in recipients of progenitor cell transplantation

Dignani MC, Mykietiuk A, Michelet M, Intile D, Mammana L, Desmery P, et al. Bone Marrow Transplant 2002; 29: 263–7.

In over 100 patients after bone marrow transplantation, equal efficacy between intravenous acyclovir and oral valacyclovir was seen compared with no prophylaxis.

Second-Line Therapies

• Foscarnet	B
• Cidofovir	A

A multicenter phase I/II dose escalation study of single-dose cidofovir gel for treatment of recurrent genital herpes

Sacks SL, Shafran SD, Diaz-Mitoma F, Trottier S, Sibbald RG, Hughes A, et al. *Antimicrob Agents Chemother* 1998; 42: 2996–9.

A randomized, double-blind, clinic-initiated, sequential dose-escalation pilot study compared the safety and efficacy of single applications of 1%, 3%, and 5% cidofovir gel with placebo in the treatment of early lesional recurrent genital herpes. At all strengths, cidofovir significantly reduced the median time to negative virus culture in a dose-dependent fashion. Single-dose application of cidofovir gel confers a significant antiviral effect on lesions of recurrent genital herpes.

Clinical potential of the acyclic nucleoside phosphonates cidofovir, adefovir, and tenofovir in treatment of DNA virus and retrovirus infections

De Clercq E. *Clin Microbiol Rev* 2003; 16: 569–96.

The acyclic nucleoside phosphonate HPMPC (cidofovir) was proven effective in vitro and in vivo against a wide variety of DNA virus and retrovirus infections, including HSV types 1 and 2.

Foscarnet treatment of acyclovir-resistant herpes simplex virus infection in patients with acquired immunodeficiency syndrome: preliminary results of a controlled, randomized, regimen-controlled trial

Hardy WD. *Am J Med* 1992; 92: 30s–5s.

Twenty-five patients with AIDS and acyclovir-resistant HSV infection were treated with foscarnet infusions for 2 weeks, followed by 8 more weeks either with 40 mg/kg daily or without further treatment. Lesions healed most quickly in those treated for a total of 10 weeks.

Third-Line Therapies

• Aspirin	B
• Resiquimod	A
• Topical imiquimod	E

Aspirin in the management of recurrent herpes simplex virus infection

Karadi I, Karpati S, Romics L. Ann Intern Med 1998; 128: 696–7.

This study showed that patients treated with aspirin 125 mg daily had significantly fewer days of active HSV infection than controls who took no antiviral or antiinflammatory drugs. Of the 21 subjects, only 2 had recurrent genital HSV; the remainder had recurrent oral HSV.

Topical resiquimod 0.01% gel decreases herpes simplex virus type 2 genital shedding: a randomized, controlled trial

Mark KE, Corey L, Meng TC, Magaret AS, Huang ML, Selke S, et al. J Infect Dis 2007; 195: 1324–31.

A randomized, double-blind, vehicle-controlled trial assessed the efficacy of resiquimod 0.01% gel for reducing human anogenital HSV-2 mucosal reactivation. Adults with genital HSV-2 applied topical resiquimod or vehicle to anogenital lesions twice weekly for 3 weeks. The median lesion and shedding rates were lower for the treatment group than in the vehicle group for both sampling periods. The length of recurrence was not influenced by resiquimod treatment.

Treatment of recalcitrant herpes simplex virus with topical imiquimod

Hirokawa D, Woldow A, Lee SN, Samie F. Cutis 2011; 88: 276–7.

In this case report, an HIV-positive man with valacyclovir-resistant genital HSV-2 was successfully treated with topical imiquimod 5% cream three times weekly for 8 weeks.

Novel and Other Therapies

- Helicase-primase inhibitors
- Psychosocial counseling
- Hygiene techniques

Effect of pritelivir compared with valacyclovir on genital HSV-2 shedding in patients with frequent recurrence: a randomized clinical trial

Wald A, Timmler B, Magaret A, Warren T, Tyring S, Johnston C, et al. JAMA 2016; 316: 2495–2503.

This phase II, randomized, double-blind, crossover trial compared oral pritelivir, a novel HSV helicase-primase inhibitor, dosed at 100 mg once daily, to oral valacyclovir 500 mg once daily. The study demonstrated a significantly lower rate of genital HSV shedding and lesions in the pritelivir arm versus the valacyclovir arm. Pritelivir thus appears to be significantly more effective than valacyclovir, though further investigation into long-term safety and efficacy is needed.

Sexually transmitted diseases treatment guidelines 2015

Centers for Disease Control and Prevention. MMWR Recomm Rep 2015; 64: 27–32.

Counseling of infected individuals serves to prevent sexual and perinatal infection and to help individuals cope with infection. Education for infected individuals seems to be of benefit both at the time of diagnosis and after resolution of the acute infection to further their understanding of the chronic nature of the disease.

Genital herpes: a review

Beauman JG, Maj MC. Am Fam Phys 2005; 72: 1527–34, 1541–2.

Prevention of secondary infection and spread of the infection can be achieved by keeping the affected area clean and dry, wearing loose-fitting clothing and cotton underwear, avoiding contact with the lesions, and washing hands immediately should contact with any sores occur.

Prevention

- Condoms
- Vaccine

- Disclosure to sexual partners

A pooled analysis of the effect of condoms in preventing HSV-2 acquisition

Martin ET, Krantz E, Gottlieb SL, Magaret AS, Langenberg A, Stanberry L, et al. Arch Intern Med 2009; 169: 1233–40.

This pooled analysis of over 5000 HSV-2–negative individuals at baseline showed that consistent use of condoms was associated with a 30% reduction in risk of acquiring HSV-2 compared with those with no condom use (HR of 0.70, 95% confidence interval (CI), 0.40–0.94, $p = 0.01$).

Knowledge of partners' genital herpes protects against herpes simplex virus type 2 acquisition

Wald A, Krantz E, Selke S, Lairson E, Morrow RA, Zeh J. J Infect Dis 2006; 194: 42–52.

This study utilized a time-to-event design to demonstrate that disclosure of genital herpes to an individual's partner increased the mean time to HSV-2 acquisition (270 days vs. 60 days, $p = 0.03$) compared with those who did not disclose their condition. Disclosure of HSV-2 infection to sexual partners has the potential to serve as a protective factor against HSV-2 transmission.

Effect of condoms on reducing the transmission of herpes simplex virus type 2 from men to women

Wald A, Langenberg AG, Link K, Izu AE, Ashley R, Warren T, et al. JAMA 2001; 285: 3100–6.

In heterosexual discordant couples in which the male is infected with HSV-2, the use of condoms confers protection against transmission in susceptible women. A concurrent reduction in sexual activity when the source partner had lesions also occurred as a result of counseling on sexual behavior.

Therapeutic vaccine for genital herpes simplex virus-2 infection: findings from a randomized trial

Bernstein D, Wald A, Warren T, Fife K, Tyring S, Lee P, et al. J Infect Dis 2017; 215: 856–64.

This double-blind, placebo-controlled, dose-escalation study evaluated a purified protein subunit vaccine currently in development for HSV-2. The vaccine was shown to have an

acceptable safety profile. It demonstrated immunogenicity and reduced recurrent episodes of viral shedding and days with lesions. Further investigation is needed to determine the optimal dose and the duration of the protective effects.

Efficacy results of a trial of a herpes simplex vaccine

Belshe RB, Leone PA, Bernstein DI, Wald A, Levin MJ, Stapleton JT, et al. *N Engl J Med* 2012; 366: 34–43.

In this randomized, double-blind trial, 8323 women seronegative for HSV-1 and HSV-2 received the investigational vaccine (20 µg of glycoprotein D from HSV-2 with alum and 3-O-deacylated monophosphoryl lipid A as an adjuvant) at months 0, 1, and 6. The vaccine was found to be effective in preventing HSV-1, but not HSV-2, disease and infection.

Herpes labialis

Jane C. Sterling

Herpes simplex virus (HSV) infects skin and mucous membranes, damaging keratinocytes and causing intense inflammation, seen as small blisters with erythema. Infections around the mouth or elsewhere on the skin are usually due to HSV-1, whereas genital infection is most commonly caused by HSV-2. The primary infection may be obvious or subclinical; once latency is established in sensory

ganglia, reactivation can occur at variable intervals. In immunosuppression, disease can be chronic, and antiviral resistance can develop.

Management Strategy

Both primary and reactivation episodes are usually self-limiting and may require no treatment. Antiseptic creams, alcohol-based tinctures, or surface dressings can be soothing self-help remedies. Antiviral therapy, such as *aciclovir* and related drugs, is available for topical and systemic use and is an effective form of treatment. Although anogenital herpes responds well, *topical aciclovir*, applied five times daily for 5 days, in cutaneous herpes results in marginal benefit. The effect in trials, when compliance is usually good, is reported to be a reduction in pain and healing time of approximately 12 hours.

Application of aciclovir with an adhesive patch inside the mouth, resulting in continuous local therapy, reduces time to healing by 1 day compared with placebo. Aciclovir 5% in combination with 1% hydrocortisone cream applied 5 times per day is safe and appears to reduce the risk of ulceration. *Oral aciclovir*, 200 mg five times daily for 5 days, will usually reduce the time to healing and duration of virus shedding more effectively than topical treatment. Shorter treatment courses with higher dose aciclovir produce similar effects. Topical or systemic treatment for an acute episode should be started early in the episode to have most benefit. In addition, pain relief may be necessary. Occlusion with gel or an adhesive patch can reduce pain and discomfort.

A failure of response to aciclovir may be due to the poor absorption and rapid clearance after ingestion or to the emergence of aciclovir resistance. *Valaciclovir*, a prodrug of aciclovir, and *famciclovir*, a prodrug of penciclovir, have improved bioavailability, and dosing is once or twice daily. A short course (single day) treatment with oral *famciclovir* can hasten healing if taken at the start of a reactivation episode. Efficacy of oral valaciclovir can be as good as intravenous aciclovir.

In frequently recurrent disease, or in immunosuppressed individuals when episodes may be severe, prophylactic antiviral treatment can be considered together with avoidance of any precipitating factors. *UV protection* may help to reduce viral reactivation in herpes labialis. To reduce frequency and severity of

attacks, antiviral treatment needs to be continuous for several weeks or months. Aciclovir 400 mg twice daily is likely to produce a decrease in the frequency of reactivation episodes; valaciclovir or famciclovir may be prescribed as alternatives. There is a potential risk of selection of resistant strains of virus with long-term therapy, but this is rare even in immunosuppressed patients. Oral antivirals may be taken as a relatively short-term course to reduce the risk of a reactivation episode before and during intense sun exposure or before dental or cosmetic procedures.

Low-intensity light from a diode laser has been shown to increase the recurrence-free interval.

In immunosuppressed individuals with spreading or persistent infection, intravenous therapy with aciclovir, or the more toxic *foscarnet* or *cidofovir*, may be necessary. Topical preparations of cidofovir have been shown to have effect but are not commercially available. *Vidarabine*, *interferons*, and *interleukin-2* and other agents have also been used but without reliable effect. Herpes simplex is a common precipitating cause of episodes of recurrent erythema multiforme (see page NPI), which can be reduced in frequency by prophylactic antiviral therapy.

Other treatments reported to have some effect in acute attacks include the antivirals *idoxuridine*, *trifluorothymidine (TFT)*, *inosine pranobex*, and *docosanol*, used topically, and low-level light therapy.

Specific Investigations

- Polymerase chain reaction (PCR) of blister fluid or biopsy
- Viral culture from swab of lesion
- Immunocytology of blister floor cells
- Electron microscopy of blister fluid
- Skin biopsy of atypical lesion
- Herpes simplex serology
- Assessment of immune function

The diagnosis is usually obvious clinically. In atypical disease, laboratory confirmation is essential. In unexplained persistent or severe disease, immunodeficiency should be excluded.

First-Line Therapies

• Topical aciclovir	A
• Topical aciclovir with hydrocortisone	A
• Oral aciclovir	A
• Occlusion with gel or patch	B

Primary cutaneous infection

Treatment of herpes simplex gingivostomatitis with aciclovir in children: a randomized double blind placebo controlled study

Amir J, Harel L, Smetana Z, Varsano I. BMJ 1997; 314: 1800–3.

A total of 61 children with herpetic gingivostomatitis were treated with aciclovir suspension 15 mg/kg or placebo five times daily for 7 days. Aciclovir reduced the duration of lesions from 10 to 4 days and reduced the period of viral shedding.

Acute reactivation episodes

Aciclovir cream for treatment of herpes simplex labialis: results of 2 randomized, double-blind, vehicle-controlled multicenter clinical trials

Spruance SL, Nett R, Marbury T, Wolff R, Johnson J, Spaulding T. Antimicrob Agents Chemother 2002; 46: 2238–43.

In two studies of a total of 1385 patients with recurrent herpes labialis, aciclovir 5% cream applied five times a day for 4 days reduced time to healing to an average of 4.4 days compared with 5.0 days when placebo was used.

Efficacy and safety of aciclovir mucoadhesive buccal tablet in immunocompetent patients with labial herpes (LIP Trial): a double-blind, placebo-controlled, self-initiated trial

Bieber T, Chosidow O, Bodsworth N, Tyring S, Hercogova J, Bloch M,

et al. *J Drugs Dermatol* 2014; 13: 791–8.

A large double-blind, placebo-controlled study of adherent buccal patch containing either aciclovir or placebo showed a reduction in time to healing of 1 day and fewer reactivation episodes in the 9 months after a single treatment.

Effectiveness of topical corticosteroids in addition to antiviral therapy in the management of recurrent herpes labialis: a systematic review and meta-analysis

Arain N, Paravastu SC, Arain MA. *BMC Infect Dis* 2015; 15: 82.

In-depth review of four studies concluding that the combination of topical aciclovir and corticosteroid reduced ulceration but did not decrease the healing rate compared with aciclovir alone.

Treatment of recurrent herpes simplex labialis with oral aciclovir

Spruance SL, Stewart JCB, Rowe NH, McKeough MB, Wenerstrom G, Freeman DJ. *J Infect Dis* 1990; 161: 185–90.

Herpes labialis was less painful and quicker to heal in 114 patients treated early with 400 mg aciclovir, five times daily for 5 days, compared with 60 given placebo treatment. The blister development and lesion size were not affected by treatment.

Evaluation of the efficacy and safety of a CS20 protective barrier gel containing OGT compared with topical aciclovir and placebo on functional and objective symptoms of labial herpes recurrences: a randomized clinical trial

Khemis A, Duteil L, Coudert AC, Tillet Y, Dereure O, Ortonne JP. *J Eur Acad Dermatol Venereol* 2012; 26: 1240–6.

Application five times a day of either aciclovir cream or the glycerol-containing gel gave similar time to healing, but those using the gel had less pain.

Second-Line Therapies

• Topical penciclovir	B
• Oral valaciclovir	A
• Oral famciclovir	A
• Low-level infrared, light	B

Recurrent herpes labialis: efficacy of topical therapy with penciclovir compared with aciclovir

Femiano F, Gombos F, Scully C. Oral Dis 2001; 7: 31–3.

Aciclovir 5% cream or penciclovir 1% cream was applied every 2 hours during waking hours for 4 days. Penciclovir treatment reduced the duration of symptoms by 1 day.

High-dose, short-duration, early valaciclovir therapy for episodic treatment of cold sores: results of two randomized, placebo-controlled multicenter studies

Spruance S, Jones T, Blatter MM, Vargas-Cortez M, Barber J, Hill J, et al. Antimicrob Agents Chemother 2003; 47: 1072–80.

Immediate treatment with either 2 g twice daily for 1 day or 2 g twice daily for 1 day plus 1 g twice daily for 1 day reduced the duration of the episode (5–5.5 days with placebo) by 0.5 to 1 day. The chance of an aborted episode was increased.

Single-dose, patient-initiated famciclovir: a randomized, double-blind, placebo-controlled trial for episodic treatment of herpes labialis

Spruance SL, Bodsworth N, Resnick H, Conant M, Oeuvray C, Gao J, et al. J Am Acad Dermatol 2006; 55: 47–53.

Famciclovir 750 mg twice daily for 1 day or famciclovir 1500 mg as a single dose were compared with placebo with 375 patients completing the study. Lesions healed in approximately 4 days in both groups taking famciclovir compared with 6 days for the placebo group.

Evaluation of the efficacy of low-level light therapy using 1072 nm infrared light for the treatment of herpes simplex labialis

Dougal G, Lee SY. Clin Exp Dermatol 2013; 38: 713–8.

In a randomized, placebo-controlled study, the light treatment, given in 3-minute irradiations six times over 2 days, reduced healing time to 5 days compared with 7 days for placebo.

Third-Line Therapies

• Intravenous aciclovir	A
• Intravenous vidarabine	C
• Intravenous foscarnet	C
• Intravenous cidofovir	C
• Topical cidofovir	C

Multicenter collaborative trial of intravenous aciclovir for treatment of mucocutaneous herpes simplex virus infection in the immunocompromised host

Meyers JD, Wade JC, Mitchell CD, Saral R, Lietman PS, Durack DT, et al. Am J Med 1982; 73: 229–35.

Aciclovir given intravenously (250 mg/m², three times per day for 7 days) to immunocompromised patients with active HSV infection (85% oral disease) was superior to placebo in reduction of pain and healing time, plus reduction in duration of virus shedding.

Foscarnet treatment of aciclovir-resistant herpes simplex virus infection in patients with acquired immunodeficiency syndrome: preliminary results of a controlled, randomized, regimen-

controlled trial

Hardy WD. Am J Med 1992; 92 (Suppl 2A): 30s–5s.

Twenty-five patients with acquired immune deficiency syndrome (AIDS) and aciclovir-resistant HSV infection were treated with foscarnet infusions for 2 weeks and then either for a further 8 weeks with 40 mg/kg daily or without further maintenance therapy. Healing of lesions was quickest in those treated for 10 weeks.

A controlled trial comparing foscarnet with vidarabine for aciclovir-resistant mucocutaneous herpes simplex in the acquired immunodeficiency syndrome

Safrin S, Crumpacker C, Chatis P, Davis R, Hafner R, Rush J, et al. N Engl J Med 1991; 325: 551–5.

Foscarnet 40 mg/kg every 8 hours produced healing of aciclovir-resistant herpetic lesions within 4 weeks in eight patients with AIDS, whereas no improvement occurred in six similar patients treated with vidarabine 15 mg/kg daily.

Treatment with intravenous (S)-1-[hydroxy-2-(phosphonylmethoxy)propyl]-cytosine of aciclovir-resistant mucocutaneous infection with herpes simplex virus in a patient with AIDS

Lalezari JP, Drew WL, Glutzer E, Miner D, Safrin S, Owen WF, et al. J Infect Dis 1994; 170: 570–2.

Treatment with four intravenous infusions of 5 mg/kg/week of HPMPC (cidofovir) produced 95% healing in a patient with severe resistant herpetic lesions.

A randomized, double-blind, placebo-controlled trial of cidofovir gel for the treatment of aciclovir-unresponsive mucocutaneous herpes simplex virus infection in patients with AIDS

Lalezari J, Schacker T, Feinberg J, Gathe J, Lee S, Cheung T, et al. J Infect Dis 1997; 176: 892–8.

Twenty patients with AIDS applied 0.3% or 1% cidofovir gel once daily for 5 days; 50% healed or improved compared with 0% of the 10 placebo-treated patients. Cidofovir produced local inflammation in a quarter of patients.

Prophylactic Treatment

• Sunscreen	A
• Oral aciclovir	A
• Oral valaciclovir	A
• Oral famciclovir	B
• Low-intensity diode laser	B

Prevention of ultraviolet-light-induced herpes labialis by sunscreen

Rooney JF, Bryson Y, Mannix ML, Dillon M, Wohlenberg CR, Banks S, et al. Lancet 1991; 338: 1419–22.

Using an experimental UV exposure to induce reactivation of herpes, lesions developed in 71% of 38 patients using a placebo but none in 35 patients using sunscreen.

Oral aciclovir to suppress frequently recurrent herpes labialis: a double-blind, placebo-controlled trial

Rooney JF, Straus SE, Mannix ML, Wohlenberg CR, Alling DW, Dumois JA, et al. Ann Int Med 1993; 118: 268–72.

Twenty patients completed a randomized 4-month crossover study receiving aciclovir 400 mg twice a day or placebo. During active treatment, there were an average of 0.85 reactivation episodes compared with 1.8 during placebo treatment.

Valaciclovir prophylaxis for the prevention of herpes simplex virus reactivation in recipients of progenitor cell transplantation

Dignani MC, Mykietiak A, Michelet M, Intile D, Mammana L,

Desmery P, et al. Bone Marrow Transplant 2002; 29: 263–7.

Comparison of intravenous aciclovir, oral valaciclovir, or no prophylaxis after bone marrow transplantation in over 100 patients showed equal efficacy of the two antivirals.

Famciclovir prophylaxis of herpes zoster virus reactivation after laser skin resurfacing

Alster TS, Nanni CA. Dermatolog Surg 1999; 25: 242–6.

The expected rate of HSV reactivation after facial cosmetic laser or chemical peel procedures is approximately 10%. With oral famciclovir, 250 or 500 mg twice daily for 10 days, the reactivation rate was similar for both doses.

The efficacy of valaciclovir in preventing recurrent herpes simplex virus infections associated with dental procedures

Miller CS, Cunningham LL, Lindroth JE, Avdiushko SA. J Am Dent Assoc 2004; 135: 1311–8.

In a placebo-controlled trial of 125 adults with recurrent herpes labialis, valaciclovir (2 g twice a day on the day of dental treatment, with 1 g twice a day the following day) reduced the incidence of reactivation episodes from 20% (placebo) to 11% with antiviral treatment.

Low-intensity laser therapy is an effective treatment for recurrent herpes simplex infection. Results from a randomized double-blind placebo-controlled study

Schindl A, Neumann R. J Invest Dermatol 1999; 113: 221–3.

Forty-eight patients with monthly reactivation were irradiated daily for 2 weeks with either placebo or 690 nm light from a diode laser during quiescence. During the 1-year follow-up period, median recurrence-free interval was 3 weeks in the placebo group and 37.5 weeks in the treatment group.

Other Therapies

Multicenter randomized study of inosine pranobex versus aciclovir in the treatment of recurrent herpes labialis and recurrent herpes genitalis in Chinese patients

You Y, Wang L, Li Y, Wang Q, Cao S, Tu Y, et al. J Dermatol 2015; 42: 596–601.

One hundred forty-four patients received either oral inosine pranobex 1 g four times per day plus placebo aciclovir or aciclovir 200 mg five times per day plus placebo inosine pranobex. The two groups were comparable in symptoms and time to healing.

Clinical efficacy of topical docosanol 10% cream for herpes simplex labialis: a multicenter, randomized, placebo-controlled trial

Sacks SL, Thisted RA, Jones TM, Barbarash RA, Mikolich DJ, Ruoff GE, et al. J Am Acad Dermatol 2001; 45: 222–30.

Docosanol 10% cream applied five times a day until healing reduced symptoms and healing by approximately 1 day.

Herpes zoster

Zeena Nawas, Michael M. Hatch, and Stephen K. Tyring

Reactivation of latent varicella zoster virus (VZV) produces the clinical syndrome herpes zoster (shingles), which manifests as a unilateral eruption along a single dermatome and is usually preceded by prodromal pain and paresthesia. The eruption lasts around 7 to 10 days and progresses from erythematous macules and papules to vesicles, then pustules, and finally crusts over. One of the most common complications of herpes zoster is postherpetic neuralgia (PHN), which is dermatomal pain persisting longer than 3 months.

Management Strategy

Early treatment—within the first 72 hours of vesicle formation—is important for antiviral efficacy, time to lesion healing, and minimizing zoster-associated pain (although initiating treatment after 72 hours may still be effective). *Aciclovir*, *valaciclovir*, and *famciclovir* are guanosine analogs that are phosphorylated by thymidine kinase to a triphosphate form that inhibits viral deoxyribonucleic acid (DNA) polymerase. The oral bioavailability of the antivirals determines the number of daily administrations. Patient compliance tends to decrease as the number of daily administrations increases. The most common side effects seen are nausea, headache, and gastrointestinal upset, but these drugs are otherwise safe and well tolerated. Patients with renal insufficiency will need an adjusted dose, as these medications are excreted by the kidneys.

Aciclovir-resistant VZV infections have been reported in immunocompromised patients (i.e., acquired immune deficiency syndrome (AIDS), transplant patients), and in these cases *foscarnet* (given intravenously 40 mg/kg three times daily) can be used as an alternative.

Acutely, *corticosteroids* may reduce zoster-associated pain, but they are associated with a risk of serious adverse events and have shown no benefit in reducing time to complete cessation of pain or prevention of PHN.

Pain management is especially difficult with conventional analgesics in zoster patients who develop PHN. Calcium channel $\alpha 2$ - δ ligands (gabapentin and pregabalin), tricyclic antidepressants, opioids, topical lidocaine ([Table 105.1](#)), selective serotonin and norepinephrine reuptake inhibitors (duloxetine and venlafaxine), and topical capsaicin have been shown to reduce the pain associated with PHN. Of these medications, only gabapentin, pregabalin, 5% lidocaine patch, and 8% capsaicin patch have been approved by the Food and Drug Administration (FDA) specifically for the treatment of PHN. Adding gabapentin to an antiviral in patients with acute herpes zoster appears to significantly reduce the incidence of PHN. In January 2011, the FDA approved Gralise as a once-daily medication for the treatment of postherpetic neuralgia. Gralise is an extended-release form of gabapentin that not only has been shown to significantly decrease PHN pain scores but may also be associated with fewer side effects than its immediate-release counterpart. In 2012

the FDA approved Horizant, gabapentin enacarbil, for the once-daily therapy of PHN.

Vaccination of patients aged 50 years and over is the most promising option for the prevention of herpes zoster and therefore PHN. As of April 2016, the only FDA-approved zoster vaccine for adults is Zostavax. In a clinical trial involving more than 38,000 adults 60 years of age or older, the vaccine was shown to reduce the incidence of herpes zoster by 51% and the incidence of PHN by 67%. In 2006 the Advisory Committee on Immunization Practices recommended a single dose of zoster vaccine for adults 60 years of age or older, whether or not they have had a previous episode of herpes zoster. A subsequent clinical trial that studied Zostavax in patients aged 50 to 59 years showed that the vaccine efficacy for preventing herpes zoster was 69.8% in this age group. In 2011 the FDA approved Zostavax for patients 50 to 59 years of age. An adjuvanted herpes zoster subunit vaccine (HZ/su), which is currently being studied but is not yet approved, was shown to significantly reduce the risk of herpes zoster among adults who were 50 years of age or older. However, unlike Zostavax, the HZ/su vaccine efficacy was well preserved among participants who were 70 years of age or older.

Specific Investigations

No investigation is usually required

- Tzanck smear
- Virology (culture, serology [acute plus chronic], electron microscopy, polymerase chain reaction)

First-Line Therapies

• Aciclovir 800 mg five times daily for 7 days	A
• Famciclovir 500 mg three times daily for 7 days	A
• Valaciclovir 1 g three times daily for 7 days	A

Valaciclovir compared with aciclovir for improved therapy for herpes zoster in immunocompetent adults

Beutner KR, Friedman DJ, Forszpaniak C, Andersen PL, Wood MJ. Antimicrob Agents Chemother 1995; 39: 1546–53.

Valaciclovir is comparable to aciclovir in the resolution of zoster eruption, but it accelerates the resolution of pain compared with aciclovir and is more convenient.

Factors influencing pain outcome in herpes zoster: an observational study with valaciclovir

Decroix J, Partsch H, Gonzalez R, Mobacken H, Goh CL, Walsh L, et al. Valaciclovir Zoster Assessment Group (VIZA). J Eur Acad Dermatol Venereol 2000; 14: 23–33.

Table 105.1

Treatment options for postherpetic neuralgia

Drug class	Examples	Initial daily dose (mg)	Titration to maximum dose
Calcium channel α 2- δ ligands	Gabapentin	100–300	Start once at night and increase to three times daily dosing; increase by 100–300 mg every 3 days to total dose of 1800–2400 mg/day
	Gabapentin enacarbil		600 mg once daily in the morning for 3 days, then increase to 600 mg twice daily
	Pregabalin	150	Titrate up to 300 or 600 mg/day
Opioids	Hydrocodone	5–10	No titration
	Oxycodone (extended release)	20	Titrate up to 60 mg daily
Tricyclic antidepressants	Nortriptyline	10–25	Increase by 10–25 mg weekly, with a target dose of 75–150 mg daily; single dose or two divided doses
	Amitriptyline	10–25	Titrate up to 100 mg daily; single dose
	Desipramine	10–25	Increase every 3 days as needed up to 150 mg daily; single dose

An open-label study using a 7-day course of valaciclovir to treat 1897 immunocompetent patients. Valaciclovir was safe, effective (even when initiated more than 72 hours after the first vesicle), and associated with very few adverse events.

Famciclovir for the treatment of acute herpes zoster: effects on acute disease and postherpetic neuralgia. A randomized, double-blind, placebo controlled trial

Tyring S, Barbarash RA, Nahlik JE, Cunningham A, Marley J, Heng M, et al. Ann Intern Med 1995; 123: 89–96.

Famciclovir recipients had faster resolution of pain after an acute episode than those receiving placebo.

Double-blind, randomized, aciclovir-controlled, parallel-group trial comparing the safety and efficacy of famciclovir and aciclovir in patients with uncomplicated herpes zoster

Shen MC, Lin HH, Lee SS, Chen YS, Chiang PC, Liu YC. J Microbiol

Immunol Infect 2004; 37: 75–81.

Famciclovir is comparable to aciclovir in the resolution of zoster cutaneous eruption but is more convenient and had a more favorable adverse event profile.

A comparative study to evaluate the efficacy and safety of aciclovir and famciclovir in the management of herpes zoster

Gopal MG, Shannoma, Kumar S, Ramesh M, Nandini AS, Manjunath NC. Clin Diagn Res 2013; 7: 2904–7.

Oral famciclovir given at 250 mg three times daily for 7 days is as effective as aciclovir 800 mg five times daily.

Oral aciclovir therapy accelerates pain resolution in patients with herpes zoster: a meta-analysis of placebo-controlled trials

Wood MJ, Kay R, Dworkin RH, Soong SJ, Whitley RJ. Clin Infect Dis 1996; 22: 341–7.

In four placebo-controlled studies aciclovir was clearly shown to accelerate pain resolution.

Antiviral treatment for preventing postherpetic neuralgia

Chen N, Li Q, Yang J, Zhou M, Zhou D, He L. Cochrane Database Syst Rev 2014; 2: CD006866.

Oral aciclovir does not significantly reduce the incidence of PHN.

Second-Line Therapies

Agents to reduce postherpetic neuralgia

• Calcium channel $\alpha 2$ - δ ligands (gabapentin, pregabalin)	A
• Tricyclic antidepressants	A
• Lidocaine patch	A
• Oxycodone	A

Pregabalin for the treatment of postherpetic neuralgia: a randomized, placebo-controlled trial

Dworkin RH, Corbin AE, Young JP, Sharma U, LaMoreaux L,

Bockbrader H, et al. Neurology 2003; 60: 1274–83.

Pregabalin is effective in the treatment of pain and sleep interference associated with PHN.

Efficacy and safety of gabapentin 1800 mg treatment for postherpetic neuralgia: a meta-analysis of randomized controlled trials

Fan H, Yu W, Zhang Q, Cao H, Li J, Wang J, et al. J Clin Pharm Ther 2014; 39: 334–42.

A meta-analysis of randomized controlled trials found gabapentin 1800 mg to significantly reduce postherpetic neuralgia up to 14 weeks. Treatment at this dose was safe up to 24 weeks. Comparison between once-daily and divided-dose gabapentin for the treatment of PHN showed no significant difference in efficacy.

Incidence of postherpetic neuralgia after combination treatment with gabapentin and valaciclovir in patients with acute herpes zoster: open-label study

Lapolla W, Digiorio C, Haitz K, Magel G, Mendoza N, Grady J, et al. Arch Dermatol 2011; 147: 901–7.

The addition of gabapentin to valaciclovir produced a significant reduction in PHN. Therefore it is recommended that gabapentin be initiated in addition to antivirals for the treatment of acute zoster with moderate to severe pain at presentation.

Gabapentin versus nortriptyline in postherpetic neuralgia patients: a randomized, double blind clinical trial: the GONIP Trial

Chandra K, Shafiq N, Pandhi P, Gupta S, Malhotra S. Int J Clin Pharmacol Ther 2006; 44: 358–63.

Gabapentin and nortriptyline are equally efficacious, but gabapentin is better tolerated.

Nortriptyline versus amitriptyline in postherpetic neuralgia: a randomized trial

Watson CP, Vernich L, Chipman M, Reed K. Neurology 1998; 51: 1166–71.

Nortriptyline is equally as effective as amitriptyline but is better tolerated.

The effects of preemptive treatment of postherpetic neuralgia with amitriptyline: a randomized, double-blind, placebo-controlled trial

Bowsher D. J Pain Symptom Manage 1997; 13: 327–31.

Low-dose amitriptyline given at the time of the acute zoster rash may reduce the incidence of PHN.

Topical lidocaine for the treatment of postherpetic neuralgia

Khaliq W, Alam S, Puri N. Cochrane Database Syst Rev 2007; 2: CD004846.

A meta-analysis combining two studies found that lidocaine is more effective than placebo, but there is insufficient evidence to recommend it as a first-line therapy. The studies cited in the review used 5% lidocaine gel applied for 8 to 24 hours or 5% lidocaine patch applied up to three times daily.

Efficacy of oxycodone in neuropathic pain: a randomized trial in postherpetic neuralgia

Watson CPN, Babul N. Neurology 1998; 50: 1837–41.

Patients on slow-release oxycodone had significantly greater pain relief and reduction in allodynia and disability.

Third-Line Therapies

• Vaccination of adults	A
• Contact with varicella or with children	C
• Topical capsaicin	A
• Topical nonsteroidal antiinflammatory cream	C
• Tramadol	A
• Sympathetic nerve block	B
• Transcutaneous electrical stimulation	B
• Methylcobalamin injection	B

A vaccine to prevent herpes zoster and postherpetic neuralgia in older adults

Oxman MN, Levin MJ, Johnson GR, Schmader KE, Straus SE, Gelb LD, et al. *N Engl J Med* 2005; 352: 2271.

A randomized, double-blind, placebo-controlled trial of live attenuated Oka/Merck VZV vaccine enrolled 38,546 immunocompetent adults aged 60 years or over. The vaccine significantly reduced morbidity from herpes zoster and PHN. It was safe and well tolerated.

Efficacy, safety, and tolerability of herpes zoster vaccine in persons aged 50 to 59 years

Schmader KE, Levin MJ, Gnann Jr, JW, McNeil SA, Vesikari T, Betts RF, et al. *Clin Infect Dis* 2012; 54: 922–8.

The Merck Zostavax vaccine was shown to reduce the incidence of herpes zoster by 69.8% in patients aged 50 to 59 years and was well tolerated.

Family history and herpes zoster risk in the era of shingles vaccination

Hernandez PO, Javed S, Mendoza N, Lapolla W, Hicks LD, Tyring SK. *J Clin Virol* 2011; 52: 344–8.

The most important risk factor for development of zoster, after age and immune status, is a family history of shingles. Therefore patients over age 50 with a family history of shingles should be particularly encouraged to receive the zoster vaccine.

Contacts with varicella or with children and protection against herpes zoster in adults: a case controlled study

Thomas SL, Wheeler JG, Hall AJ. *Lancet* 2002; 360: 678–82.

Social contact with many children outside the household, or occupational contacts with children ill with chickenpox, results in a graded protection against zoster.

A randomized vehicle-controlled trial of topical capsaicin in the treatment of postherpetic neuralgia

Watson CP, Tyler KL, Bickers DR, Millikan LE, Smith S, Coleman E. *Clin Ther* 1993; 15: 510–26.

Capsaicin 0.075% cream applied three to four times per day was

effective. The only side effect was burning or stinging at sites of application.

Benzydamine cream for the treatment of postherpetic neuralgia: minimum duration of treatment periods in a cross-over trial

McQuay HJ, Carroll D, Moxon A, Glynn CJ, Moore RA. *Pain* 1990; 40: 131–5.

Some patients benefit from 3% benzydamine hydrochloride cream applied six times daily.

Tramadol in postherpetic neuralgia: a randomized, double-blind, placebo-controlled trial

Boureau F, Legallicier P, Kabir-Ahmadi M. *Pain* 2003; 104: 323–31.

A double-blind study with 127 patients found tramadol to be effective in reducing pain intensity and increasing the percentage of pain relief compared with placebo. All patients were treated for 6 weeks with doses ranging from 100 to 400 mg based on therapeutic response. Patients over 75 years of age received divided doses (morning and night); others received a single-dose regimen.

Neuraxial and sympathetic blocks in herpes zoster and postherpetic neuralgia: an appraisal of current evidence

Kumar V, Krone K, Mathieu A. *Regional Anesth Pain Med* 2004; 29: 454–61.

Sympathetic blocks for herpes zoster and PHN appear to be useful but require randomized, controlled trials for validation.

Modified Jaipur block for the treatment of post-herpetic neuralgia

Puri N. *Int J Dermatol* 2011; 50: 1417–20.

Subcutaneous injections of 2% Xylocaine and 0.5% bupivacaine in 4 mg/mL methylprednisolone can provide significant pain relief in persistent PHN. Approximately 90% of patients in a recent study experienced complete pain relief after three rounds of subcutaneous injections administered at 6-week intervals.

Transcutaneous electrical nerve stimulation for chronic postherpetic neuralgia

Ing MR, Hellreich PD, Johnson DW, Chen JJ. *Int J Dermatol*. 2015; 54: 476–80.

A randomized study of patients with PHN refractory to other

medical treatments found that transcutaneous electrical nerve stimulation produced a statistically significant reduction in pain scores.

Cryoanalgesia for postherpetic neuralgia: a new treatment

Calandria L. *Int J Dermatol* 2011; 50: 746–50.

Liquid nitrogen applied in a nonfreezing manner can safely reduce PHN pain. In a recent study, 75% of patients reported a >70% reduction in pain after a total of five weekly sessions.

A single-center randomized controlled trial of local methylcobalamin injection for subacute herpetic neuralgia

Xu G, Lv ZW, Feng Y, Tang WZ, Xu GX. *Pain Med* 2013; 14: 884–94.

Local methylcobalamin injection was effective in relieving pain and discomfort caused by subacute herpetic neuralgia and was well tolerated.

Corticosteroids for preventing postherpetic neuralgia

Han Y, Zhang J, Chen N, He L, Zhou M, Zhu C. *Cochrane Database Syst Rev* 2013; 3: CD005582.

A systematic review and meta-analysis of randomized controlled trials found moderate-quality evidence that corticosteroids given acutely during herpes zoster infection are ineffective in preventing postherpetic neuralgia.

Hidradenitis Suppurativa

Noah Scheinfeld, and Gregor Jemec

Hidradenitis suppurativa (HS) is a common, chronically relapsing skin disease characterized by recurring inflamed painful nodules, abscess and sinus formation, and scarring most likely due to aberrant cellular immunity stimulated by commensal bacteria (most commonly coagulase-negative *Staphylococcus* [CONS]). The disease can occur on any area where hair follicles are located. It is a follicular disease, distinct from acne vulgaris and staphylococcosis or other simple

primary infections. Pain and suppuration cause considerable morbidity and significantly reduce quality of life in patients. The disease is associated with important comorbidities and an increased all-cause mortality compared with healthy controls and an increased cardiovascular mortality compared with psoriasis patients. Diseases associated with HS may include depression, obesity, smoking, polycystic ovarian disease, ulcerative colitis, Crohn disease, pyoderma gangrenosum, hormonal abnormalities, spondyloarthropathy, arthritis, metabolic syndrome, dyslipidemia, psychiatric disorders, drug dependence, hypertension, diabetes, thyroid disease, alcohol dependence, and lymphoma.

Management Strategy

HS is a clinical diagnosis, based on the identification of morphology, location, and the chronic/recurrent nature of lesions. The morphology may include noninflamed or inflamed nodules, abscesses, nondraining or draining sinus tracts (tunnels), and scars. The locations are bilateral and must involve one or more of these areas: axillae, inframammary area, and groin (including genitals). Chronicity may be defined as at least two flares in 6 months. No pathognomonic test exists. Preclinical follicular changes can be identified with ultrasound or histologic investigation. Age of onset is usually in the third decade of life and is rare before puberty. An underlying endocrine disorder must be considered in prepubertal cases.

Hurley stage I lesions are often “blind” boils (i.e., deep and rounded nodules). These may be transient and flare to become abscesses that subside. Gradually scarring and sinus formation occur in separate areas of the affected regions (stage II), and ultimately scarring and sinuses coalesce to form stage III lesions. Early lesions can remit without treatment. Sinus tracts and scars limit nonsurgical treatment options. Clinically HS can often be distinguished from furunculosis (often large randomly occurring boils and not limited to inverse areas) or epidermal cysts (usually solitary, clinically stable lesions), pyogenic granulomas, and scarring folliculitis. HS is fundamentally a sterile disease, and cultures are usually negative because CONS is usually sifted on bacterial culture. Microbiology is most useful when presentations are atypical and in later stages of disease when superinfection may occur. If suspicion exists that a

mimic of HS is present, for example, mycobacterial infection, squamous cell carcinoma, or Crohn disease, skin biopsies and/or additional relevant tests should be performed.

Current medical practice is mainly empiric. International guidelines have been suggested for the management of HS. A three-pronged approach gives structure to patient management: The first prong consists of adjuvant therapy, which includes pain management, treatment of established superinfections, weight loss, and tobacco cessation. Treatment of superinfections is defined by bacterial culture sensitivities. Patients should be provided access to appropriate bandaging of suppurating lesions.

The second prong involves medical therapy, which may be topical in mild cases. *Topical clindamycin* has been shown to have an effect on early lesions. *Topical gentamycin* may also be useful. Intralesional corticosteroids (single dose) or *resorcinol 15% BID* can be used as first-line treatment for HS. Systemic tetracycline (500 mg BID) or doxycycline may be used as an alternative for more disseminated disease. Cohort studies support coadministering *oral clindamycin 300 mg BID*, and *rifampicin 300 mg BID* may induce a remission of limited HS. Adalimumab has been shown effective in moderate to severe HS when administered in routine inflammatory bowel disease doses (week 0: 160 mg, week 2: 80 mg, and from week 4: 40 mg every week). Onset of effect has been shown to be at week 2 of treatment. A post hoc analysis of a smaller randomized controlled trial (RCT) indicated that infliximab 5 mg/kg may also be effective. Anakinra (100 mg daily) has also been found effective in a small trial. Although intravenous antibiotic therapy involving an imipenem-class drug has been reported, more research needs to be done before this can be recognized as part of the therapeutic ladder for HS.

Palliative medication includes systemic antiinflammatory drugs such as *oral corticosteroid*, *dapsone*, and *ciclosporine*. Patients may also benefit from *acitretin 25 mg BID/TID*, although this treatment is often limited by side effects and teratogenicity. Hormonal therapy with *cyproterone acetate* may be helpful in some females but requires high and continued use, which raises safety concerns. A study found that spironolactone at doses ranging from 25 mg BID to 100 mg BID might be useful in the treatment of HS.

An initial antiinflammatory response may be followed by relapse; continued and sustained immune responses can cause the HS to worsen, increasing morbidity, clinical manifestation of HS, and

complication. HS shows little sign of improvement with isotretinoin.

The third prong of treatment is surgery. In milder cases this involves *minor surgery*—that is, localized excisions or exteriorization of sinus tracts. Only fluctuating obvious abscesses should undergo lancing. Lancing of inflamed nodules is painful to the patient and causes scarring. Nonfluctuating symptomatic lesions are better treated using intralesional corticosteroids. A CO₂ laser can be used to evaporate lesions. More advanced cases require major surgery, which should involve excision of the affected tissue or careful exteriorization (deroofting) of all sinus tracts (tunnels). The recurrence rate is inversely proportional to the extent of surgery, and wide excisions therefore offer a better chance of remission. Similarly, it is suggested that secondary intentional healing is superior to primary closure of postexcisional wounds. Secondary healing requires longer periods of wound management but generally does not preclude resumption of work after 3 to 4 weeks of treatment.

Specific Investigation

The diagnosis is clinical based on morphology, location, and chronicity/recurrence. Specific investigation may be necessary to rule out differential diagnosis depending on clinical findings.

First-Line Therapies

• Antibiotics – topical clindamycin or oral tetracycline	B
• Oral clindamycin and rifampin for 10 weeks	B
• Surgery	B
• Intralesional Kenalog	D

Topical treatment of hidradenitis suppurativa with clindamycin

Clemmensen OJ. Int J Dermatol 1983; 22: 325–8.

Topical clindamycin for 3 months was significantly more effective than placebo in early lesions.

A randomised trial of topical clindamycin vs. systemic tetracycline in hidradenitis suppurativa with special reference to disease assessment

Jemec GBE, Wendelboe P. J Am Acad Dermatol 1998; 39: 971–4.

Clinical equivalence of efficacy between topical clindamycin and oral tetracycline in 46 patients.

Combination therapy with clindamycin and rifampicin for hidradenitis suppurativa: a series of 116 consecutive patients

Gener G, Canoui-Poitrine F, Revuz JE, Faye O, Poli F, Gabison G, et al. Dermatology 2009; 219: 148–54.

Disease severity assessed by Sartorius score reduced by 50% after 10 weeks.

De-roofing: a tissue-saving surgical technique for the treatment of mild to moderate hidradenitis suppurativa lesions

van der Zee HH, Prens EP, Boer J. J Am Acad Dermatol 2010; 63: 475–80.

Deroofing appears to be a useful form of limited surgery of sinus tracts (tunnels).

Recurrence of hidradenitis suppurativa after surgical management: a systematic review and meta-analysis

Mehdizadeh A, Hazen PG, Bechara FG, Zwingerman N, Moazenzadeh M, Bashash M, et al. J Am Acad Dermatol 2015; 73 (Suppl 1): S70–7.

Drainage alone carries a recurrence rate of up to 100%; radical excision has a recurrence rate of 25% at a median interval of 20 months. Success of surgery is affected by such variables as location, extent, and duration of disease.

Intralesional corticosteroid injections as a treatment option for acute lesions in patients diagnosed with hidradenitis suppurativa

Maini P, Posso-De Los Rios C, Gooderham M. J Amer Acad Derm 2015; 72 (Suppl 1): AB51.

A total of 33 (29%) patients received intralesional triamcinolone acetonide injections at concentrations of 2.5 mg/mL (14.3%), 3.33 mg/mL (34.7%), 5.0 mg/mL (38.8%), or 10 mg/mL (12.2%) as treatment to control acute lesions. Only 6/25 (25%) female subjects treated with intralesional injections required concomitant systemic antibiotics

during flare-ups. The mean follow-up duration was 10.1 months for females and 23.2 months for males. An 8-year experience involving intralesional triamcinolone injections effectively treated inflammatory HS and reduced the use of systemic antibiotics.

Second-Line Therapies

• Metformin	C
• Acitretin	C
• Quinolone with rifampin and metronidazole	C
• Spironolactone	C
• 1064 nm (for prevention rather than treatment of lesions) surgery	B
• CO ₂ laser	B

Metformin for the treatment of hidradenitis suppurativa: a little help along the way

Verdolini R, Clayton N, Smith A, Alwash N, Mannello B. J Eur Acad Dermatol Venereol 2013; 27: 1101–8.

Open case series describing benefits of monotherapy using metformin.

Acitretin treatment for hidradenitis suppurativa: a prospective series of 17 patients

Matusiak L, Bieniek A, Szepietowski JC. Br J Dermatol 2014; 171: 170–4.

Eight of 17 patients (47%) experienced benefit; relapses occurred 2 to 8 months after stopping therapy.

A study on the management of hidradenitis suppurativa with retinoids and surgical excision

Puri N, Talwar A. Indian J Dermatol 2011; 56: 650–1.

The relapse rate after surgery was reduced from 40% to 20% by subsequent treatment with acitretin.

Efficacy of rifampin-moxifloxacin-metronidazole combination therapy in hidradenitis suppurativa

Join-Lambert O, Coignard H, Jais JP, Guet-Revillet H, Poirée S, Fraitag S, et al. *Dermatology* 2011; 222: 49–58.

Twenty-eight consecutive HS patients, including 6, 10, and 12 Hurley stage I, II, and III patients, respectively. Complete remission, defined as a clearance of all inflammatory lesions, including hypertrophic scars, was obtained in 16 patients, including 6/6, 8/10, and 2/12 patients with Hurley stage I, II, and III, after up to 12 months of treatment.

A case series of 20 women with hidradenitis suppurativa treated with spironolactone

Lee A, Fischer G. *Australas J Dermatol* 2015; 56: 192–6.

A total of 17 out of 20 (85%) responded to spironolactone who had failed other therapies at a 3-month follow-up from initial presentation.

Prospective controlled clinical and histopathologic study of hidradenitis suppurativa treated with the long-pulsed neodymium:yttrium-aluminium-garnet laser

Mahmoud BH, Tierney E, Hexsel CL, Pui J, Ozog DM, Hamzavi IH. *J Am Acad Dermatol* 2010; 62: 637–45.

In patients with milder disease treated with topical benzoyl peroxide and clindamycin, weekly treatment with long-pulsed neodymium:yttrium-aluminum-garnet laser for 4 months was significantly more effective than the aforementioned topical treatment alone.

Surgical treatment of chronic hidradenitis suppurativa: CO₂ laser stripping-secondary intention technique

Lapins J, Marcusson JA, Emtestam L. *Br J Dermatol* 1994; 131: 551–6.

CO₂ evaporation of diseased tissue under visual control, followed by secondary healing.

Third-Line Therapies

• TNF-alpha monoclonal antibodies	A
• Immunosuppressants	D

Adalimumab for the treatment of moderate to severe hidradenitis suppurativa: a parallel randomized trial

Kimball AB, Kerdel F, Adams D, Mrowietz U, Gelfand JM, Gniadecki R, et al. Ann Intern Med 2012; 157: 846–55.

Significant effect of adalimumab 40 mg every week was noted during 12 weeks of treatment.

Efficacy and safety of adalimumab in patients with moderate to severe hidradenitis suppurativa: results from PIONEER II, a phase 3, randomized, placebo-controlled trial

Jemec G, Gottlieb A, Forman S, et al. J American Acad Dermatol 2015; 72 (Suppl 1): AB45.

The FDA approved dose adalimumab dosage in HS dosed at week 0: 160 mg, week 2: 80 mg, and from week 4: 40 mg every week, there after for 12 weeks effectively treated hidradenitis.

Two Phase 3 Trials of Adalimumab for Hidradenitis Suppurativa

Kimball AB, Okun MM, Williams DA, Gottlieb AB, Papp KA, Zouboulis CC, et al. N Engl J Med 2016; 375: 422–34.

In 2 phase 3 studies entitled PIONEER, 307 patients were enrolled in PIONEER I and 326 were enrolled in PIONEER II. Clinical response rates at week 12 were significantly higher for the groups receiving adalimumab 40 mg weekly than for the placebo groups: 41.8% versus 26.0% in PIONEER I ($p=0.003$) and 58.95 versus 27.6% in PIONEER II ($P<0.001$). Patients receiving adalimumab had significantly greater improvement than the placebo groups in rank-ordered secondary outcomes (lesions, pain, and the modified Sartorius score for disease severity) at week 12 in PIONEER II only. In PIONEER I, patients receiving oral antibiotic agents for hidradenitis suppurativa were required to stop treatment for at least 28 days before baseline; in PIONEER II, patients were allowed to continue treatment with antibiotics (tetracycline class) in stable doses.

Infliximab therapy for patients with moderate to severe hidradenitis suppurativa: a randomized, double-blind, placebo-controlled crossover trial

Grant A, Gonzalez T, Montgomery MO, Cardenas V, Kerdel FA. J Am Acad Dermatol 2010; 62: 205–17.

A randomized controlled trial indicating the effect of infliximab in post hoc analysis.

Safety and efficacy of anakinra in severe hidradenitis suppurativa: a randomized clinical trial

Tzanetakou V, Kanni T, Giatrakou S, Katoulis A, Papadavid E, Netea MG, et al. JAMA Dermatol 2016; 152: 52–9.

Seven out of nine (78%) achieved clinical response in the actively treated group (100 mg daily).

Dapsone therapy for hidradenitis suppurativa: a series of 24 patients

Yazdanyar S, Boer J, Ingvarsson G, Szepietowski JC, Jemec GB. Dermatology 2011; 222: 342–6.

Nine of 24 patients (38%) experienced benefits from therapy with dapsone.

Ciclosporin treatment of severe hidradenitis suppurativa – a case series

Anderson MD, Zauli S, Bettoli V, Boer J, Jemec GB. J Dermatolog Treat 2016; 27: 247–50.

Nine of 18 previously extensively treated patients (50%) experienced benefits from therapy with ciclosporin.

Histoplasmosis

Mahreen Ameen, and Wanda Sonia Robles

Histoplasmosis is an endemic mycosis caused by a dimorphic fungus, *Histoplasma capsulatum*, of which there are two varieties that are pathogenic to humans. The most common variety worldwide is *H. capsulatum* var. *capsulatum*, which is highly endemic in the United States, particularly in the Mississippi and Ohio valleys. *H. capsulatum* var. *duboisii* is endemic only in Central and West Africa (where it coexists with *H. capsulatum* var. *capsulatum*), and it is therefore sometimes referred to as *African histoplasmosis*. The infection is usually contracted through inhalation of spores in dry soil or bird or bat

droppings. Disease progression and severity depend on the intensity of exposure to *H. capsulatum* and host immunity. There is a wide clinical spectrum of disease. Acute pulmonary disease is the most common presentation, and most cases are either asymptomatic or mild and self-limiting. Chronic pulmonary histoplasmosis, usually occurring in patients with underlying lung disease, produces cavities and later progression to pulmonary fibrosis. Hematogenous dissemination occurs within the first few weeks but resolves with the development of cell-mediated immunity to *H. capsulatum*. Progressive disseminated histoplasmosis occurs in the immunocompromised. Patient groups at risk include those with AIDS or hematologic malignancies, those on immunosuppressive therapy (including corticosteroids and tumor necrosis factor [TNF] antagonists), transplant recipients, and infants. Disseminated histoplasmosis is an AIDS-defining illness. It is usually a reactivation of prior infection and a sign of advanced immunosuppression, generally occurring in those with CD4 counts <150 cells/mm³.

Disseminated histoplasmosis can involve every organ system, most commonly presenting with hepatosplenomegaly and mucocutaneous lesions. Molluscum-like papules, nodules, or ulcerative lesions affect the skin and are usually localized to the face, upper chest, and arms. Oropharyngeal ulcers affect the buccal mucosa, tongue, gingiva, lips, pharynx, and larynx. Histoplasmosis may also present to the dermatologist as a cause of erythema multiforme or erythema nodosum, which are thought to be a hypersensitivity response to the *H. capsulatum* antigen. Rarely, primary cutaneous lesions may arise from direct inoculation.

Management Strategy

Pulmonary forms of histoplasmosis in the acute phase usually resolve spontaneously and only require treatment if symptoms persist for more than 1 month. Oral itraconazole is the treatment of choice for mild to moderate histoplasmosis. Severe pulmonary infection, disseminated histoplasmosis, and infection in the immunocompromised, particularly in association with AIDS, should be treated with amphotericin B (AmB) formulations (AmB deoxycholate, liposomal AmB, or AmB lipid complex). The lipid formulations carry a lower risk of nephrotoxicity but are more expensive. Treatment is commenced with AmB until there is clinical

improvement and then stepped down to oral itraconazole.

Fluconazole and ketoconazole are second-line alternatives to itraconazole. Ketoconazole carries higher risks of adverse effects than do the other azoles. The new triazoles, voriconazole and posaconazole, demonstrate in vitro activity against *H. capsulatum* and have been successfully used in individual cases for different forms of histoplasmosis infection.

Patients with AIDS-related histoplasmosis who undergo antiretroviral treatment have better outcomes than do those who are not treated with antiretrovirals. Some clinicians defer commencement of antiretroviral therapy until there is a reduction in fungal burden to avoid precipitating immune reconstitution inflammatory syndrome (IRIS). However, IRIS is a rare complication of histoplasmosis and is not usually severe. Therefore others advocate early antiretroviral therapy to improve cellular immunity, a key defense against *H. capsulatum*.

Specific Investigations

- Culture
- Histology
- Serology
- Serology for HIV (where relevant)
- Imaging studies to detect disseminated disease (chest x-ray/computed tomography/magnetic resonance imaging)

The gold-standard method for diagnosing histoplasmosis is the isolation of *H. capsulatum* from culture. The use of several specimens (sputum, bronchoalveolar lavage, skin lesions, blood, bone marrow, or liver) for culture will increase the yield. Culture is highly specific but is limited by slow growth, and plates must be kept for as long as 12 weeks. Blood culture using the lysis-centrifugation system is more rapid and increases sensitivity. Histopathology is also more rapid, but its sensitivity is <50% in patients with disseminated disease and even lower in pulmonary histoplasmosis. Biopsy specimens may demonstrate the distinctive 2- to 4- μ m oval, narrow-based budding yeasts of *H. capsulatum*. Serologic tests are rapid but may be falsely negative in immunosuppressed patients and during the first 2 months after exposure while antibodies are still developing. In addition, elevated antibody titers persist for several years after initial infection.

Antigen detection is a rapid means of diagnosis and can be useful in individuals who are immunocompromised when antibody production may be impaired. Sensitivity is greater with urine and plasma compared with other body fluids. Antigen quantitation enables treatment response to be monitored.

In disseminated disease, general laboratory tests will reveal a pancytopenia, hyperbilirubinemia, elevated liver enzyme, and serum lactate dehydrogenase levels.

Histoplasmosis: up-to-date evidence-based approach to diagnosis and management

Hage CA, Azar MM, Bahr N, Loyd J, Wheat LJ. *Semin Respir Crit Care Med* 2015; 36(5): 729–45.

This is a comprehensive and up-to-date review. Liposomal amphotericin B is recommended for more severe cases and itraconazole for milder cases and “step-down” therapy after response to amphotericin B.

Histoplasmosis complicating tumor necrosis factor- α blocker therapy: a retrospective analysis of 98 cases

Vergidis P, Avery RK, Wheat LJ, Dotson JL, Assi MA, Antoun SA, et al. *Clin Infect Dis* 2015; 61(3): 409–17.

Disseminated histoplasmosis is a potential complication of anti-TNF- α therapy. This is a multicenter retrospective review of 98 patients diagnosed with histoplasmosis between 2000 and 2011. The most commonly used biologic agent was infliximab (67.3%). Based on these data the authors recommend that antifungal therapy be administered for at least 12 months. Thereafter resumption of TNF- α blocker therapy appears safe. They also conclude that disease outcomes were generally favorable.

Histoplasmosis in HIV-infected patients: a review of new developments and remaining gaps

Adenis AA, Aznar C, Couppié P. *Curr Trop Med Rep* 2014; 1: 119–28.

This review outlines the impact of HIV on the prevalence and clinical manifestations of histoplasmosis. It assesses the data on clinical trials of drug therapy for histoplasmosis in HIV-infected individuals and discusses the relative merits of amphotericin and itraconazole and their limitations in terms of drug interactions in HIV-infected individuals.

First Line Therapies

• Amphotericin B	B
• Itraconazole	B

Disseminated histoplasmosis in patients with AIDS in Panama: a review of 104 cases

Gutierrez ME, Canton A, Sosa N, Puga E, Talavera L. Clin Infect Dis 2005; 40(8): 1199–202.

In this study from Panama, the authors report that before the spread of AIDS, disseminated histoplasmosis was rarely seen. Now it is often the first manifestation of AIDS in this region and must be suspected in anyone with fever, respiratory symptoms, weight loss, diarrhea, and a CD4 cell count <100 cells/ μ L. One hundred of 104 (96%) patients with AIDS-related disseminated histoplasmosis received amphotericin B deoxycholate induction therapy, most receiving 1 g in total before being switched over to oral itraconazole. Forty patients had therapy-related adverse effects with hypokalemia reported in 50% and an increased creatinine level in 43%.

Itraconazole therapy for blastomycosis and histoplasmosis

NIAID Mycoses Study Group. Dismukes WE, Bradsher RW Jr, Cloud GC, Kauffman CA, Chapman SW, George RB, et al. Am J Med 1992; 93(5): 489–97.

This was a prospective, nonrandomized, multicenter open trial where 37 patients with histoplasmosis received itraconazole 200 to 400 mg daily. Eighty-one percent ($n = 30$) were cured after a median treatment period of 9 months. Treatment failure occurred only in those patients with chronic cavitary pulmonary disease. Twenty-nine percent ($n = 25$) experienced minor adverse effects, requiring therapy withdrawal in only one patient.

Itraconazole treatment of disseminated histoplasmosis in

patients with the acquired immunodeficiency syndrome

AIDS Clinical Trial Group. Wheat J, Hafner R, Korzun AH, Limjoco MT, Spencer P, Larsen RA, et al. Am J Med 1995; 98: 336–42.

A multicenter, nonrandomized prospective trial. Itraconazole 300 mg twice daily for 3 days followed by 200 mg twice daily was given for 12 weeks. Evaluation of 59 patients showed that 50 (85%) responded well to therapy. Five withdrew from the study because of progressive infection. One died within the first week of therapy, and two withdrew because of itraconazole-related adverse effects.

Resolution of systemic symptoms occurred after a median of 3 weeks in the less severely affected, and 6 weeks in the moderately severe cases. Fungemia cleared after a median period of 1 week.

Itraconazole demonstrates efficacy in the treatment of mild disseminated histoplasmosis in patients with AIDS. For patients with moderately severe or severe histoplasmosis, amphotericin B is the drug of first choice, which can be switched to itraconazole after clinical improvement.

Safety and efficacy of liposomal amphotericin B compared with conventional amphotericin B for induction therapy of histoplasmosis in patients with AIDS

Johnson PC, Wheat LJ, Cloud GA, Goldman M, Lancaster D, Bamberger DM, et al. US National Institute of Allergy and Infectious Diseases Mycoses Study Group. Ann Intern Med 2002; 137: 105–9.

A multicenter, randomized, controlled trial compared amphotericin B deoxycholate with liposomal amphotericin B for induction therapy of moderate to severe disseminated histoplasmosis in patients with AIDS. The trial demonstrated a higher response rate (88% vs. 64%) and lower mortality rate (2% vs. 13%) in patients who were treated with liposomal amphotericin ($n = 51$) than in those treated with amphotericin B deoxycholate ($n = 22$). Infusion-related side effects were greater with amphotericin B deoxycholate (63%) than with liposomal amphotericin B (25%) ($p = 0.002$). Nephrotoxicity was also higher with amphotericin B deoxycholate (37%) than with liposomal amphotericin B (9%) ($p = 0.003$).

This study demonstrated that liposomal amphotericin is associated with higher efficacy, lower mortality, and better tolerance during induction treatment of disseminated histoplasmosis.

Safety of discontinuation of maintenance therapy for

disseminated histoplasmosis after immunologic response to antiretroviral therapy

Goldman M, Zackin R, Fichtenbaum CJ, Skiest DJ, Koletar SL, Hafner R, et al. AIDS Clinical Trials Group A5038 Study Group. Clin Infect Dis 2004; 38: 1485–89.

Traditionally, lifelong maintenance therapy with itraconazole had been the standard of care in order to reduce the risk of relapse of histoplasmosis infection. This was a prospective observational study to assess the safety of stopping maintenance therapy for disseminated histoplasmosis in patients with HIV infection after treatment with antiretroviral therapy. The study concluded that discontinuation of antifungal therapy after 12 months appears to be safe in patients with previously treated disseminated histoplasmosis that have sustained immunologic improvement with antiretroviral therapy.

Disseminated histoplasmosis: a comparative study between patients with acquired immunodeficiency syndrome and non-human immunodeficiency virus-infected individuals

Tobon AM, Agudelo CA, Rosero DS, Ochoa JE, De Bedout C, Zuluaga A, et al. Am J Trop Med Hyg 2005; 73(3): 576–82.

In this study of 52 patients with disseminated histoplasmosis, 30 patients had AIDS. Skin lesions were significantly higher in patients with AIDS, occurring in 53% of them ($p = 0.001$). *H. capsulatum* was isolated more often in AIDS patients ($p < 0.05$), but antibodies to *H. capsulatum* were detected more frequently in non-HIV patients ($p < 0.05$). Itraconazole treatment was less effective in AIDS patients ($p = 0.012$), but in this group, too, highly active antiretroviral therapy (HAART) improved the response to antifungals compared with individuals who were not given HAART ($p = 0.003$), who exhibited higher mortality rates ($p = 0.025$). These results indicate the need to promote restoration of the immune system in patients with AIDS and histoplasmosis.

The authors highlight that the skin constitutes a more important target organ for H. capsulatum in HIV-infected Latin American patients than in HIV-infected North American patients.

Literature review and case histories of *Histoplasma capsulatum* var. *duboisii* infections in HIV-infected patients

Loulergue P, Bastides F, Baudouin V, Chandenier J, Mariani-Kurkdjian P, Dupont B, et al. Emerg Infect Dis 2007; 13(11): 1647–52.

African histoplasmosis caused by *H. capsulatum* var. *duboisii* is much rarer than histoplasmosis caused by variety *capsulatum*, and its association with HIV infection is rarely reported. This article reports three such cases and reviews the literature on similar cases. All cases were successfully treated initially with amphotericin B, which was subsequently switched to itraconazole. No clinical trials or efficacy studies have been performed for African histoplasmosis, and therefore its treatment is usually extrapolated from the guidelines of the Infectious Diseases Society of America established for histoplasmosis due to variety *capsulatum*.

Disseminated primary cutaneous histoplasmosis successfully treated with itraconazole

Singhi MK, Gupta L, Kacchawa D, Gupta D. Indian J Dermatol Venereol Leprol 2003; 69(6): 405–7.

Primary cutaneous histoplasmosis is rare. This is a report of a case of disseminated primary cutaneous histoplasmosis caused by *H. capsulatum* in an immunocompetent patient. The patient presented with a 2-year history of progressive erythematous nodules and plaques distributed mainly over the trunk. There was no evidence of systemic involvement. There was an excellent response to itraconazole 100 mg BID. Lesions began improving within 4 weeks and cleared within 16 weeks, and the total treatment period was 24 weeks. There was no recurrence 6 months after cessation of treatment.

Second-Line Therapies

• Ketoconazole	B
• Fluconazole	B
• Posaconazole	D
• Voriconazole	D

Treatment of blastomycosis and histoplasmosis with ketoconazole. Results of a prospective randomized clinical trial

Dismukes WE, Cloud G, Bowles C, National Institute of Allergy and Infectious Diseases Mycoses Study Group. Ann Intern Med 1985; 103(6 Pt 1): 861–72.

This was a multicenter, prospective, randomized trial evaluating the efficacy and toxicity of low-dose (400 mg/d) and high-dose (800 mg/d) oral ketoconazole in the treatment of histoplasmosis. Among 19 patients with chronic cavitary histoplasmosis treated for 6 months or more, both regimens were equally effective (overall success rate, 84%). In 20 patients with localized or disseminated histoplasmosis treated for 6 months or more, low-dose treatment was more effective (100% vs. 57% success rate, $p = 0.03$). The success rate for all patients with histoplasmosis treated for 6 months or more was 85%. Adverse effects occurred in 60% of patients and were more common with the high-dose regimen. Ketoconazole is effective for non-life-threatening histoplasmosis in immunocompetent patients. Because of the higher frequency of side effects associated with the high dose, the authors suggested that ketoconazole therapy should be initiated at the lower dose.

With the availability of better-tolerated and new-generation azoles, there are no recent studies evaluating ketoconazole therapy for histoplasmosis.

However, it is still a drug that is commonly used in endemic settings because of its availability and low cost.

Fluconazole therapy for histoplasmosis. The National Institute of Allergy and Infectious Diseases Mycoses Study Group

McKinsey DS, Kauffman CA, Pappas PG, Cloud GA, Girard WM, Sharkey PK, et al. Clin Infect Dis 1996; 23(5): 996–1001.

Twenty-seven patients were enrolled in this trial. Two had acute pulmonary histoplasmosis, 11 had chronic pulmonary histoplasmosis, and 14 had disseminated histoplasmosis. Twenty patients received fluconazole 400 to 800 mg/day, and seven patients received fluconazole 200 mg daily. Successful treatment was reported in 17 patients (63%). There were no significant adverse effects. The authors concluded that fluconazole was only moderately effective and should be reserved for patients intolerant to itraconazole.

Treatment of histoplasmosis with fluconazole in patients with acquired immunodeficiency syndrome

National Institute of Allergy and Infectious Diseases, Acquired Immunodeficiency Syndrome Clinical Trials Group and Mycoses Study Group. Wheat J, MaWhinney S, Hafner R, McKinsey D, Chen D, Korzun A, et al. Am J Med 1997; 103: 223–32.

This was a multicenter, open-label, nonrandomized, prospective trial. The aim of the study was to assess the efficacy and safety of fluconazole in patients with AIDS and mild to moderate disseminated histoplasmosis. The initial protocol of fluconazole 1200 mg on day 1 followed by 600 mg daily for 8 weeks demonstrated a high failure rate of 50%. The therapy schedule was revised to 1600 mg on day 1 followed by 800 mg daily for 12 weeks, and then maintenance therapy with 400 mg daily for at least 1 year. Seven patients failed to respond to induction therapy, with progression of histoplasmosis leading to death in one patient. Two withdrew due to liver toxicity. Seventy-three percent (36/49 patients) responded, but 30.5% (11/36) subsequently relapsed, and one died. On the basis of historical comparison, maintenance therapy to prevent relapse with fluconazole 400 mg daily was less effective than itraconazole 200 to 400 mg daily or amphotericin B 50 mg weekly.

Fluconazole may have a role in the treatment of non–AIDS-related histoplasmosis. However, this study of AIDS-related infection demonstrated a comparatively poor efficacy rate with even high-dose fluconazole induction

therapy and an unacceptably high relapse rate with maintenance therapy.

Salvage treatment of histoplasmosis with posaconazole

Restrepo A, Tobón A, Clark B, Graham DR, Corcoran G, Bradsher RW, et al. J Infect 2007; 54(4): 319–27.

Six patients with severe histoplasmosis infection were successfully treated with oral posaconazole (800 mg/day in divided doses) having previously failed on amphotericin B, itraconazole, fluconazole, or voriconazole. One patient had pulmonary disease and the rest had disseminated infection. Treatment duration ranged from 6 to 34 weeks. Significant clinical improvement was noted within the first month of treatment.

Although the patient numbers are small, this study suggests that posaconazole may be a useful treatment option for disseminated histoplasmosis refractory to other drug therapies.

Voriconazole use for endemic fungal infections

Freifeld A, Proia L, Andes D, Baddour LM, Blair J, Spellberg B, et al. Antimicrob Agents Chemother 2009; 53(4): 1648–51.

Nine patients with mostly disseminated histoplasmosis who had either failed or were intolerant of amphotericin B and itraconazole were treated with voriconazole. All of them improved or remained clinically stable after treatment, and responses were apparent within the first 2 months of voriconazole initiation. However, two of the patients whose response was “stable” had to discontinue treatment because of high costs. The others received treatment from 31 to 640 days.

Clinical practice guidelines for the management of patients with histoplasmosis: 2007 update by the Infectious Diseases Society of America

Wheat LJ, Freifeld AG, Kleiman MB, Baddley JW, McKinsey DS, Loyd JE, et al; Infectious Diseases Society of America. Clin Infect Dis 2007; 45(7): 807–25.

Evidence-based guidelines for the management of patients with histoplasmosis.

Mild Acute Pulmonary Histoplasmosis

Treatment is usually unnecessary unless symptoms persist for more

than 1 month, when itraconazole is given at a loading dose (200 mg three times daily for 3 days) followed by 200 mg once or twice daily for 6 to 12 weeks.

Severe Acute Pulmonary Histoplasmosis

Parenteral amphotericin B (deoxycholate formulation, 0.7–10 mg/kg daily, or lipid formulation, 3–5 mg/kg daily) for 1 to 2 weeks followed by “step-down” itraconazole therapy, with an initial loading dose and then 200 mg twice daily for a total of 12 weeks.

Chronic Cavitory Pulmonary Histoplasmosis

Itraconazole, initial loading dose, and then 200 mg once or twice daily for at least 12 months.

Mild Disseminated Histoplasmosis

Itraconazole, initial loading dose, and then 200 mg twice daily for at least 12 months.

Severe Disseminated Histoplasmosis

Amphotericin B (doses as earlier for severe pulmonary infection) for 1 to 2 weeks followed by oral itraconazole, initial loading dose, and then 200 mg twice daily for at least 12 months.

Central Nervous System Histoplasmosis

Liposomal amphotericin B (5 mg/kg daily for a total of 175 mg/kg given over 4–6 weeks) followed by itraconazole 200 mg two or three times daily for at least 1 year and until resolution of cerebrospinal fluid (CSF) abnormalities, including *Histoplasma* antigen levels.

Treatment of Histoplasmosis in Pregnancy

Azoles are teratogenic, and therefore amphotericin B is recommended.

Immunosuppressed patients may require lifelong suppressive therapy with itraconazole (200 mg daily) if immunosuppression cannot be reversed. For those on long-term itraconazole therapy,

blood itraconazole levels need to be measured 2 weeks after initiation of treatment. Women of childbearing age who are being treated with azoles need to use effective contraception during treatment and for 2 months after the drug is stopped.

An official American Thoracic Society statement: treatment of fungal infections in adult pulmonary and critical care patients

Limper AH, Knox KS, Sarosi GA, Ampel NM, Bennett JE, Catanzaro A, et al. American Thoracic Society Fungal Working Group. *Am J Respir Crit Care Med* 2011; 183(1): 96–128.

The American Thoracic Society convened a working group of experts in fungal infections to develop a concise clinical statement of current therapeutic options. The document discusses drug therapy for the different manifestations of histoplasmosis, including asymptomatic as well as symptomatic lung disease in immunocompetent hosts and disease in immunocompromised hosts.

Hydroa vacciniforme

Herbert Hönigsmann

Hydroa vacciniforme (HV) is a very rare, idiopathic photodermatosis that mainly starts in childhood, frequently resolving by adolescence or young adulthood. Its prevalence is 0.1 to 0.5 cases per 100,000 per year. It is characterized by recurrent crops of papulovesicles or vesicles, most commonly on the face and the dorsa of the hands, but other sun-exposed areas of the skin, such as the lower lips, may also be involved. The vesicles resolve with pocklike scarring. The disease was first described by Bazin in 1862, and it is possible that before the clear definition of erythropoietic protoporphyria by Magnus et al. in 1961, some cases may have been protoporphyria rather than hydroa because of the similarity of symptoms. There are now many reports of an association with

Epstein–Barr virus (EBV) infection originally from Japan and China, but not all these cases are typical: they are associated with natural killer (NK)/T-cell lymphoproliferative disorders with a frequently fatal outcome. More recently such cases were also reported from other areas in the world. These lesions are now classified as hydroa vacciniforme–like lymphomas.

Management Strategy

HV usually presents in childhood, sometimes with spontaneous improvement during adolescence. Parents generally seek specialist advice because their children are unable to tolerate sunshine (play outdoors or travel abroad) and because the eruption can result in considerable scarring, both of which cause significant morbidity.

HV is almost always refractory to any treatment, but *restriction of sun exposure, appropriate clothing, and regular use of broad-spectrum sunscreens with an effective UVA filter* can help in mild to moderate disease. Windows in the car and home can be covered with films that filter UV wavelengths less than 380 nm.

In patients with more severe disease, however, courses of *narrowband UVB phototherapy* or *psoralen with UVA (PUVA)* administered as for polymorphic light eruption may help occasionally. Both phototherapy regimens usually consist of thrice-weekly treatments for an average of 3 to 4 weeks. It is important to administer these therapies carefully to avoid provoking disease exacerbations.

Antimicrobial therapy has also been tried, as have antimalarials and systemic immunosuppressive therapy, including intermittent oral corticosteroids, but although occasionally helpful, none of these appear to be reliably effective. β -Carotene, used in several studies, has mostly been ineffective.

For severe and refractory HV unresponsive to other therapies, immunosuppressive agents including *azathioprine* and *cyclosporine* may be effective, but *thalidomide* only exceptionally is. However, the use of immunosuppressive drugs for an admittedly unpleasant, but otherwise benign, disease should be carefully considered.

In four reports, *dietary fish oil* rich in omega-3 polyunsaturated fatty acids was associated with clinical improvement in three of four patients. The mechanism may be through inhibition of prostanoid production and by their proposed buffering effect against free

radical-induced damage.

The rare nature of this condition means that there are no large or randomized trials. Evidence for treatment is based on case series or single reports.

Specific Investigations

- Erythrocyte and plasma protoporphyrin levels, red cell photohemolysis, and stool analysis
- Photoprovocation testing with UVA
- Serology for antinuclear antibody and extractable nuclear antigens
- Screening for EBV infection and detection of EBV-infected cells by T-cell receptor- γ gene rearrangement with polymerase chain reaction
- A porphyrin screen will exclude erythropoietic protoporphyria

Photoprovocation testing induces typical blisters. Light tests are abnormal in the UVA range. Photographs to the right of the figure show the result of photoprovocation with UVA (three times 30 J/cm² on 3 consecutive days): (A) after 24 hours; (B) after 48 hours; and (C) after 2 weeks.

Serology for antinuclear antibody and extractable nuclear antigens (anti-Ro, La, and Sm) will exclude bullous lupus erythematosus, which quite commonly can be ruled out by its clinical symptoms.

Rare cases have been associated with metabolic disorders, such as Hartnup disease, and so aminoaciduria should be ruled out.

Screening for EBV should be done in view of the increasing number of reports of the possible association.

Hydroa vacciniforme – aktionsspektrum

Jaschke E, Hönigsmann H. *Hautarzt* 1981; 32: 350–3.

Successful photoprovocation with UVA in one case.

Hydroa vacciniforme: a review of ten cases

Sonnex TS, Hawk JLM. *Br J Dermatol* 1988; 118: 101–8.

Successful photoprovocation with UVA in several cases.

Hydroa vacciniforme: a clinical and follow-up study of 17 cases

Gupta G, Man I, Kemmett D. J Am Acad Dermatol 2000; 42: 208–13.

Eight of 14 patients were sensitive in the UVA spectrum. UVA provocation tests showed a papulovesicular response in 6 of 14 patients.

There is now strong evidence that UVA radiation is the causal factor. In addition to reduced UVA minimal erythema dose values, repetitive broad-spectrum UVA has been shown to reproduce lesions that are clinically and histologically identical to those produced by natural sunlight and that heal with scarring. All cases seen so far by this author (H.H.) had their action spectrum in the UVA range.

Pathogenic link between hydroa vacciniforme and Epstein–Barr virus-associated hematologic disorders

Iwatsuki K, Satoh M, Yamamoto T, Oono T, Morizane S, Ohtsuka M, et al. Arch Dermatol 2006; 142: 587–95.

T cells positive for EBV-encoded small nuclear RNA (EBER) were detected to various degrees in cutaneous infiltrates in 28 (97%) of 29 patients, including all 6 patients with definite HV having a positive phototest reaction.

Hydroa vacciniforme is associated with increased numbers of Epstein-Barr virus-infected $\gamma\delta$ T cells

Hirai Y, Yamamoto T, Kimura H, Ito Y, Tsuji K, Miyake T, et al. J Invest Dermatol 2012; 132: 1401–8.

The observations indicate that cutaneous lesions of both typical and severe HV are induced by EBER+ T cells, associated with a larger number of EBER–cytotoxic T lymphocytes, without apparent involvement of NK cell infiltration.

Epstein-Barr virus involvement in the pathogenesis of hydroa vacciniforme: an assessment of seven adult patients with long-term follow-up

Verneuil L, Gouarin S, Comoz F, Agbalika F, Creveuil C, Varna M, et al. Br J Dermatol 2010; 163: 174–82.

EBV was involved in HV pathogenesis and persisted in adult patients with HV. A positive EBV DNA load, specific to HV in the spectrum of photosensitive disorders, might be a useful biomarker in HV.

Hydroa vacciniforme: a rare photodermatosis

Haddad JM, Monroe HR, Hardin J, Diwan AH, Hsu S. *Dermatol Online J* 2014; 20: pii: 13030/qt7961b22b.

The case of a 9-year-old girl with EBV-associated HV is presented. The discussion offers a good summary of the current diagnosis and management of HV.

First-Line Therapy

• High-factor broad-spectrum sunscreens and behavioral sunlight avoidance	C
---	---

Hydroa vacciniforme: a clinical and follow-up study of 17 cases

Gupta G, Man I, Kemmett D. *J Am Acad Dermatol* 2000; 42: 208–13.

Disease in 9 of 15 patients was controlled satisfactorily with high-factor broad-spectrum sunscreens and sunlight avoidance.

Hydroa vacciniforme: a review of ten cases

Sonnex TS, Hawk JLM. *Br J Dermatol* 1988; 118: 101–8.

Disease severity was reduced in 8 of 10 patients using either Coppertone Supershade 15 or RoC factor 10.

These sunscreens do not meet the standards as required nowadays. Modern sunscreens now must offer broad-spectrum protection against both UVB and UVA.

Borrowing from museums and industry: two photo-protective devices

Dawe R, Russell S, Ferguson J. *Br J Dermatol* 1996; 135: 1016–7.

The Museum 200 Film (manufactured by Sun Guard, Florida, USA) prevents transmission of all wavelengths less than 380 nm.

This is a clear, lightweight film that can be stuck on to any glass surface without causing visual impairment. It may be a useful adjunct in the treatment of most photodermatoses, but in some patients with HV, particularly those who are sensitive in the 380- to 400-nm wavelengths, it may not be beneficial.

Second-Line Therapies

• Narrowband UVB phototherapy (TL-01)	C
• PUVA	D
• Acyclovir/valacyclovir	D

Narrow-band UVB (TL-01) phototherapy: an effective preventative treatment for the photodermatoses

Collins P, Ferguson J. Br J Dermatol 1995; 132: 956–63.

This was an open clinical trial in which four patients were treated on average 10 times on a daily basis. Two of these patients reported an increase in tolerance to sunshine from 1 hour to 3 to 6 hours.

Hydroa vacciniforme: a clinical and follow-up study of 17 cases

Gupta G, Man I, Kemmett D. J Am Acad Dermatol 2000; 42: 208–13.

Five of 15 patients who had not responded to conservative measures were treated with narrowband UVB phototherapy. In three patients there was good or moderate disease control. In the other two, narrowband UVB phototherapy was not helpful.

Narrowband ultraviolet B (UVB) phototherapy in children

Jury CS, McHenry P, Burden AD, Lever R, Bilsland D. Clin Exp Dermatol 2006; 31: 196–9.

Narrowband UVB phototherapy is a useful and well-tolerated treatment for children with severe or intractable inflammatory skin disease.

Hydroa vacciniforme: a review of ten cases

Sonnex TS, Hawk JLM. Br J Dermatol 1988; 118: 101–8.

Two of 10 patients were treated with UVB and had improvement of their disease. There was a flare of the one patient treated with PUVA.

It is likely that broadband UVB was used in this report, but the methodology is unclear.

Hydroa vacciniforme – aktionsspektrum

Jaschke E, Hönigsmann H. Hautarzt 1981; 32: 350–3.

One patient received PUVA therapy and had good control of his disease.

Photosensitivity disorders: cause, effect and management

Millard TP, Hawk JL. *Am J Clin Dermatol* 2002; 3: 239–46.

A review of the management of various photodermatoses, with reference to the use of UVB and PUVA.

Antiviral therapy in children with hydroa vacciniforme

Lysell J, Wiegleb Edström D, Linde A, Carlsson G, Malmros-Svennilson J, Westermarck A, et al. *Acta Derm Venereol* 2009; 89: 393–7.

Successful treatment in four children. Acyclovir/valacyclovir therapy is a safe treatment and should be tried. However, further studies are required to confirm these results.

Antiviral treatment of a boy with EBV-associated hydroa vacciniforme

Pahlow Mose A, Eisker N, Clemmensen O, Bygum A.

BMJ Case Rep 2014; 2014: pii: bcr2014206488.

Marked improvement of EBV-associated HV in a young boy treated initially with acyclovir, followed by valacyclovir. The authors raise the intriguing question if antiviral therapy in patients with EBV-associated HV could decrease the risk of lymphoproliferative disease in these patients.

Third-Line Therapies

• Antimalarials	D
• β -Carotene	E
• Azathioprine	E
• Cyclosporine	E
• Dietary fish oil	E
• Thalidomide	E

Hydroa vacciniforme: a review of ten cases

Sonnex TS, Hawk JLM. Br J Dermatol 1988; 118: 101–8.

Four of 10 patients were treated with either hydroxychloroquine (2 patients) or chloroquine (2 patients). Hydroxychloroquine 100 mg daily was ineffective, but the two patients on chloroquine (100–125 mg daily) had a reduction in the severity of their disease.

Hydroa vacciniforme: an unusual clinical manifestation

Leenutaphong V. J Am Acad Dermatol 1991; 25: 892–5.

One patient treated with chloroquine phosphate 500 mg daily did not find it beneficial.

Hydroa vacciniforme

Ketterer R, Morier P, Frenk E. Dermatology 1994; 189: 428–9.

One patient treated with chloroquine 100 mg daily and broad-spectrum sunscreens showed good disease control.

It is unclear whether the response was due to chloroquine or the sunscreen.

Hydroa vacciniforme

Bickers DR, Demar LK, DeLeo V, Poh-Fitzpatrick MB, Aronberg JM, Harber LC. Arch Dermatol 1978; 114: 1193–6.

Two patients reported an improvement of their disease with β -carotene 180 mg daily.

Hydroa vacciniforme: induction of lesions with ultraviolet A

Halasz CLG, Leach EE, Walther RR, Poh-Fitzpatrick MB. J Am Acad Dermatol 1983; 8: 171–6.

The one patient treated with β -carotene 180 mg daily reported some subjective improvement.

Hydroa vacciniforme: diagnosis and therapy

Goldgeier MH, Nordlund JJ, Lucky AW, Sibrack LA, McCarthy MJ, McGuire J. Arch Dermatol 1982; 118: 588–91.

β -Carotene 120 mg daily for 2 months in the one patient was ineffective.

Hydroa vacciniforme presenting in an adult successfully treated with cyclosporin A

Blackwell V, McGregor JM, Hawk JLM. Clin Exp Dermatol 1998; 23: 73–6.

There was good control of disease with cyclosporine 3 mg/kg daily over a 2-month period.

The report does not provide details of follow-up.

Efficacy of ω -3 polyunsaturated fatty acids for the treatment of refractory hydroa vacciniforme

Durbec F, Reguiaï Z, Léonard F, Pluot M, Bernard P. Pediatr Dermatol. 2012; 29: 118–9.

One patient was successfully treated with dietary fish oil after unsuccessful treatment with other measures.

Dietary fish oil as a photoprotective agent in hydroa vacciniforme

Rhodes LE, White SI. Br J Dermatol 1998; 138: 173–8.

Three patients were treated with dietary fish oil, five capsules daily, for 3 months. A mild to good improvement was noted in two patients,

but no improvement in the third. The latter patient responded to azathioprine.

Hydroa vacciniforme: major and minor forms

Cruces MJ, de la Torre C. Photodermatology 1986; 3: 109–10.

In the one patient treated with thalidomide there was initial improvement.

Thalidomide for the treatment of hydroa vacciniforme-like lymphoma: report of four pediatric cases from Peru

Beltrán BE, Maza I, Moisés-Alfaro CB, Vasquez L, Quiñones P, Morales D, et al. Am J Hematol 2014; 89: 1160–1.

Two out of four children responded.

Hydroa vacciniforme presenting in an adult successfully treated with cyclosporin A

Blackwell V, McGregor JM, Hawk JLM. Clin Exp Dermatol 1998; 23: 73–6.

In the one patient, thalidomide 100 mg daily was ineffective. Cyclosporine proved helpful at 3 mg/kg/day. Azathioprine 2.5 to 3.5 mg/kg daily was ineffective in the one patient studied.

Hyperhidrosis

James A.A. Langtry

Hyperhidrosis is the result of increased secretion of eccrine sweat. This can be annoying, disabling (at work or socially), or indicative of an underlying systemic disease. The eccrine gland is unusual in that the sympathetic sudomotor fibers are cholinergic rather than adrenergic.

Hyperhidrosis can be classified as *idiopathic* or *pathologic*. *Idiopathic* hyperhidrosis is defined as excessive sweating that is symmetric;

localized to the palms, soles, or axillae (singly or in combination); and independent of thermoregulation. Craniofacial hyperhidrosis is a similar but rarer condition. The other characteristics include its episodic nature, occurrence in response to stimuli, and onset at or after puberty; there is commonly a family history. There is an absence of bromhidrosis and little or no seasonal variation.

Pathologic hyperhidrosis may be localized or generalized. Localized hyperhidrosis may result from injury to the central or peripheral nervous systems, syringomyelia, neuritis, myelitis, tabes dorsalis, or localized vascular diseases, including cold injury, arteriovenous malformation, and erythrocyanosis. Localized hyperhidrosis can occur as a functional nevus in which a normal number of eccrine glands are oversensitive to acetylcholine. Localized areas of hyperhidrosis can develop as a compensatory phenomenon when extensive anhidrosis develops in Ross syndrome (bilateral Holmes Adie pupils, tendon areflexia, generalized anhidrosis). Hyperhidrosis may occur in hereditary conditions, including blue rubber bleb nevus syndrome. The causes of generalized hyperhidrosis include febrile illnesses; metabolic and endocrine diseases (diabetes, hyperthyroidism, gout, acromegaly, pregnancy, porphyria, pheochromocytoma, carcinoid syndrome, alcohol intoxication); congestive cardiac failure and shock; internal malignancy; central nervous system (CNS) diseases (tumors and injury); and hereditary syndromes (Chediak–Higashi syndrome and phenylketonuria).

Management Strategy

The treatments discussed here apply primarily to the symptomatic management of idiopathic hyperhidrosis.

Local treatments, including medical, electrical, or surgical modalities, aim to stop or reduce sweating sufficiently to control symptoms. Treatments with the lowest risk should be considered first, as dictated by the severity of the condition and a discussion with the patient to assess the balance of risk and benefit.

Topical aluminum chloride hexahydrate (ACH) 20% to 25% solution in ethanol is the first-line treatment. The mechanism of action may result from occlusion of the intraepidermal eccrine duct below the level of the stratum corneum. Correct application technique is critical to compliance: in the axillae, the solution should be applied nightly to the unshaven skin, with or without occlusion, and washed off the

next morning before daytime sweating is established. The presence of moisture results in the formation of hydrochloric acid and resultant skin irritation. Mild-potency topical corticosteroids may be used to reduce the common problem of skin irritation, which is the usual reason for treatment failure. ACH solution should not be applied again in the morning. An oral anticholinergic (e.g., 1 mg of sodium glycopyrrolate) 45 minutes before the application of ACH may increase its efficacy by reducing sweating at the time of application, allowing the ACH to be retained on the skin and exert its effect on the sweat pores. The oral anticholinergic may be discontinued after several treatments have initiated a reduction in sweating.

Hyperhidrosis may take 2 to 3 weeks to be controlled with topical ACH, at which time application can be reduced to once a week or at an interval that maintains control.

Other topical therapies include *formaldehyde*, which is a common contact sensitizer, and *glutaraldehyde*, which stains the skin. *Methenamine gel* releases formaldehyde but does not appear to produce contact allergy frequently. The anticholinergic *glycopyrrolate* in 1.5% to 2% concentrations topically in an aqueous cream base or as glycopyrrolate pads may be effective.

Iontophoresis is the process of introducing salt ions in solution through the skin into the tissues and may be effective in treating palmoplantar and axillary hyperhidrosis. Several iontophoretic devices are commercially available. Current is transmitted to electrodes in two trays filled with tap water, and the hands or feet are placed flat in the bottom of the trays. The current is increased until the patient experiences slight discomfort (average 15 mA on the palms and 20 mA on the soles). A special electrode for axillary use is available for some iontophoretic devices. The mechanism of reduction of sweating is not known. Current densities below the threshold of damage to the acrosyngium are employed, and mechanical obstruction does not occur. Iontophoresis is contraindicated in pregnancy and in patients with cardiac pacemakers and metal implants. Twenty-minute sessions three times a week are continued until sweating is sufficiently reduced; thereafter once- or twice-monthly maintenance therapies are instituted. Anticholinergic drugs such as glycopyrronium bromide may also be introduced by iontophoresis. A recent report suggests that botulinum toxin delivered by iontophoresis to the palms may be effective in the treatment of palmar hyperhidrosis.

Oral anticholinergic drugs and minor tranquilizers produce a dose-related inhibition of sweating and are therefore limited by side effects. Anticholinergic effects, including dry mouth, pupillary dilatation and photophobia, glaucoma, urinary retention, constipation, vomiting, and tachycardia, may, however, occur at doses that produce satisfactory sweat inhibition, thereby limiting their use. The oral anticholinergics most commonly used are *glycopyrronium bromide* (Robinul), up to 2 mg three times daily; *propantheline* 15 mg three times daily; or *oxybutynin* up to 5 mg twice daily. Oral glycopyrronium bromide is not licensed for use in hyperhidrosis in the UK.

Other systemic drugs that have been used include the calcium channel blocker *diltiazem*, the CNS inhibitor *clonidine*, and *tricyclic antidepressants*, although these are the subject of few anecdotal reports.

More aggressive treatments may be sought as a result of treatment failure, inconvenience of the treatments, or side effects.

Botulinum toxin injected intradermally produces sustained anhidrosis and is shown to be effective in treating axillary, palmar, craniofacial, postamputation stump hyperhidrosis, compensatory sweating, and Frey syndrome. There are eight known serotypes of botulinum toxin, type A exotoxin (BTX-A). The commercially available BTX-A products differ in their potency and are not equivalent unit for unit. Botulinum toxin type B has been shown to be effective in the treatment of axillary hyperhidrosis and may be used as an alternative to BTX-A products, especially where antibody formation has resulted in a loss of clinical benefit to BTX-A. It is recommended that experience be gained with one of the products. BTX-A produces its effect by irreversibly blocking the release of acetylcholine from cholinergic junctions. Treatment of the axilla is simple and well tolerated. Multiple injections, 2 cm apart, are performed in the axillary vault corresponding to the area of maximum sweating (an area of approximately 200 cm²). Palmar skin is painful to inject (may require a regional nerve block); injection is less well tolerated, and there is a potential for producing weakness of the intrinsic hand musculature. Administration of BTX-A to the palms by needle-free injector may be effective and less painful. It is not a practical treatment for plantar hyperhidrosis. Inactivation of affected cholinergic junctions is permanent, but new cholinergic junctions are produced through the natural process of tissue turnover and repair,

so the effect is temporary. Onset of anhidrosis after injection occurs at 24 to 72 hours and lasts 3 to 6 months. A number of reports describe the increase in duration of efficacy of repeated BTX-A treatments over time for axillary hyperhidrosis. There are reports of efficacy of BTX-A utilizing iontophoresis and Dermojet as delivery systems to affected areas.

Surgical and physical techniques that have been employed in the management of axillary hyperhidrosis include:

- Cryotherapy (very painful and poorly tolerated).
- Thermal injury of localized sweat glands using a microwave-based device or Nd:YAG laser.
- Methods that remove subcutaneous tissue alone. A number of skin flaps/incisions are described to gain access to the subcutaneous axillary tissues, and the deep dermis and adjacent subcutis are trimmed away. Subcutaneous curettage and axillary liposuction are other methods described for achieving this objective.
- Methods that excise skin and subcutaneous tissue.
- Methods that combine cutaneous excision and resection of subcutaneous tissue.

Selective ablation of the sympathetic innervation of the palms, axillae, and soles reduces sweating effectively. A number of side effects are associated with sympathectomy, including compensatory hyperhidrosis, Horner syndrome, pneumothorax, and intraoperative cardiac arrest. Satisfactory long-term results are generally achieved, although recurrence of sweating usually occurs. It is best reserved for severe palmar hyperhidrosis (upper thoracic sympathectomy T2/T3 ganglia), avoiding denervation of the axillary sweat glands and thereby minimizing side effects. This is performed as an open surgical technique or endoscopically (by a transthoracic route) using electrocautery or laser. Percutaneous chemical sympathectomy with ethanol has also been used, a technique that may be employed in lumbar sympathectomy to treat plantar hyperhidrosis. However, this is not generally recommended given the significant risk of sequelae, including ejaculatory failure, impotence, and anorgasmia.

Specific Investigations

- Starch iodine to define areas of maximum sweating
- Gravimetric tests can be used for quantification

Tests are not necessary for diagnosis of idiopathic hyperhidrosis. Investigation appropriate to the clinical history and physical signs is necessary when hyperhidrosis is not idiopathic.

First-Line Therapy

• Topical ACH solution in ethanol	B
-----------------------------------	----------

Aluminium chloride hexahydrate versus palmar hyperhidrosis. Evaporimeter study

Goh CL. Int J Dermatol 1990; 29: 368–70.

A single-blind study of unilateral palmar treatment with 20% ACH daily for 4 weeks in 12 patients. Efficacy was reported for all patients; however, four experienced skin irritancy, three patients clearing after 1 week of stopping treatment, and one patient withdrew from the study.

Axillary hyperhidrosis. Local treatment with aluminium-chloride hexahydrate 25% in absolute ethanol with and without supplementary treatment with triethanolamine

Glent-Madsen L, Dahl JC. Acta Dermatol Venereol 1988; 68: 87–9.

A randomized, double-blind, half-sided experiment in 30 volunteers. Triethanolamine in 50% ethanol was applied after treatment to one axilla to neutralize the pH and reduce skin irritation. The combined treatment was found to be less irritating, but also less effective in reducing sweating, although the reduction in efficacy was not noted by the volunteers.

Second-Line Therapies

• Topical anticholinergics	B
• Oral anticholinergics	D
• Iontophoresis	B
• Botulinum A neurotoxin	A
• Botulinum A neurotoxin delivered by Dermojet	C
• Botulinum A neurotoxin delivered by iontophoresis	D
• Botulinum B neurotoxin	C
• Liposuction and surgical excision (axillae only)	C
• Sympathectomy	B

Topical glycopyrrolate for patients with facial hyperhidrosis

Kim WO, Kil HK, Yoon KB, Yoon DM. Br J Dermatol 2008; 158: 1094–7.

Twenty-five patients were treated with 2% topical glycopyrrolate pads to one half of the forehead; the other side was treated with a placebo. Gravimetric testing showed a reduction in sweating on the treated side in the majority of patients.

Topical glycopyrrolate reduces axillary hyperhidrosis

Baker DM. J Eur Acad Dermatol Venereol 2016; 30: 2131–6.

A nonrandomized consecutive patient treatment comparison of 1% and 2% glycopyrrolate spray and subcutaneous botulinum toxin type A injections reporting effectiveness of 2% glycopyrrolate spray.

Propantheline bromide in the management of hyperhidrosis associated with spinal cord injury

Canaday BR, Stanford RH. Ann Pharmacother 1995; 29: 489–92.

Generalized hyperhidrosis after spinal injury was suppressed with careful titration of propantheline, starting at 15 mg daily and increasing to 15 mg three times daily.

Use of oral glycopyrronium bromide in hyperhidrosis

Baja V, Langtry JAA. Br J Dermatol 2007; 157: 118–21.

In this retrospective analysis of 19 patients with idiopathic hyperhidrosis of varying distribution, 79% reported response to treatment at a dose of 2 mg twice daily, increasing to 2 mg three times daily. In one third of patients treatment was limited by side effects.

Systemic therapy for primary hyperhidrosis: a retrospective study of 59 patients treated with glycopyrrolate or clonidine

Walling HW. J Am Acad Dermatol 2012; 66: 387–92.

Results of systemic anticholinergic treatment in 71 patients of whom 59 (mean age 29 years, 37 females, mean follow-up 19.5 months) had at least 2 months' follow-up data. Forty-two had palmoplantar or axillary, nine had generalized, and eight had craniofacial hyperhidrosis. Thirty out of 45 responded to glycopyrrolate at 1 to 2 mg twice daily. In the 15 treatment failures, 6 were nonresponders and 9 had adverse effects. Six out of 13 responded to clonidine 0.1 mg twice a day. In the seven treatment failures, three were nonresponders and four had adverse effects relating to hypotension. One patient responded to treatment with oxybutynin 5 mg twice a day.

A randomized placebo-controlled trial of oxybutynin for the initial treatment of palmar and axillary hyperhidrosis

Wolosker N, de Campos JRM, Kauffamn P, Puech-Leon P. J Vasc Surg 2012; 55: 1696–700.

A study on 50 patients with palmar or axillary hyperhidrosis treated with either placebo or oxybutynin 5 mg twice a day for 6 weeks and assessed by clinical questionnaire and for quality of life. Improvement was noted in the oxybutynin-treated group in 70% with palmar and axillary hyperhidrosis, and in 90% with plantar hyperhidrosis; 65% showed improvement in quality of life, although 48% experienced dry mouth.

Iontophoresis with alternating current and direct current offset (AC/DC iontophoresis): a new approach for the treatment of hyperhidrosis

Reinauer S, Neusser A, Schauf G, Holzle E. Br J Dermatol 1993; 129: 166–9.

Palmar hyperhidrosis was controlled after an average of 11 treatments, with both the conventional DC and the AC/DC iontophoresis units studied. The AC/DC method, however,

eliminated skin irritation and discomfort.

The effectiveness of tap water iontophoresis for palmo-plantar hyperhidrosis using a Monday, Wednesday, Friday treatment regime

Siah TW, Hampton PJ. *Dermatol Online J* 2013; 19: 14.

A retrospective study of 23 patients reported effective treatment with this regimen.

Treatment of hyperhidrosis

Heymann WR. *J Am Acad Dermatol* 2005; 52: 509–10.

A review of the treatments available for hyperhidrosis, focusing on botulinum toxin.

Botulinum toxin A for axillary hyperhidrosis (excessive sweating)

Heckmann M, Ceballos-Baumann AO, Plewig G. *N Engl J Med* 2001; 344: 488–93.

A multicenter trial in 145 patients with axillary hyperhidrosis comparing 200 U and 100 U of BTX-A (Dysport) per axilla. Changes in the rates of sweat production were measured gravimetrically. Two weeks after injection, sweat production was slightly less in the axilla injected with 200 U, and sweat reduction in both was significantly more than with placebo. After 24 weeks, sweat rates after 100 and 200 U were almost identical and less than half the baseline rate. Ninety-eight percent of the patients said they would recommend this therapy to others.

Botulinum toxin therapy for palmar hyperhidrosis

Shelley WB, Talanin NY, Shelley ED. *J Am Acad Dermatol* 1998; 38: 227–9.

Four patients with severe palmar hyperhidrosis were treated under regional nerve blocks of the median and ulnar nerve. Anhidrosis lasted for 12, 7, 7, and 4 months, respectively, and one patient experienced mild weakness of a thumb lasting 3 weeks.

A double-blind, randomized, comparative study of Dysport™ vs. Botox™ in primary palmar hyperhidrosis

Simonetta Moreau M, Cauhepe C, Magues JP, Senard JM. *Br J Dermatol* 2003; 149: 1041–5.

Eight patients were treated with intradermal injections of Botox in

one palm and Dysport in the other (using a conversion factor of 1:4) after regional nerve blocks. Similar efficacy was reported for the two BTX-A products.

Effective treatment of frontal hyperhidrosis with botulinum toxin A

Kinkelin I, Hund M, Naumann M, Hamm H. Br J Dermatol 2000; 143: 824–7.

Ten men with focal frontal hyperhidrosis are reported to have had a good response to treatment with BTX-A injections.

Treatment of palmar hyperhidrosis with needle injection versus low-pressure needle-free jet injection of onabotulinum toxin A: an open label study

Vadeboncoeur S, Richer V, Nantel-Battista M, Benohanain A. Dermatol Surg 2017; 43: 264–9.

A prospective open-label study showing efficacy of onabotulinum toxin A treatment with needle-free injector.

BOTOX™ delivery by iontophoresis

Kavanagh GM, Oh C, Shams K. Br J Dermatol 2004; 151: 1093–5.

Two patients with palmar hyperhidrosis had treatment with BTX-A (Botox) delivered by iontophoresis. Control of approximately 70% was achieved for 3 months, without side effects.

Botulinum toxin type B: a new therapy for axillary hyperhidrosis

Nelson L, Bachoo P, Holmes J. Br J Plast Surg 2005; 58: 228–32.

The efficacy of BTX-B (NeuroBloc) was demonstrated in the treatment of 13 patients with axillary hyperhidrosis.

Liposuction for the treatment of axillary hyperhidrosis

Lillis PJ, Coleman WP. Dermatol Clin 1990; 8: 479–82.

The authors suggest that this technique shows promise as the surgical treatment of choice for axillary hyperhidrosis resistant to other modalities.

Surgical treatment of axillary hyperhidrosis in 123 patients

Bretteville-Jensen G, Mossing N, Albrechsten R. Acta Derm Venereol 1975; 55: 73–8.

Excision of the axillary vault and reconstruction with a modified Z-

plasty is described. Of 123 patients, 57% achieved a 75% to 100% reduction of axillary sweating and 36% achieved a 50% to 75% reduction. Complications included hematomas in 6 patients, limited flap necrosis in 5, and minor complications in 10 patients. There were no cases of keloid formation or restricted arm movement from wound contracture.

Transthoracic endoscopic sympathectomy for palmar hyperhidrosis in children and adolescents: analysis of 350 cases

Lin TS. J Laparoendosc Adv Surg Tech A 1999; 9: 331–4.

A total of 699 sympathectomies were performed in 350 patients aged 5 to 17 years (mean 12.9 years). There were no surgical deaths. The mean follow-up was 25 months (range 5–44 months), with highly satisfactory results reported in 95% of patients, although compensatory hyperhidrosis (86%) affected the axillae (12%), back (86%), abdomen (48%), or lower limbs (78%). The recurrence rates of palmar hyperhidrosis were 0.6% in the first year, 1.1% in the second, and 1.7% in the third.

Thoracoscopic sympathectomy for disabling palmar hyperhidrosis: a prospective randomized comparison between two levels

Baumgartner FJ, Reyes M, Sarkisayan GG, Iglesias A. Ann Thorac Surg 2011; 92: 2015–9.

Bilateral sympathectomy for severe palmar hyperhidrosis at the second costal head (R2 in 61 patients) versus the third costal head (R3 in 60 patients). R2 failed in 5 of 122 extremities and R3 in 5 of 120 extremities. R2 patients showed a trend toward higher levels of compensatory hyperhidrosis compared with R3 patients. R2 and R3 were found to be effective for disabling palmar hyperhidrosis with a low incidence of severe compensatory hyperhidrosis.

Severe plantar hyperhidrosis: an effective solution

Reisfeld R, Pasternack GA, Danials PD, Basseri E, Nish GK, Berliner KI. Ann Surg 2013; 79: 845–53.

Endoscopic lumbar sympathectomy using the clamping method was reported in 154 patients. Anhidrosis was achieved in 97% with two complications and six conversions to an open surgical procedure.

Third-Line Therapies

• Microwave-based devices	B
• Lasers and photodynamic therapy	D
• Biofeedback and behavioral modification	D
• Diltiazem	E
• Clonazepam	E
• Clonidine	E

Radiofrequency thermotherapy for treating axillary hyperhidrosis

Schick CH, Grallath T, Schick KS, Hashmonai M. *Dermatol Surg* 2016; 42: 624–30.

Thirty-three patients treated with radiofrequency thermotherapy with noninsulated microneedle three times at intervals of 6 weeks with average reduction of sweating reported to be 72%.

New treatment techniques for axillary hyperhidrosis

Mordon SR, Trelles MA, Leclerc FM, Betrouni N. *J Cosmet Laser Ther* 2014; 16: 230–5.

The use of Nd:YAG laser, diode laser, and photodynamic therapy is described as potential new treatments for axillary hyperhidrosis.

Clinical evaluation of a microwave based device for treating axillary hyperhidrosis

Hong HC, Lupin M, O'Shaughnessy KF. *Dermatol Surg* 2012; 38: 728–35.

The aim is to selectively heat the interface between the skin and fat and thereby inhibit sweat gland excretion. Thirty-one patients with primary axillary hyperhidrosis had one to three treatments to both axillae over 6 months. At 12 months 90% had a 50% reduction in axillary sweating from baseline and 85% had a reduction of at least 5 points on the DLQI.

Use of biofeedback in treating chronic hyperhidrosis

Duller P, Gentry WD. Br J Dermatol 1980; 103: 143–8.

Biofeedback and behavioral modification can be tried, but is helpful in only a small number of patients.

Emotional eccrine sweating. A heritable disorder

James WD, Schoomaker EB, Rodman OG. Arch Dermatol 1987; 123: 925–9.

Two members of a family with palmar hyperhidrosis showed reduced palmar sweat secretion during administration of diltiazem.

Unilateral localized hyperhidrosis responding to treatment with clonazepam

Takase Y, Tsushimi K, Yamamoto K, Fukusako T, Morimatsu M. Br J Dermatol 1992; 126: 416.

A case of unilateral hyperhidrosis responding to this benzodiazepine antiepileptic agent.

Clonidine treatment in paroxysmal localized hyperhidrosis

Kuritzky A, Hering R, Goldhammer G, Bechar M. Arch Neurol 1984; 41: 1210–1.

Improvement of paroxysmal localized hyperhidrosis is described in two patients with oral clonidine hydrochloride 0.25 mg three times a day. Control of sweating was maintained with continuous treatment at 12-month follow-up.

Hypertrichosis and hirsutism

Shannon Harrison, Najwa Somani, and Wilma F. Bergfeld

Introduction

Hirsutism is the excessive growth of terminal hairs in women in male androgen-dependent areas (face, breasts, upper thighs, abdomen, and back). It adversely affects quality of life. Although defined by a modified Ferriman–Gallwey (F-G) score of ≥ 8 , race and ethnicity

affect this criterion.

Hirsutism can result from endogenous androgens (ovarian or adrenal), exogenous androgens, or from increased hair follicle sensitivity to normal androgen levels. Common causes are polycystic ovarian syndrome (PCOS) and idiopathic hirsutism. Rarer causes are endocrinopathies, non-classical congenital adrenal hyperplasia and androgen-secreting tumors.

Hypertrichosis, by contrast, results from increased vellus hair growth in an androgen-independent, nonsexual distribution. Causes are familial or secondary to medications or an underlying systemic disorder.

Main Causes of Hirsutism

Ovarian

- **Polycystic ovary (PCOS) syndrome** (menstrual irregularities, infertility, and metabolic syndrome*)
- **HAIR-AN syndrome** (hyperandrogenism, severe metabolic syndrome*, acanthosis nigricans)
- **Hyperthecosis** (menstrual irregularities and metabolic syndrome*)
- **Ovarian tumors and hyperplasia** (irregular menses, virilization symptoms)

Adrenal

- **Congenital adrenal hyperplasia** – classical and nonclassical types (irregular menses, primary amenorrhea)
- **Cushing syndrome** (striae, fat redistribution, fragile skin, proximal muscle weakness, mood disturbance, insulin resistance)
- **Adrenal tumors** (virilization symptoms)

Pituitary**

- **Cushing disease** (striae, fat redistribution, fragile skin, proximal muscle weakness, mood disturbance, insulin resistance)
- **Acromegaly** (coarse facies and enlarged hands)
- **Hyperprolactinemia** (galactorrhea)

Idiopathic

- Occult functional hyperandrogenism

- Abnormalities in peripheral 5 α -reductase or androgen receptor

Exogenous (androgenic medications)

- Testosterone, adrenocorticotrophic hormone (ACTH), valproic acid, anabolic steroids, androgenic progestins

* Metabolic syndrome: obesity, insulin resistance/diabetes mellitus type 2, lipid abnormalities, cardiovascular disease.

** Pituitary tumors can also present with visual field disturbances.

Management Strategy

A thorough history and physical examination should identify any underlying cause of hypertrichosis and hirsutism. Offending drugs should be discontinued.

Most hirsute women have raised circulating androgen levels. In idiopathic hirsutism, circulating androgen levels appear normal, and menstrual cycles are regular. Polycystic ovarian syndrome (PCOS) and the rarer HAIR-AN syndrome and ovarian hyperthecosis present with signs of hyperandrogenism and metabolic syndrome. In obese women, weight loss improves markers of metabolic syndrome and reduces cardiovascular risk. Body mass index (BMI) is the most important risk factor for hirsutism severity in PCOS.

Acute onset or rapid progression of hirsutism or presence of virilization indicate possible adrenal or ovarian tumor. In nonclassical congenital adrenal hyperplasia, glucocorticoid therapy assists with ovulation induction, but hirsutism often requires systemic antiandrogen therapy. For classical congenital adrenal hyperplasia, glucocorticoids address both ovulation induction and hirsutism.

Physical hair removal methods

Mechanical hair removal is the first-line treatment choice for hirsutism and hypertrichosis. *Bleaching* with hydrogen peroxide preparations disguises dark facial hair but can irritate. Painless depilatory methods remove hair shafts at the skin surface. *Chemical depilatory creams* are quick to use but can irritate, and skin folds should be avoided. *Shaving* is inexpensive but is time consuming and not acceptable to most women except for the axillae and legs. Shaving

does not affect the diameter or rate of growth of hair.

Epilatory hair removal methods remove the entire hair, including the root, and are painful. *Tweezing or plucking* is used in areas with fewer hairs. *Waxing* is used where hair density is higher. Epilation with *electrolysis* can achieve permanent reduction in hair growth but is time consuming, requires multiple treatments, and is operator dependent. It can be used on any skin or hair color. A fine needle is inserted into the hair follicle, which delivers direct current (galvanic electrolysis), high-frequency alternating current (thermolysis), or a blend of the two currents to damage the hair follicle. Side effects of all mechanical hair removal methods include erythema, folliculitis, pseudofolliculitis, infection, scarring, and dyspigmentation.

Photoepilation lasers include ruby (694 nm), alexandrite (755 nm), diode (800–810 nm), Nd:YAG (neodymium:yttrium-aluminum-garnet) laser (1064 nm) and IPL (intense pulsed light) noncoherent sources of 590 to 1200 nm. Lasers and IPL give partial short-term hair reduction up to 6 months, and efficacy improves with repeat treatments. No laser can achieve complete or persistent hair removal. Ideal candidates have fair skin and dark hair. Side effects include erythema, scarring, burns, dyspigmentation, and rarely with IPL, a paradoxical increase in hair growth.

Twice-daily *eflornithine hydrochloride* cream is approved by the Food and Drug Administration (FDA) for facial hirsutism and slows the rate of hair growth by irreversibly inhibiting ornithine decarboxylase. Benefits reverse after 8 weeks of discontinuation. Side effects include acne, pseudofolliculitis barbae, and irritant and allergic contact dermatitis. Adjuvant use with laser hair removal improves efficacy.

Systemic therapies for hirsutism

Although several meta-analyses and treatment guidelines are published, evidence supporting hirsutism treatments are limited due to small sample sizes and limited methodology of studies.

Combined oral contraceptive pills (estrogen and progestin OCP) are a first-line treatment for hirsutism. They reduce hyperandrogenism predominantly by suppressing ovarian androgen synthesis, increasing sex hormone-binding globulin levels, and suppressing free plasma testosterone levels. OCPs with low androgenic progestins (desogestrel or norgestimate) and progestins with antiandrogenic properties (cyproterone acetate, drospirenone) are preferred.

However, potential risks (e.g., deep venous thrombosis) and benefits should be weighed, especially when choosing a second- or third-generation OCP. Clinical response requires 6 to 12 months of treatment. Combination treatment with another antiandrogen (e.g., spironolactone) is considered if response to monotherapy is limited.

Hirsutism can result from endogenous androgens (ovarian or adrenal), exogenous androgens, or from increased hair follicle sensitivity to normal androgen levels. Common causes are polycystic ovarian syndrome (PCOS) and idiopathic hirsutism. Rarer causes are endocrinopathies, non-classical congenital adrenal hyperplasia and androgen-secreting tumors.

Spironolactone is an antiandrogen that inhibits androgen biosynthesis and blocks the androgen receptor. The usual dose for hirsutism is 100 to 200 mg daily. Side effects include hyperkalemia, hypotension, and irregular menses. Tumorigenicity has been shown in animals, but relevance in humans is questionable. All antiandrogens, including spironolactone, have feminizing teratogenic potential and should be used with a reliable form of contraception. Hence, all pharmacologic therapy for hirsutism should not be commenced in women planning pregnancy.

Cyproterone acetate inhibits the androgen receptor. It can be used either in a sequential way for the first 10 days of the menstrual cycle (25–100 mg) with an OCP or a low dose (2 mg) in a combined OCP (Diane-35). Side effects are similar to OCPs. It is not available in the United States.

Finasteride is a type II 5-alpha-reductase inhibitor. It is pregnancy category X. Benefit is shown with oral therapy but not when used topically in a compounded formulation. No reports exist for dutasteride, a type I and II 5-alpha-reductase inhibitor for the treatment of hirsutism.

Flutamide and *insulin-lowering drugs* are not recommended for the treatment of hirsutism. Flutamide has specific indications but comes with significant risk of hepatotoxicity.

GnRH analogs are not recommended in the treatment of hirsutism unless oral contraceptives and antiandrogen treatments fail and hyperandrogenism is severe. Gonadotropin-releasing hormone (GnRH) treatment reduces estrogen to menopausal levels, causing hot flashes and osteoporosis risk.

Specific Investigations

Screening test

- Testosterone level (free and total)
- Consider β hCG level

If testosterone level raised or underlying endocrinopathy or tumor suspected

- Sex hormone-binding globulin level
- Dehydroepiandrosterone sulfate level

Androstenedione level

- Follicle-stimulating hormone level (FSH)

Luteinizing hormone level (LH)

- Serum prolactin
- 17-hydroxyprogesterone level (morning, follicular phase)

24-hour urinary free cortisol

- Somatomedin C level (IGF-1)
- Thyrotropin level

Special tests

- Transvaginal ovarian ultrasound
- Dexamethasone suppression test
- Computed tomography/magnetic resonance imaging (CT/MRI) abdomen or pelvis
- Cranial MRI

Investigations can identify underlying pathology. Moderate to severe hirsutism, hirsutism with signs of hyperandrogenism (e.g., clitoromegaly, central obesity, acanthosis nigricans, infertility, or irregular menstrual cycles), and acute-onset or rapidly progressing hirsutism should be investigated. Although controversy exists on obtaining androgen levels in mild isolated hirsutism (F-G score 8–15), we suggest testosterone screening on all patients.

An LH:FSH ratio >2 suggests, but does not confirm, PCOS. Transvaginal ultrasound detects polycystic ovaries, the presence or absence of which alone neither confirms nor refutes the diagnosis. Metabolic screening is essential. Early-morning serum 17-

hydroxyprogesterone level detects nonclassical congenital adrenal hyperplasia. Twenty-four-hour urine cortisol and dexamethasone suppression tests evaluate for Cushing disease. Prolactin level and somatomedin-C (IGF-1) level screen for hyperprolactinemia and acromegaly, respectively. Suspicion of a pituitary tumor requires MRI scanning of the brain. Transvaginal ultrasound or abdominal CT or MRI scan can exclude an ovarian or adrenal tumor. Rarely, pregnancy and hypothyroidism can cause hirsutism and should be excluded.

The hirsute woman: challenges in evaluation and management

Paparodis R, Dunaif A. Endocrine Practice 2011; 17: 807–18.

A review of the etiology and diagnostic approach to hirsutism.

Epidemiology, diagnosis and management of hirsutism: a consensus statement by the Androgen Excess and Polycystic Ovary Syndrome Society

A review of the diagnosis and management of hirsutism.

The evaluation and treatment of androgen excess

Practice Committee of the American Society for Reproductive Medicine. Fertil Steril 2006; 86: S241–7.

This article reviews clinical diagnosis and laboratory testing for hirsutism.

The clinical evaluation of hirsutism

Somani N, Harrison S, Bergfeld WF. Dermatol Ther 2008; 21: 376–91.

The article has tables on history, examination templates, and diagnostic algorithms for evaluation of hirsutism.

First-Line Therapies

• Treat specific underlying pathology	
• Temporary hair removal/camouflage	B
• Weight loss if obese with PCOS	B
• Electrolysis	D
• Laser therapy and IPL	B
• Eflornithine	B
• Eflornithine with laser/IPL	C

American Association of Clinical Endocrinologists, American College of Endocrinology, and Androgen Excess and PCOS Society Disease State Clinical Review: guide to the best practices in the evaluation and treatment of polycystic ovarian syndrome – part 1

Goodman NF, Cobin RH, Futterweit W, Glueck JS, Legro RS, Carmina E. Endocrine Practice 2015; 21: 1291–300.

A thorough review of clinical features, investigations, and treatment for PCOS.

Lifestyle changes in women with polycystic ovary syndrome

Moran LJ, Hutchison SK, Norman RJ, Teede HJ. Cochrane Database Syst Rev 2011; 7: CD007506.

Limited studies show a small benefit from counseling on lifestyle modification in conjunction with other treatments for hirsutism, especially in PCOS. Smoking cessation, particularly in the case of OCPs use, is prudent.

Hirsutism

Mofid A, Alinaghi SA, Zansieh S, Yazdani T. Int J Clin Pract 2008; 62: 433–43.

A review of diagnostic strategies with user-friendly tables on hair removal methods and pharmacotherapies.

A comparative study of axillary hair removal in women: plucking versus the blend method

Urushibata O, Kasa K. *J Dermatol* 1995; 22: 738–42.

There are no randomized controlled trials on electrolysis. This small comparative study showed electrolysis was more effective than plucking for reduction of axillary hair.

Electrolysis: observations from 13 years and 140,000 hours of experience

Richards RN, Meharg GE. *J Am Acad Dermatol* 1995; 33: 662–6.

Side effects and efficacy are operator dependent.

Laser and photoepilation for unwanted hair growth

Haedersdal M, Gøtzsche PC. *Cochrane Database Syst Rev* 2006; 4: CD004684.

Diode and alexandrite lasers conferred short-term 50% hair reduction lasting up to 6 months after treatment. IPL, neodymium:YAG, or ruby lasers have limited evidence of benefit.

Evidence based review of hair removal using lasers and light sources

Haedersdal M, Wulf HC. *J Eur Acad Dermatol Venerol* 2006; 20: 9–20.

Meta-analysis showing laser and IPL hair reduction as more effective short term than shaving, waxing, electrolysis, and epilation. The relative efficacy of different hair removal lasers and IPL has been compared in several studies, but small sample sizes can introduce type 2 errors.

Meta-analysis of hair removal laser trials

Sadoghha A, Mohaghegh Zahed G. *Lasers Med Sci* 2009; 24: 21–5.

Hair reductions 6 months posttreatment were 57.5%, 42.3%, 54.7%, and 52.8% after three treatments for diode, Nd:YAG, alexandrite, and ruby lasers, respectively.

Photoepilation with a diode laser vs. intense pulsed light: a randomized, inpatient left-to-right trial

Klein A, Steinert S, Baeumler W, Landthaler M, Babilas P. *Br J Dermatol* 2013; 168: 1287–93.

Diode laser more effectively decreased axillary hair counts in 30 patients compared with IPL. Mean reductions from baseline at 3 and

12 months after six treatment sessions were 59.7% and 69.2% for diode laser and 42.4% and 52.7% for IPL ($P < 0.01$), respectively. Diode treatment was more painful than IPL.

Randomized, double blind clinical evaluation of the efficacy and safety of topical eflornithine HCl 13.9% cream in the treatment of women with facial hair

Wolf JE Jr, Shander D, Huber F, Jackson J, Lin C-S, Mathes BM, et al. Eflornithine Study Group. *Int J Dermatol* 2007; 46: 94–8.

Using a physician's global rating, at week 24, 58% of eflornithine-treated patients were improved compared with 34% of vehicle-treated patients.

A randomized bilateral vehicle controlled study of eflornithine cream combined with laser treatment versus laser treatment alone for facial hirsutism in women

Hamzavi I, Tan E, Shapiro J, Lui H. *J Am Acad Dermatol* 2007; 57: 54–9.

Eflornithine cream combined with six sessions of long-pulse alexandrite laser resulted in statistically significant differences in hair count analysis ($P < 0.01$) and blinded patient grading ($P < 0.029$) compared with laser alone for upper lip hirsutism in 31 patients.

Second-Line Therapies

• Oral contraceptives	B
• Spironolactone	B
• Cyproterone acetate	B

Hirsutism: an evidence-based treatment update

Somani N, Turvy D. *Am J Clin Dermatol* 2014; 15: 247–66.

A detailed clinical update and literature review of treatments for hirsutism with informative treatment tables.

Evidence-based approach to cutaneous hyperandrogenism in women

Schmidt TH, Shinkai K. *J Am Acad Dermatol* 2015; 73: 672–690.

A detailed analysis of management and treatments for cutaneous hyperandrogenism, including hirsutism.

Interventions for hirsutism (excluding laser and photoepilation therapy alone): review

Van Zuuren EJ, Fedorowicz Z, Carter B, Pandis N. *Cochrane Database Syst Rev* 2015; 4: CD010334.

Overall, published evidence on hirsutism treatment is limited, with small sample sizes and lack of blinding. Pooled data for OCP with ethinyl estradiol (EE) and cyproterone acetate vs. an OCP with EE and desogestrel demonstrated that both were effective in reducing F-G scores without significant difference between the two (mean difference [MD]: -1.84, 95% confidence interval [CI]: -3.86 to -0.18). Spironolactone 100 mg daily was more effective than placebo in reducing F-G scores (MD: -7.69, 95% CI: -10.12 to -5.26). Flutamide and finasteride had similar efficacies. Finasteride 5 mg and GnRH analogs showed inconsistent results in several studies. GnRH has significant side effects. Metformin showed no benefit over placebo.

Cyproterone acetate for hirsutism

Van der Spuy ZM, Le Roux PA. *Cochrane Database Syst Rev* 2003; 4: CD001125.

There are no studies comparing cyproterone acetate alone with placebo. One small placebo-controlled trial exists with cyproterone acetate 2 mg with EE OCP showing that it was more effective than placebo in reducing hirsutism scores.

Spironolactone versus placebo or in combination with steroids for hirsutism and/or acne (review)

Brown J, Farquhar C, Lee O, Toomath R, Jepson RG. *Cochrane Database Syst Rev* 2009; 2: CD000194.

Subjective improvement in hair growth was noted with spironolactone compared with placebo.

Third-Line Therapies

• Oral finasteride	B
• Topical finasteride	D
• Flutamide	B
• Insulin-lowering monotherapy	B
• GnRH agonist analogs	B

Antiandrogens for the treatment of hirsutism: a systematic review and meta-analyses of randomized controlled trials

Swiglo BA, Cosma M, Flynn DN, Kurtz DM, LaBella ML, Mullan RJ, et al. J Clin Endocrinol Metab 2008; 93: 1153–60.

Two trials showed spironolactone (100 mg/d) was superior to placebo in improving hirsutism. Meta-analysis showed both finasteride and flutamide to be superior to placebo in reducing F-G scores. Antiandrogens were superior to metformin, and when spironolactone or finasteride are combined with OCPs, or when flutamide is combined with metformin, these regimens are superior to monotherapy with OCPs and metformin, respectively.

A randomized double blind, vehicle controlled bilateral comparison study of the efficacy and safety of finasteride 0.5% solution in combination with IPL in the treatment of facial hirsutism

Farshi S, Mansouri P, Rafie F. J Cosmet Laser 2012; 14: 193–9.

Addition of 0.5% finasteride solution in a split-face, vehicle-controlled trial of 75 women with chin hirsutism who were treated with three sessions of IPL showed minimal additional clinical improvement.

Evaluation and treatment of hirsutism in premenopausal women:

an Endocrine Society clinical practice guideline

Martin KA, Chang J, Ehrmann DA, Ibanez L, Lobo RA, Rosenfield RL, et al. J Clin Endocrinol Metab 2008; 93: 1105–20.

Combined analysis of studies showed that OCPs are associated with a reduction in hirsutism scores. Meta-analysis concluded that no therapeutic advantages exist for GnRH treatment compared with other antiandrogens and OCPs.

Insulin sensitizers for the treatment of hirsutism: a systematic review and metaanalyses of randomized controlled trials

Cosma M, Swiglo BA, Flynn DN, Kurtz DM, LaBella ML, Mullan RJ, et al. J Clin Endocrinol Metab 2008; 93: 1135–42.

Metformin and the thiazolidinediones provided little or no important benefit.

Hypopigmented disorders

Seemal Desai, and Sneha Ghunawat

Hypomelanotic disorders are skin conditions presenting with light-colored areas due to reduced melanin content in the lesional skin. Depigmented lesions, on the other hand, present clinically as milky white patches secondary to total destruction of melanocytes in the

lesion. The disorders can be classified according to age of onset, extent of lesion, and underlying cause. This chapter briefly reviews the common hypopigmented dermatosis along with a brief overview of treatment options available.

Postinflammatory Hypomelanosis

Many dermatoses such as psoriasis, atopic dermatitis, seborrheic dermatitis, lupus erythematosus, sarcoidosis, lichen striatus, etc., lead to hypopigmented patches on resolving. Cutaneous injuries, burn, and cosmetic procedure (dermabrasion, chemical peels, and cryosurgery) can also lead to pigment loss. This loss of pigment is proposed to be secondary to alternation in the melanogenic pathway, destruction of melanocytes, or decrease in melanosome transfer. The severity of the pigment loss is proportionate to the degree of initial inflammation. The distribution also coincides with the distribution of the original lesions. It is seen in all skin types but is more frequently reported among dark-skinned individuals due to marked color contrast with the normal skin. The tendency of an individual to develop hypopigmentation/hyperpigmentation after initial inflammation is determined by the “chromatic tendency” of the patient. It is genetically determined and has an autosomal-dominant inheritance. Light microscopy from the lesions reveals loss of melanin content with a variable degree of lymphohistiocytic infiltrate in the upper dermis with occasional melanophages. The lesions may repigment spontaneously, such as after the procedure or may remain depigmented permanently, such as after lesions of lupus erythematosus.

Pityriasis Alba

It is an eczematous disorder seen commonly among children with a personal or family history of atopy, such as atopic dermatitis, conjunctivitis, rhinitis, asthma, etc. Lesions present with hypopigmented macules 0.5 to 3 cm in diameter located commonly on the face, neck, shoulders, and upper extremities. The lesions are covered with fine white scales. Erythema and pruritus are other common findings. The lesions are self-limiting. The generalized form of pityriasis alba is seen in adolescents and young adults with no personal or family history of atopy. The lesions are numerous,

persistent, and involve the trunk and extremities.

Pityriasis Versicolor

This condition, which is also known as *tinea versicolor*, is a superficial infection of the keratin layer of the epidermis. The etiologic agent is a lipophilic yeast, *Pityrosporum orbiculare*, that is part of the normal flora of the skin. The organism is found more commonly in the budding form. The disease is seen when the form changes to hyphae.

Potassium hydroxide mount of the lesion demonstrates “spaghetti and meatball” appearance. The sites involved include those that possess a high density of sebaceous glands such as the shoulders and upper back. The lesions clinically present with well-defined hypopigmented macules, which often coalesce into small patches with overlying fine scaling. The hypopigmentation is attributed to the formation of dicarboxylic acid by the organism. One such product, azelaic acid, inhibits tyrosinase in the melanogenesis pathway. Rarely the lesions can also be hyperpigmented to erythematous in color.

Leprosy (Hansen Disease)

It is an infectious disorder caused by *Mycobacterium leprae*. The bacteria affect the skin and peripheral nerves. The cutaneous lesions present clinically as well- to ill-defined hypopigmented macules with variable degrees of scaling and induration. The lesions classically are hypoesthetic, and examination reveals enlarged peripheral nerves.

Hypopigmented Variants of Common Dermatoses

Many common skin dermatoses such as mycosis fungoides, sarcoidosis, morphea, and scleroderma present with hypopigmented variants.

The hypopigmented variant of mycosis fungoides presents with ill-defined, light-colored macules and patches distributed primarily on sun-protected sites such as the back and buttocks. Histopathology reveals the presence of atypical lymphocytes in the epidermis (epidermotropism).

Lichen sclerosus is a chronic inflammatory disorder presenting clinically with hypopigmented to depigmented porcelain white

plaques. The disease affects women in the fifth to sixth decades of life. The mechanism of depigmentation includes a decrease in melanin content and lack of transfer to melanosomes. Common sites of involvement are anogenital areas.

Morphea and systemic sclerosis also commonly present with hypopigmentation. The lesions are classically indurated. The typical presentation of the lesions includes a “salt and pepper” appearance. This refers to the perifollicular hyperpigmentation seen in hypopigmented patches. Differentiation from repigmenting patches of vitiligo can be difficult.

Hypopigmented variants of sarcoidosis are a less common presentation of the disease. It is more common among darker-colored individuals. The lesions favor the extremities. Clinical clues to the diagnosis include induration and yellowish tinge on diascopy.

Idiopathic Guttate Hypomelanosis

Idiopathic guttate hypomelanosis, also called *senile depigmented spots* and *symmetric progressive leukopathy of extremities*, is a common cause of acquired leukoderma seen in older patients and occasionally in young adults. It presents clinically with porcelain-white, guttate, oval-to-round lesions 2 to 5 mm in diameter present over the sun-exposed area of extremities. The number of lesions tends to increase with age. Although the lesions are asymptomatic, it is a cause of cosmetic concern for the patient. Etiology of this disorder is largely unknown. Multiple factors have been implicated such as HLA DQ 3, trauma, chronic sun exposure, and autoimmunity. Light microscopy reveals hyperkeratotic stratum corneum, atrophic epidermis, and flattened rete ridges. Decrease in the number of melanocytes and melanin content is noted in the lesions. The dermis shows changes of actinic damage such as elastorrhexis, collagen homogenization, and basophilia.

Progressive Macular Hypomelanosis

It is an acquired cause of hypomelanosis presenting commonly in individuals of mixed genetic background with skin type IV to VI. Common synonyms of this condition include *idiopathic multiple large macule hypomelanosis*, *nummular and confluent hypomelanosis of the trunk*, *cutis trunci variata*, and *creole dyschromia*. The etiology of this disorder

is largely unknown. The presence of hormonal influences and *Propionibacterium* spp. has been implicated, although the exact pathogenic factors still need to be identified. It presents clinically with round, pale, coalescent macules over the back and less frequently on the abdomen. The lesions tend to be confluent in the midline. Microscopy reveals disruption in the maturation and distribution of melanosomes in the lesional skin. The clinical course of this disorder is unpredictable; spontaneous cure is reported over decades to years.

Chemical Leukoderma

The lesions present as depigmented macules initially developing at the sites of contact with industrial chemicals such as phenols, catechol, and hydroquinone. The lesions later spread to distant sites. The lesions are depigmented and clinically resemble vitiligo. Careful history is thus important in establishing the diagnosis. History of exposure to offending chemicals, along with similar history in other people at the workplace, is crucial in establishing the diagnosis.

Vitiligo is the subject of a separate chapter.

Management Strategy

The importance of a good history and thorough clinical examination cannot be underestimated when dealing with hypopigmented dermatosis. Detailed history regarding the age of onset, history of preceding lesions, associated symptoms, exposure to chemicals, family history, etc., is indispensable for reaching a correct diagnosis. Detailed note of the nature of pigmentary loss (hypo/depigmentation); site and distribution of lesions; and presence of associated findings such as induration, scaling, and sensory loss is to be made to reach a correct diagnosis.

Wood lamp examination helps to differentiate between hypopigmented and depigmented lesions. Progressive macular hypomelanosis displays punctate red fluorescence, whereas pityriasis versicolor displays a coppery-orange hue. Confocal laser scanning microscopy helps to access the melanin content and distribution patterns. Histopathology aids in identifying the primary disease process.

Sun exposure helps in repigmentation of lesions when there are residual functional melanocytes. Ultraviolet light stimulates

melanocytes and melanin synthesis. However, overexposure may also carry a risk of increased color contrast due to skin tanning.

First-Line Therapies

• Photochemotherapy	D
• Topical corticosteroids	D
• Topical calcineurin inhibitors	D

Laser resurfacing induced hypopigmentation: histologic alterations and repigmentation with topical photochemotherapy

Grimes PE, Bhawan J, Kim J, Chiu M, Lask G. Dermatol Surg 2001; 27: 515–20.

Ten patients of post–laser resurfacing hypopigmentation were included in the study. Baseline biopsies were performed and assessed for epidermal melanin content, melanophages in dermis, perivascular inflammation, and dermal fibrosis. Patients underwent treatment with topical 0.001% 8 methoxypsoralen twice a week. The hydrophilic ointment was applied on the lesions for 30 minutes followed by ultraviolet A exposure at an initial dose of 0.2 to 0.5 J/cm² and increased by 0.2 to 0.5 J/cm² weekly. Topical photochemotherapy-induced moderate to excellent repigmentation was seen in 71% of patients. Adverse effects reported were minimal.

Topical 0.05% clobetasol propionate versus 1% pimecrolimus ointment in vitiligo

Coskun B, Saral Y, Turgut D. Eur J Dermatol 2005; 15: 88–91.

Ten vitiligo patients with bilaterally symmetric lesions were included in the study. Clobetasol propionate 0.05% was applied twice daily on the right side, whereas 1% pimecrolimus ointment was applied twice daily on the left side. Both sides showed comparable repigmentation at the end of the study.

Pilot trial of 1% pimecrolimus cream in the treatment of seborrheic dermatitis in African American adults with associated hypopigmentation

High WA, Pandya AG. J Am Acad Dermatol 2006; 54: 1083–8.

Five African Americans suffering from seborrheic dermatitis with hypopigmentation were in the pilot trial. Pimecrolimus was applied on the affected areas twice daily for 16 weeks. Hypopigmentation was assessed using a Mexameter. Marked improvement was noted 2 weeks onward.

Second-Line Therapies

• Laser	D
• Cosmetic camouflage	B
• Melanocyte grafting	C

The safety and efficacy of the 308-nm excimer laser for pigment correction of hypopigmented scars and striae alba

Alexiades-Armenakas MR, Bernstein LJ, Friedman PM, Geronemus RG. Arch Dermatol 2004; 140: 955–60.

Total of 31 adults with hypopigmented scars (22) and striae alba (9) were enrolled. Lesions were treated with xenon chloride excimer laser (308 nm, 3.2 cm², 30 ns). Initially treatment was started at 50 mJ/cm² minus the minimal erythema dose of the patient. Treatment was done biweekly until 50% to 75% pigment reaction was obtained, followed by two weekly sessions until a maximum of 10 treatment sessions, 75% calorimetric measurement, and 100% visual pigment correction. If no improvement was noted, the dose was increased by 50 mJ/cm² per treatment; otherwise, the same dose was maintained. Posttreatment evaluation was done in 1, 2, and 4 months. Statistically significant improvement was noted using colorimetric analysis after

the first treatment. Sixty percent to 70% visual improvement was noted compared with control sites.

Melanocyte autologous grafting for treatment of leukoderma

Suvanprakorn P, Dee-Ananlap S, Pongsomboon C, Klaus SN. *J Am Acad Dermatol* 1985; 13: 968–74.

Patients with vitiligo, idiopathic guttate hypomelanosis, and postinflammatory hypomelanosis were included in the study. Blisters were created by suction/liquid nitrogen at the affected and healthy site. The roof of the bullae from the donor site was transferred to the affected area. Repigmentation was noted 7 to 14 days later.

Cosmetic camouflage

Antoniou C, Stefanaki C. *J Cosmet Dermatol* 2006; 5: 297–301.

A good cosmetic camouflage has been shown to be helpful for patients not relieved by conventional treatment, especially when a lesion is located over a cosmetically important site such as the face. The products may be oil or water based, depending on the skin type.

Ichthyoses

Rajani Nalluri, Georgina Devlin, and Timothy H. Clayton

The ichthyoses represent a group of disorders of keratinization characterized by scaly skin. They may be inherited or acquired. Severity and extent vary widely from mild ichthyosis vulgaris (IV) to life-threatening harlequin ichthyosis. Inherited ichthyosis is classified broadly into syndromic and nonsyndromic ichthyosis, keratinopathic ichthyosis, and autosomal-recessive congenital ichthyosis. Whole genome sequencing is a comprehensive approach to diagnosing inherited ichthyoses at an early stage; a gene therapy approach and topical targeted therapy are future treatments with the potential to

alleviate and even prevent disease in susceptible individuals.

Management Strategy

The key to management, where possible, is to establish an exact diagnosis. This provides a platform to plan therapy, discuss prognosis, and consider genetic counseling. It is important to identify the age of onset; the presence or absence of collodion membrane; blistering or erythroderma in the neonatal period; and the type, color, and distribution of scale. Family members should be examined. The Ichthyosis Support Group (ISG) provides a support network for families with resources and information sheets (www.ichthyosis.org.uk). In the United States families should contact the Foundation for Ichthyosis and Related Skin Types (FIRST) (www.firstskinfoundation.org).

Causative genes for a number of the inherited ichthyoses have recently been identified. IV is the most common disorder of cornification, with an incidence of 1:250. It is not usually present at birth. Clinical features include dry skin with associated fine white powdery scale on extensor surfaces, palmar hyperlinearity, and keratosis pilaris. Mutations in the *filament aggregating protein (filaggrin) gene (FLG)* have recently been identified as the cause of IV. Loss-of-function mutations in FLG have also been strongly associated with atopic dermatitis. Patients with ichthyosis have reduced epidermal barrier function, increased transepidermal water loss, and reduced pliability of the stratum corneum and hyperkeratosis. Topical treatment involves hydration, lubrication, and keratolysis. Emollients are widely used as a first-line treatment. The effect of moisturizers in atopic dermatitis and related disorders has been documented in a large number of clinical trials of varying design and quality, but data are lacking on comparisons among different emollients. In mild to moderate cases urea-containing emollients alone are often sufficient, as they may have a humectant and keratolytic effect. Increasing the environmental humidity has also been shown to be beneficial. *Emollient baths* aid in softening the stratum corneum and facilitate mechanical debridement of thickened hyperkeratosis.

Keratolytics such as salicylic acid, urea, lactic acid, and propylene glycol reduce the adhesion of keratinocytes. However, because of the impaired barrier function, care should be taken to prevent salicylate toxicity. We do not advocate the use of topical salicylic acid in

children due to the increased surface area-to-volume ratio. Cutaneous infection occurs as a result of impaired barrier function, and consideration should be given to prophylactic measures, such as antiseptic soaps or baths. Skin infection may require topical and systemic *antibacterials*, particularly in *epidermolytic ichthyosis (EI)* (formerly referred to as *epidermolytic hyperkeratosis, EHK*), which often requires long-term antibiotic therapy.

Topical retinoids (e.g., tretinoin, adapalene, tazarotene) may be beneficial. *N*-acetylcysteine is a new addition to the topical treatments. They reduce the cohesiveness of epithelial cells, stimulate mitosis and turnover, and suppress keratin synthesis.

The severe ichthyoses usually respond to *systemic retinoid therapy*. *Acitretin* (1 mg/kg/day) and *isotretinoin* (1–2 mg/kg/day) have been shown to reduce scaling and discomfort and improve heat tolerance and sweating. However, recurrence of ichthyotic skin occurs on discontinuing treatment, thereby necessitating long-term use. Long-term treatment involves a higher risk of chronic skeletal toxicity, such as calcification of tendons and ligaments, hyperostoses, and osteoporosis, which requires regular monitoring. *Alitretinoin* may provide a safer alternative to *acitretin*, and further studies are necessary to assess its efficacy.

Retinoic acid metabolism-blocking agents have been shown to inhibit the cytochrome P450-dependent 4-hydroxylation of retinoic acid, resulting in increased tissue levels of retinoic acid and a reduction in epidermal proliferation and scaling. *Liarozole* showed clinical improvement and tolerability in a recent phase II/III trial.

Acquired ichthyoses are associated with a number of systemic disorders, including HIV, malignancy, sarcoidosis, leprosy, thyroid disease, hyperparathyroidism, nutritional disorders, chronic renal failure, and autoimmune diseases. They will often improve with treatment of the underlying condition. There have been few publications in recent years relating to acquired ichthyosis.

Specific Investigations

- Follow algorithm (see the figure later)
- Genetic screening: refer to www.genetests.org
- Fatty alcohol: NAD + oxidoreductase activity (Sjögren–Larsson)
- Steroid sulfatase activity

- Vitamin D status

Acquired ichthyosis

- Malignancy screening
- Infection screen, including HIV
- Metabolic screening
- Skin biopsy

Revised nomenclature and classification of inherited ichthyoses: results of the First Ichthyosis Consensus Conference in Soréze 2009

Oji V, Tadini G, Akiyama M, Bardon CB, Bodemer C, Bourrat E, et al. J Am Acad Dermatol 2010; 69: 607–41.

A useful reference for all clinicians and an aid for future research.

Impact of next generation sequencing on diagnostics in a genetic skin disease clinic

Takeichi T, Nanda A, Liu L, Salam A, Campbell P, Fong K, et al. Exp Dermatol 2013; 22: 825–31.

The role of whole-exome sequencing as a comprehensive approach to diagnosing inherited skin diseases at an early stage is discussed.

Update on autosomal recessive congenital ichthyosis: mRNA

analysis using hair samples is a powerful tool for genetic diagnosis

Sugiura K, Akiyama M. *J Dermatol Sci* 2015; 79: 4–9.

Autosomal recessive congenital ichthyosis (ARCI) includes harlequin ichthyosis, lamellar ichthyosis, and congenital ichthyosiform erythroderma. To date nine genes are causally associated with ARCI. This is an update on the molecular mechanisms, causative genes, clinical phenotypes, and possible effective therapies. It also discusses mRNA analysis of hair samples and next-generation sequencing as a genetic diagnosis method.

Expanding the keratin mutation database: novel and recurrent mutations and genotype–phenotype correlation in 28 patients with epidermolytic ichthyosis

Arin MJ, Oji V, Emmert S, Housser I, Traupe H, Krieg T, et al. *Br J Dermatol* 2011; 164: 442–7.

This paper discusses the identification of novel mutations and genotype–phenotype correlations in EHK, which allows improved understanding of disease pathogenesis and improved patient management.

Clinical expression and new SPINK5 splicing defects in Netherton syndrome: unmasking a frequent founder synonymous mutation and unconventional intronic mutations

Lacroix M, Lacaze-Buzy L, Furio L, Tron E, Valari M, Van der Weir G, et al. *J Invest Dermatol* 2012; 132: 575–82.

Netherton syndrome (NS) results from loss-of-function mutations in SPINK5 (serine protease inhibitor Kazal type 5), which encodes the serine protease inhibitor LEKTI (lymphoepithelial Kazal-type related inhibitor). A description of new SPINK5 defects in 12 patients, widening the clinical and molecular spectrum of NS.

The multifunctional role of filaggrin in allergic skin disease

McAleer MA, Irvine AD. *J Allergy Clin Immunol* 2013; 131: 280–91.

The role of mutations in the human filaggrin gene (FLG), which confer risk not only for atopic dermatitis but also for the associated allergic diseases of food allergy, asthma, and allergic rhinitis, is described.

Comprehensive analysis of the gene encoding filaggrin uncovers

prevalent and rare mutations in ichthyosis vulgaris and atopic eczema

Sandilands A, Terron-Kwiatkowski A, Hull PR, O'Regan GM, Clayton TH, Watson RM, et al. *Nature Genet* 2007; 39: 650–4.

Common FLG null mutations cause ichthyosis vulgaris and predispose to eczema and secondary allergic diseases. This paper illustrates that the common European mutations are ancestral variants carried on conserved haplotypes.

Vitamin D deficiency and rickets in children and adolescents with ichthyosiform erythroderma in type IV and V skin

Chouhan K, Sethuraman G, Gupta N, Sharma VK, Kabra M, Khaitan BK, et al. *Br J Dermatol* 2012; 166: 608–15.

A controlled study examining the prevalence of vitamin D deficiency in adolescents with ichthyosiform erythroderma due to keratinizing disorders. All patients in the disease group had clinical, biochemical, or radiologic evidence of rickets.

The potential for vitamin D deficiency should be considered in patients with an ichthyotic disorder.

Acquired ichthyosis

Patel N, Spencer LA, English JC, Zirwas MJ. *J Am Acad Dermatol* 2006; 55: 647–56.

This review provides a useful algorithm for the evaluation of patients presenting with acquired ichthyosis.

First-Line Therapies

• Humidification of environment	E
• Bathing/soaking	E
• Emollients	A

Association of glycerol and paraffin in the treatment of ichthyosis in children: an international, multicentric, randomized,

controlled, double-blind study

Blanchet-Bardon C, Tadini G, Machado Matos M, Delarue A. J Eur Acad Dermatol Venereol. 2012; 26:1014-9.

This large study assessed the efficacy of a 15% glycerol and 10% paraffin (plus vehicle) emollient (Dexeryl) compared with placebo in a heterogeneous group of children with various ichthyotic disorders. Significant improvement was observed, and treatment was well tolerated.

Clinical effectiveness of moisturizers in atopic dermatitis and related disorders: a systematic review

Lindh JD, Bradley M. Am J Clin Dermatol 2015; 16: 341–59.

The majority of studies have shown that moisturizers have beneficial effects on clinical symptoms, and it is well documented for urea- and glycerin-based emollients.

Second-Line Therapies

• Keratolytics (salicylic acid [avoid in children], urea, α -hydroxy acids [e.g., lactic acid], propylene glycol)	A
• Topical retinoids (tretinoin, tazarotene)	C
• Topical liarozone	C
• Topical calcipotriol	C
• Topical <i>N</i> -acetylcysteine	D
• Topical pimecrolimus 1%	E
• Narrowband Ultraviolet B (UVB) phototherapy (Netherton syndrome)	E

Efficacy of urea therapy in children with ichthyosis. A multicenter randomized, placebo-controlled, double-blind, semilateral study

Kuster W, Bohnsack K, Rippke F, Upmeyer HJ, Groll S, Traupe H. Dermatology 1998; 196: 217–22.

Sixty children were treated for 8 weeks with 10% urea lotion on one side and lotion base on the other. Improvement was 78% after 8 weeks for 10% urea lotion and 72% for urea-free lotion base.

Improved topical treatment of lamellar ichthyosis: a double-blind study of four different cream formulations

Gånemo A, Virtanen M, Vahlquist A. Br J Dermatol 1999; 141: 1027–

32.

Combination preparation of 5% lactic acid and 20% propylene glycol reduced scaling and dryness significantly and was preferred in most patients compared with 5% urea.

Treatment of ichthyosiform diseases with topically applied tazarotene: risk of systemic absorption

Nguyen V, Cunningham BB, Eichenfield LF, Alió AB, Buka RL. J Am Acad Dermatol 2007; 57: 123–5.

This open-label pilot study of nine patients showed that little systemic absorption was observed when tazarotene 0.05% or 0.1% cream or gel was used daily for 1 month on 20% to 90% body surface area (BSA). Treatment may be safe for longer, as the majority of patients were using it for over 12 months.

Successful topical adapalene treatment for the facial lesions of an adolescent case of epidermolytic ichthyosis

Ogawa M, Akiyama M. J Am Acad Dermatol 2014; 71: e103–5.

An adolescent with epidermolytic ichthyosis showed significant improvement of hyperkeratosis after 6 months of topical 0.1% adapalene gel.

Topical liarozole in ichthyosis: a double-blind, left–right comparative study followed by a long-term open maintenance study

Lucker GPH, Verfaillie CJ, Heremans AMC, Vanhoutte FP, Boegheim JPJ, Steijlen PPM. Br J Dermatol 2005; 152: 566–9.

Liarozole 5% cream improved a range of ichthyoses in this study on 12 adults.

Successful treatment with topical N-acetylcysteine in urea in five children with congenital lamellar ichthyosis

Bassotti A, Moreno S, Criado E. Pediatr Dermatol 2011; 28: 451–5.

Topical 10% N-acetylcysteine emulsion prepared in urea 5% applied twice daily showed marked improvement in five children after 4 months.

The safety and efficacy of pimecrolimus 1%, cream for the treatment of Netherton syndrome

Yan AC, Honig PJ, Ming ME, Weber J, Shah KN. Arch Dermatol 2010;

146: 57–62.

A single-arm, open-label study of three children treated for a period of 18 months with 1% pimecrolimus. Treatment was well tolerated, with improvement in quality of life and severity scores. Serum levels of pimecrolimus were much lower than expected despite application to up to 50% BSA.

Narrowband UVB phototherapy as a novel treatment for Netherton syndrome

Kaminska EC, Ortel B, Sharma V, Stein SL. Photodermatol Photoimmunol Photomed 2012; 28: 162–4.

A case report of a 16-year-old patient with a clinical diagnosis of Netherton syndrome responsive to narrowband ultraviolet B (NB-UVB). Oral prednisolone (20 mg once daily) was started in a tapering dose at NB-UVB initiation. UVB was continued over a 4-year period.

The authors suggest NB-UVB may be useful for the atopic component of Netherton syndrome. Further studies are required.

Third-Line Therapies

• Acitretin/etretinate	B
• Isotretinoin	B
• Alitretinoin	E
• Liarozole	B

Oral retinoid therapy for disorders of keratinization: single-center retrospective 25 years' experience on 23 patients

Katugampola RP, Finlay AY. Br J Dermatol 2006; 154: 267–76.

This study provides the longest follow-up safety data on children

and adults with disorders of keratinization on oral retinoid therapy. One patient developed diffuse idiopathic skeletal hyperostosis after 21 years of retinoid therapy. Abnormalities of the fasting lipid profile and liver function were seen in a small percentage.

Oral alitretinoin in congenital ichthyosis: a pilot study shows variable effects and risk of central hypothyroidism

Gånemo A, Sommerlund M, Vahlquist A. Acta Derm Venereol 2012; 92: 256–7.

An uncontrolled study of four patients with ichthyosis treated with alitretinoin 10 to 30 mg once daily. If no improvement was observed after 1 month, the dose was increased to 40 to 60 mg daily. Higher doses were needed in patients with lamellar ichthyosis. Thyroid disturbance was observed in two of the cases.

Alitretinoin may be an alternative to acitretin in those contemplating pregnancy and has a quicker washout period. Further trial data are required.

Oral liarozole in the treatment of patients with moderate/severe lamellar ichthyosis: results of a randomized, double-blind, multinational, placebo-controlled phase II/III trial

Vahlquist A, Blockhuys S, Steijlen P, van Rossem K, Didona B, Blanco D, et al. Br J Dermatol 2014; 170: 173–81.

Once-daily oral liarozole, 75 and 150 mg, improved scaling and Dermatology Life Quality Index (DLQI) and was well tolerated in patients with moderate/severe lamellar ichthyosis, although the primary efficacy variable was not statistically significant in this study involving 64 patients.

Oral liarozole versus acitretin in the treatment of ichthyosis: a phase II/III multicenter, double-blind, randomized, active-controlled study

Verfaille CJ, Vanhoutte FP, Blanchet-Bardon C, van Steensel MA, Steijlen PM. Br J Dermatol 2007; 156: 965–73.

Thirty-two patients were randomized to either liarozole 75 mg twice daily or acitretin 10 mg in the morning and 2.5 mg at night for 12 weeks. Improvement was seen in both groups. Retinoid side effects were observed less frequently in the liarozole group.

Sjögren–Larsson syndrome: a study of clinical symptoms and dermatologic treatment in 34 Swedish patients

Gänemo A, Jagell Vahlquist A. Acta Derm Venereol 2009; 89: 68–73.

An observational study of all patients with Sjögren-Larsson syndrome (SLS) in Sweden. Fifty-six percent of patients were on oral acitretin (10 mg/week–25 mg once daily). The majority improved on introduction of acitretin, and ichthyosis severity scores were lower than in those not on oral retinoids.

This study is a useful reference regarding clinical variation, treatment, and long-term follow-up of a large cohort of patients with SLS.

High survival rate of harlequin ichthyosis in Japan

Shibata A, Ogawa Y, Sugiura K, Muro Y, Abe R, Suzuki T, et al. J Am Acad Dermatol 2014; 70: 387–8.

In this study, 91.7% of patients who were administered systemic retinoids survived, whereas only 50% who did not receive oral retinoids survived. Of these 62.5% received intensive care in a neonatal intensive care unit (NICU).

Improving outcomes for harlequin ichthyosis

Milstone LM, Choate KA. J Am Acad Dermatol 2013; 69: 808–9.

The article describes respiratory failure as a major contributing factor in 50% of neonatal deaths and suggests a lower threshold for considering intubation and intensive neonatal care.

Harlequin ichthyosis: a review of clinical and molecular findings in 45 cases

Rajpopat S, Moss C, Mellerio J, Vahlquist A, Gänemo A, Hellstrom-Pigg M, et al. Arch Dermatol 2011; 147: 681–6.

A review of 45 cases of harlequin ichthyosis. Overall survival rate was 56%. Ages of survivors ranged between 10 months and 25 years at the time of the study. Early introduction of oral retinoids may improve survival. All deaths were associated with homozygous mutations.

Impetigo

Michael Sladden, and Robert M Burd

Impetigo is a common superficial bacterial infection of the skin, caused by *Staphylococcus aureus* or *Streptococcus pyogenes*. The infection is highly contagious and can easily spread to other body sites or close contacts. Impetigo usually affects children but can occur in people of any age. The worldwide population of children suffering from

impetigo at any one time is estimated at 162 million, making impetigo a global major public health problem.

Impetigo can be primary, with direct bacterial invasion of previously normal skin, or secondary, where infection develops when the skin barrier is disrupted by underlying disease, such as scabies.

Impetigo is classified as nonbullous or bullous. In the more common nonbullous form, thin-walled vesicles rupture to form superficial erosions with yellowish-brown crusts, which eventually heal without scarring. Bullous impetigo is characterized by larger bullae or blisters, which may continue to develop for several days.

Most cases of nonbullous impetigo are caused by *S. aureus* but *S. pyogenes*, alone or in combination with *S. aureus*, may also be implicated. In cooler climates, staphylococcal impetigo predominates, whereas in warmer and more humid climates, streptococcal impetigo is more common. Bullous impetigo is almost always caused by exfoliative toxin-producing strains of *S. aureus*. Secondary impetigo is usually caused by *S. aureus*.

Management Strategy

The main aim of treatment is to eradicate the infecting bacteria to allow rapid skin healing and control the spread of infection. The ideal treatment should be effective, inexpensive, easily accessible, have limited adverse effects, and not promote bacterial resistance. This requires the use of an appropriate antimicrobial delivered in an effective manner. Antibiotics may be administered either orally or topically. The choice between topical or oral therapy depends on:

- The experience of the practitioner
- The preference of the patient
- The extent and severity of the disease
- The local bacterial resistance patterns
- The cost and availability of local resources

Topical or oral antibiotics with proven efficacy against *S. aureus* are the first choice of therapy. It is reasonable to use short courses of topical antibiotics for mild, limited impetigo, while reserving oral antibiotics for recalcitrant, extensive disease. Globally, the majority of isolates of *S. aureus* are resistant to penicillin, and erythromycin resistance is also becoming more common. It is important to consider local patterns of antibiotic resistance when choosing appropriate therapy.

In developing countries, where *Streptococcus* is often the predominant pathogen, topical agents are expensive and may be unavailable. Treatment strategies have to be sufficiently flexible to meet local needs.

Historically, topical treatment of impetigo was difficult due to bacterial resistance and contact sensitivity to topical agents. More recently introduced topical antibiotics appear as effective as traditional oral antibiotics. When used in courses of less than 2 weeks, bacterial resistance does not seem to be a major problem. Recent studies of topical retapamulin indicate that it is effective and safe in the treatment of primary impetigo.

Strains of bacteria causing impetigo are often extremely virulent. Patients therefore need to be educated on personal hygiene methods to avoid the spread of infection. Evidence regarding the value of disinfecting measures is limited. However, common sense would indicate that cleaning lesional skin with soap and water or a mild, nonirritant antiseptic will aid the application of topical antibiotics and reduce the spread of infection.

Nasal carriage of *S. aureus* occurs in a high proportion of both patients and asymptomatic family members. Therefore in recurrent cases or multiple familial cases, *treatment of nasal and pharyngeal carriage* may be necessary.

Increasingly, methicillin-resistant *Staphylococcus aureus* (MRSA) has become an important cause of impetigo. MRSA poses a challenge because of its enhanced virulence and resistance to standard antibiotic therapy. Antibiotic treatment should be guided by knowledge of the likely causative agent and local resistance patterns, as well as bacterial susceptibility testing.

Specific Investigations

- Skin swabs for microbiologic assessment (Gram stain), culture, and sensitivity
- Nasal swabs from patients and immediate relatives in recalcitrant cases

A Gram stain of a swab from the lesion or exudate will reveal gram-positive cocci, confirming the clinical diagnosis. Bacterial culture and sensitivity from a pretreatment swab are useful to assess suitable alternative antibiotics in cases that do not respond to

conventional treatment.

Interventions for impetigo (Cochrane Review)

Koning S, van der Sande R, Verhagen AP, van Suijlekom-Smit LW, Morris AD, Butler CC, et al. Cochrane Database Syst Rev 2012; 1: CD003261.

Reviews the epidemiology and treatment of impetigo. Worldwide, bacteria causing impetigo show increasing rates of resistance for commonly used antibiotics. No resistance has yet been reported for retapamulin.

The global epidemiology of impetigo: a systematic review of the population prevalence of impetigo and pyoderma

Bowen AC, Mahé A, Hay RJ, Andrews RM, Steer AC, Tong SY, et al. PLoS One 2015; 28; 10: e0136789.

The global prevalence of childhood impetigo is estimated to be in excess of 162 million.

Contemporary causes of skin and soft tissue infections in North America, Latin America, and Europe: report from the SENTRY Antimicrobial Surveillance Program (1998–2004)

Moet GJ, Jones RN, Biedenbach DJ, Stilwell MG, Fritsche TR. Diagn Microbiol Infect Dis 2007; 57:7–13.

Antimicrobial surveillance confirms that *S. aureus* is the predominant pathogen causing skin and soft tissue infections in all studied geographic areas.

Impetigo in epidemic and nonepidemic phases: an incidence study over 4½ years in a general population

Rortveit S, Rortveit G. Br J Dermatol 2007; 157: 100–5.

S. aureus was the causal bacterium in 89% (117/132) and 68% (84/123) of impetigo cases during epidemic and nonepidemic periods, respectively ($p < 0.01$). *S. aureus* was resistant to fusidic acid in 84% (98/117) and 64% (54/84) of cases in epidemic and nonepidemic periods, respectively ($p < 0.01$).

DNA heterogeneity of *Staphylococcus aureus* strains evaluated by Sma1 and SgrA1 pulsed field gel electrophoresis in patients with impetigo

Capoluongo E, Giglio A, Leonetti F, Belardi M, Giannetti A, Caprilli F,

et al. Res Microbiol 2000; 151: 53–61.

Samples from lesional skin, nose, and pharynx were taken from 26 patients and their families, and the strain of *S. aureus* was typed; 54% of the patients had the same strain in both the nose and the lesion. In over half the families at least one other family member was found to be carrying the same strain as the patient's lesion.

NVC-422 topical gel for the treatment of impetigo

Iovino SM, Krantz KD, Blanco DM, Fernández JA, Ocampo N, Najafi A, et al. Int J Clin Exp Pathol 2011; 4: 587–95.

In 129 patients with clinically diagnosed impetigo, the majority of the infections were caused by *S. aureus* alone (106/125, 85%), of which 10% were MRSA.

First-Line Therapies

• Topical mupirocin, fusidic acid, or retapamulin	A
• Oral flucloxacillin, cloxacillin, dicloxacillin, cephalexin, or erythromycin	A

Interventions for impetigo (Cochrane Review)

Koning S, van der Sande R, Verhagen AP, van Suijlekom-Smit LW, Morris AD, Butler CC, et al. Cochrane Database Syst Rev 2012; 1: CD003261.

A systematic review of 68 trials, including 5578 participants, reporting on 50 different treatments, including placebo. There is good evidence that topical mupirocin and topical fusidic acid are equal to, or possibly more effective than, oral antibiotics for people with limited impetigo. Fusidic acid, mupirocin, and retapamulin are probably equally effective. Due to lack of studies in patients with extensive impetigo, it is unclear whether oral antibiotics are superior to topical antibiotics in this group.

No clear preference can be given for B-lactamase-resistant narrow-spectrum penicillins such as flucloxacillin, cloxacillin, or dicloxacillin or for broad-spectrum penicillins such as amoxicillin with clavulanic acid, cephalosporins, or macrolides. Penicillin was not as effective as most other antibiotics.

Impetigo: diagnosis and treatment

Hartman-Adams H, Banvard C, Juckett G. Am Fam Physician 2014; 15; 90: 229–35.

This review tabulates treatment regimens for impetigo.

Treatment of impetigo: oral antibiotics most commonly prescribed

Bolaji RS, Dabade TS, Gustafson CJ, Davis SA, Krowchuk DP, Feldman SR. J Drugs Dermatol 2012; 11: 489–94.

Oral antibiotics are the most common class of medications used to treat impetigo. There is an opportunity for physicians to take advantage of the equally efficacious topical antibiotics for treating impetigo. A shift toward topical antibiotics would likely decrease adverse effects associated with use of oral agents.

Common skin infections in children

Sladden MJ, Johnston GA. Br Med J 2004; 329: 95–9.

The authors suggest using topical mupirocin TID (three times per day) or fusidic acid TID for 7 days in mild impetigo. Oral antibiotics should be reserved for recalcitrant or extensive disease.

Topical retapamulin ointment, 1%, versus sodium fusidate ointment, 2%, for impetigo: a randomized, observer-blinded, noninferiority study

Oranje AP, Chosidow O, Sacchidanand S, Todd G, Singh K, Scangarella N, et al. Dermatology 2007; 215: 331–40.

Retapamulin 1% ointment BID (twice daily) for 5 days and sodium fusidate ointment 2% TID for 7 days had comparable clinical efficacies (94.8% and 90.1%). Success rates in the small numbers of sodium fusidate-, methicillin, and mupirocin-resistant *S. aureus* were good for retapamulin (9/9, 8/8, and 6/6, respectively). Both drugs were well tolerated. Retapamulin is a highly effective and convenient new treatment option for impetigo, with efficacy against isolates resistant to existing therapies.

Topical retapamulin ointment (1% wt/wt) twice daily for 5 days versus oral cephalexin twice daily for 10 days in the treatment of secondarily infected dermatitis: results of a randomized controlled trial

Parish LC, Jorizzo JL, Breton JJ, Hirman JW, Scangarella NE, Shawar

RM, et al. J Am Acad Dermatol 2006; 55: 1003–13.

Retapamulin was as effective as cephalexin 500 mg BID (clinical success rates: 85.9% and 89.7%, respectively) in the treatment of patients with secondarily infected dermatitis. Microbiologic success rates were 87.2% for retapamulin and 91.8% for cephalexin.

Retapamulin was well tolerated, and the topical formulation was preferred over the oral drug.

Topical mupirocin treatment of impetigo is equal to oral erythromycin therapy

Mertz PM, Marshall DA, Eaglstein WH, Piovonetti Y, Montalvo J. Arch Dermatol 1989; 125: 1069–73.

Seventy-five patients were treated in an investigator-blinded study comparing topical mupirocin applied three times daily with oral erythromycin 30 to 50 mg/kg daily. The mupirocin-treated patients experienced similar clinical results to those treated with oral erythromycin, although mupirocin was superior in the microbiological eradication of *S. aureus*.

The emergence of resistance to penicillin and erythromycin is so common in isolates of S. aureus that alternative antibiotics should be considered.

Second-Line Therapies

• Intravenous antibiotics	C
• Other oral antibiotics, depending on sensitivity, including rifampicin and fusidic acid	B
• Topical antiseptics	B

Fusidic acid tablets in patients with skin and soft-tissue infection: a dose-finding study

Carr WD, Wall AR, Georgala-Zervogiani S, Stratigos J, Gouriou K. Eur J Clin Res 1994; 5: 87–95.

Fusidic acid tablets, 250 mg twice daily, 500 mg twice daily, and 500 mg thrice daily, were compared in a randomized, double-blind study in 617 patients with skin and soft tissue infections. Each treatment was given for 5 to 10 days. Cure rates after 5 days of treatment were 34.7%, 37.8%, and 37.2%, respectively. End of treatment cure rates were 75.5%, 81.1%, and 74.0%, respectively.

Addition of rifampin to cephalexin therapy for recalcitrant staphylococcal skin infections – an observation

Feder Jr HM, Pond KE. Clin Pediatr 1996; 35: 205–8.

Two children with staphylococcal infections failing to respond to standard antibiotics responded when rifampin was added.

Hydrogen peroxide cream: an alternative to topical antibiotics in the treatment of impetigo contagiosa

Christensen OB, Anehus S. Acta Dermatol Venereol 1994; 74: 460–2.

A prospective comparison of hydrogen peroxide 1% cream with fusidic acid 2% cream (both applied two to three times daily) in 256 patients with impetigo. Over a 3-week treatment period, 92 patients of 128 (72%) in the hydrogen peroxide group were classified as healed, compared with 105 of 128 (82%) in the fusidic acid group. This difference was not statistically significant.

Effect of handwashing on child health: a randomised controlled trial

Luby SP, Agboatwalla M, Feikin DR, Painter J, Billhimer W, Altaf A, et al. Lancet 2005; 366: 225–33.

In squatter settlements in Karachi, children younger than 15 years in households that received plain soap and handwashing promotion had a 34% lower incidence of impetigo than controls (95% CI, –52% to –16%).

Third-Line Therapy

• Systemic antibiotic, topical antibiotic plus a formal antistaphylococcal regimen to reduce nasal and pharyngeal carriage to prevent cross infection	E
---	---

Use of 0.3% triclosan (Bacti-Stat) to eradicate an outbreak of methicillin-resistant *Staphylococcus aureus* in a neonatal nursery

Zafar AB, Butler RC, Reese DJ, Gaydos LA, Mennonna PA. Am J Infect Control 1995; 23: 200–8.

A nosocomial outbreak of infection with MRSA in a neonatal nursery proved difficult to control even with aggressive conventional measures. Additional use of a handwashing and bathing soap containing 0.3% triclosan immediately ended the outbreak.

Prevention and control of nosocomial infection caused by methicillin-resistant *Staphylococcus aureus* in a premature infant ward: preventive effect of a povidone-iodine wipe of neonatal skin

Aihara M, Sakai M, Iwasaki M, Shimakawa K, Kozaki S, Kubo M, et al. *Postgrad Med J* 1993; 69: S117–21.

An outbreak of MRSA causing impetigo was halted by wiping the body surface of the infants once daily with a diluted Isodine solution (10% povidone–iodine; 1:100 dilution).

Treatment of bullous impetigo and the staphylococcal scalded skin syndrome in infants

Johnston GA. *Expert Rev Anti Infect Ther* 2004; 2: 439–46.

It is important to swab the skin for bacteriologic confirmation and antibiotic sensitivities. Nasal swabs from the patient and immediate relatives should be performed to identify asymptomatic nasal carriers of *Staphylococcus aureus*. In the case of outbreaks on wards and in nurseries, health care professionals should also be swabbed.

Failure of first-line therapy suggests the presence of bacterial resistance or poor patient compliance. The choice of antibiotic should be based on the sensitivities of organisms cultured from the pretreatment swab. In recurrent cases, consider the possibility of nasal or pharyngeal colonization with pathogenic S. aureus in either the patient or a close family member. This may require eradication by the use of a systemic antibiotic in conjunction with the nasal application of a topical antibiotic and an antiseptic skin cleanser. Topical antiseptics have also proved useful in nosocomial outbreaks.

An example of a 5-day Staphylococcus decolonization procedure used by one of the authors (MS) consists of daily hair and body washing with 4% chlorhexidine solution and thrice-daily application of nasal mupirocin ointment. Personal clothing and underwear, towels, washcloths, and bed linens are washed daily for 5 days. For resistant cases, oral antibiotics are also used (rifampicin 300 mg BID and fusidic acid 500 mg BID).

Inducible urticarias, aquagenic pruritus, and cholinergic pruritus

Clive E.H. Grattan, and Frances Lawlor

Inducible urticarias

About 25% of patients with chronic urticaria have a definable and reproducible inducing trigger that distinguishes them from those with spontaneous urticaria and urticarial vasculitis. Inducible urticarias are defined by the predominant inducing stimulus ([Table 114.1](#)). More than one inducing stimulus elicits urticaria in some patients, and inducible urticarias can overlap with spontaneous urticaria. Physical urticarias caused by a physical stimulus (symptomatic dermographism, delayed pressure, heat and cold contact and solar urticarias, and vibratory angioedema) are now included within the inducible urticarias.

Management Strategy

Pharmacologic

The presentation of inducible urticarias may vary in morphology and severity. Milder forms may require little more than *avoidance of triggers* and a preemptive dose of H_1 antihistamine before anticipated exposure, whereas a very severe attack involving anaphylaxis could potentially require emergency treatment with *intramuscular epinephrine (adrenaline)*. Acute presentations of severe inducible urticaria may require short courses of *oral corticosteroids* (e.g., prednisolone 0.5 mg/kg body weight daily for 5 days) in addition to regular nonsedating H_1 antihistamines. Drug management should be guided by the degree of disability or impairment in quality of life.

Nonpharmacologic

The triggering stimulus should be avoided where possible. Cold tolerance induction in cold urticaria and exercise tolerance induction in cholinergic urticaria has been described but is difficult to achieve and sustain. There is no evidence that exclusion diets are effective.

Specific Investigations

- Challenge (provocation) tests
- Blood tests (cryoproteins, specific IgE)

With the exceptions of testing for cryoglobulins in cold urticaria

and specific IgE in food- and exercise-induced anaphylaxis, laboratory investigations are unnecessary and should not be undertaken except to monitor treatment or screen for eligibility (e.g., glucose-6-phosphatase dehydrogenase in patients being considered for dapsone or sulfasalazine).

The EAACI/GA(2) LEN/EDF/WAO Guideline for the definition, classification, diagnosis, and management of urticaria: the 2013 revision and update

Zuberbier T, Aberer W, Asero R, Bindslev-Jensen C, Brzoza Z, Canonica GW, et al. *Allergy* 2014; 69: 868–87.

The latest and most quoted European guideline on urticaria.

The definition, diagnostic testing and management of chronic inducible urticarias—update and revision of the EAACI/GA(2) LEN/EDF/UNEV 2009 consensus panel recommendations

Magerl M, Altrichter S, Borzova E, Giménez-Arnau A, Grattan CE, Lawlor F. *Allergy* 2016; 71: 780–802.

A comprehensive updated summary of provocation testing protocols.

Table 114.1

Classification of inducible urticarias by the eliciting stimulus (in approximate reducing frequency of occurrence)

Symptomatic dermographism	Stroking or rubbing the skin
Cholinergic urticaria (pale, papular wheals with red flares)	Rise in core temperature and other causes of sweating (exercise, hot baths, spicy food, and stress)
Cold urticaria	Rewarming of skin after cooling (localized or systemic)
Delayed pressure urticaria	Sustained perpendicular pressure
Solar urticaria	Ultraviolet or visible solar radiation
Localized heat urticaria	Local heat contact
Aquagenic urticaria	Local water contact at any temperature
Exercise-induced anaphylaxis	Exercise, but not hot baths
Food- and exercise-induced anaphylaxis	Exercise after a heavy food load or eating specific foods
Vibratory angioedema	Vibration

Cold urticaria syndromes: historical background, diagnostic classification, clinical and laboratory characteristics, pathogenesis and management

Wanderer AA. *J Allergy Clin Immunol* 1990; 85: 965–81.

A review of cold urticaria and its investigation.

Food-dependent exercise-induced anaphylaxis

Kidd JM, Cohen SH, Sosman AJ, Fink JN. J Allergy Clin Immunol 1983; 71: 407–11.

Anaphylaxis may rarely result from exercise after a heavy food load or eating certain foods (e.g., wheat, prawns, beef) for which specific IgE can be demonstrated by skin prick or ImmunoCAP testing.

First-Line Therapy

• Nonsedating (“second generation”) antihistamines	A
--	---

Nonsedating antihistamines ([Table 114.2](#)) should always be prescribed in preference to classical antihistamines, which are often sedating and can impair psychomotor performance. Up-dosing of second-generation H₁ antihistamines is now widely practiced, although sedation at higher-than-licensed doses is a potential risk.

Therapeutic effects of cetirizine in delayed pressure urticaria: clinicopathological findings

Kontou-Fili K, Maniatakou G, Demaka P, Gonianakis M, Palaiologos G, Aroni K. J Am Acad Dermatol 1991; 24: 1090–3.

A double-blind, placebo-controlled study in 11 patients, showing a reduction in weight-induced wheal area and lesional eosinophil numbers on cetirizine 10 mg three times daily.

High-dose desloratadine decreases wheal volume and improves cold provocation thresholds compared with standard-dose treatment in patients with acquired cold urticaria: a randomized, placebo-controlled, cross-over study

Siebenhaar F, Degener F, Zuberbier T, Martus P, Maurer M. J Allergy Clin Immunol 2009; 123: 672–9.

Fourfold up-dosing a second-generation antihistamine has additional inhibitory effects on wheal formation in cold urticaria.

Rupatadine and its effects on symptom control, stimulation time, and temperature thresholds in patients with acquired cold urticaria

Metz M, Scholz E, Ferrán M, Izquierdo I, Giménez-Arnau A, Maurer M. Ann Allergy Asthma Immunol 2010; 104: 86–92.

A crossover, randomized, double-blind, placebo-controlled study of double-dose rupatadine, a second-generation H₁ antihistamine. Fifty-two percent of patients showed a complete response. There was also a significant improvement in critical cold stimulation time and critical temperature threshold.

Table 114.2

Examples of nonsedating and mildly sedating H₁ antihistamines

Acrivastine	Nonsedating, three-times-daily dosing
Bilastine	Nonsedating, once-daily dosing
Cetirizine	Mildly sedating, once-daily dosing
Levocetirizine	The active enantiomer of cetirizine
Fexofenadine	Nonsedating, once-daily dosing
Loratadine	Nonsedating, once-daily dosing
Desloratadine	The active metabolite of loratadine
Mizolastine	Nonsedating, once-daily dosing
Rupatadine	Nonsedating, once-daily dosing

Second-Line Therapies

Symptomatic dermographism

• Narrowband UVB phototherapy	C
• Omalizumab	D
• H ₂ antihistamines	B

Cholinergic urticaria

• Danazol	B
• Omalizumab	D
• Anticholinergics	E

Cold urticaria

• Omalizumab	D
• Leukotriene receptor antagonists	E
• Antibiotics “curative therapy”	E
• Cold tolerance (desensitization)	E

Heat urticaria

• Omalizumab	D
--------------	----------

Delayed pressure urticaria

• Omalizumab	D
• Leukotriene receptor antagonists	B
• Sulfasalazine	C
• Dapsone	C

Solar urticaria

• Induction of tolerance (phototherapy and photochemotherapy)	D
• Omalizumab	D

Narrow-band ultraviolet B phototherapy is beneficial in antihistamine-resistant symptomatic dermographism: a pilot study

Borzova E, Rutherford A, Konstantinou G, Leslie K, Grattan CEH. J Am Acad Dermatol 2008; 59: 752–7.

A small open study of H₁ antihistamine–unresponsive symptomatic dermographism showing subjective and objective improvement in itch and whealing after 6 weeks' treatment, but relapse 6 to 12 weeks after stopping.

Anti-immunoglobulin E treatment of patients with recalcitrant physical urticaria

Metz M, Altricher S, Ardelean E, Kessler B, Krause K, Magerl M, et al. Int Arch Allergy Immunol 2011; 154: 177–80.

One of two patients with symptomatic dermographism cleared completely within days of their first injection of omalizumab and remained clear on continuing treatment in this report, although other patients did not respond.

Retreatment with omalizumab results in rapid remission in chronic spontaneous and inducible urticaria

Metz M, Ohanyan T, Church MK, Maurer M. JAMA Dermatol 2014;

150: 288–90.

In dermographic urticaria H₂ receptor antagonists have a small but therapeutically irrelevant additional effect compared with H₁ antagonists alone

Sharpe GR, Shuster S. Br J Dermatol 1993; 129: 575–9.

In this double-blind, crossover study, 19 patients were randomized to treatment with cetirizine 10 mg at night plus either ranitidine 150 mg twice daily or placebo. There was an increase in whealing threshold with additional H₂ blockade, but no subjective benefit on itch.

Addition of an H₂ to an H₁ antihistamine may provide better control of some inducible urticarias despite the lack of trial evidence.

Beneficial effects of danazol on symptoms and laboratory changes in cholinergic urticaria

Wong E, Eftekhari N, Greaves MW, Milford Ward A. Br J Dermatol 1987; 116: 553–6.

Seventeen male patients treated with danazol 200 mg three times daily in a double-blind crossover study had sustained improvement in the number of exercise-induced wheals over 12 weeks.

Anabolic steroids should only be considered for severe cholinergic urticaria not responding adequately to up-dosed H₁ antihistamines, because of their potential for virilization and hepatotoxicity. Danazol should be reserved for severe cases and avoided during pregnancy. Androgenic adverse effects may be dose-limiting in women.

Successful treatment of cholinergic urticaria with anti-immunoglobulin E therapy

Metz M, Bergmann P, Zuberbier T, Maurer M. Allergy 2008; 63: 247–8.

One patient with highly symptomatic cholinergic urticaria who had not responded to several antihistamines, montelukast, and propranolol made a complete and sustained response to omalizumab 300 mg every 2 weeks.

Failure of omalizumab in cholinergic urticaria

Sabroe R. Clin Exp Dermatol 2009; 35:e217–9.

A patient with disabling cholinergic urticaria was completely unresponsive to omalizumab subcutaneously at 300 mg every 2

weeks for 4 months.

Clinical experience with omalizumab for cholinergic urticaria indicates that it can be highly effective but not every patient will respond. Cholinergic urticaria is an unlicensed indication.

Severe cholinergic urticaria successfully treated with scopolamine butylbromide in addition to antihistamines

Ujiie H, Shimizu T, Natsuga K, Arita K, Tomizawa K, Shimizu H. Clin Exp Dermatol 2006; 31: 978–81.

Although this case report suggests that anticholinergics may be successful for cholinergic urticaria, the general experience with this class of drugs is disappointing, and unwanted effects often outweigh any benefits.

Successful treatment of cold-induced urticaria/anaphylaxis with anti-IgE

Boyce JA. J Allergy Clin Immunol 2006; 117: 1414–8.

A trial of omalizumab in a 12-year-old atopic girl with increasingly severe cold-contact urticaria led to complete resolution of her symptoms over 5 months, but her symptoms recurred when she missed two doses of omalizumab.

An increasing number of reports illustrate the good response that some patients with cold urticaria have with omalizumab given off-license.

Improvement of cold urticaria by treatment with the leukotriene receptor antagonist montelukast

Hani N, Hartmann K, Casper C, Peters T, Schneider LA, Hunzelmann N, et al. Acta Derm Venereol 2000; 80: 229.

A case report of a patient with acquired cold-contact urticaria responding subjectively and objectively to montelukast 10 mg daily after only 4 days.

It is not clear whether montelukast was given as monotherapy or in combination with an antihistamine.

Treatment of acquired cold urticaria with cetirizine and zafirlukast in combination

Bonadonna P, Lombardi C, Senna G, Canonica GW, Passalacqua G. J Am Acad Dermatol 2003; 49: 714–6.

Two patients with severe cold-contact urticaria improved subjectively and objectively on a combination of cetirizine 10 mg once

daily and zafirlukast 20 mg twice daily. Combination therapy was better than either drug alone.

Further studies are required to clarify what place (if any) leukotriene receptor antagonists have in the management of antihistamine-unresponsive cold urticaria.

Acquired cold urticaria: clinical picture and update on diagnosis and treatment

Siebenhaar F, Weller K, Mlynek A, Magerl M, Altrichter S, Vieira Dos Santos R, et al. Clin Exp Dermatol 2007; 32: 241–5.

Examples of antibiotic regimens used for “curative therapy” are given as phenoxymethylpenicillin 1 MU/day for 2 to 4 weeks, intramuscular benzylpenicillin 1 MU/day for 20 days, or doxycycline 200 mg/day for 3 weeks.

The authors claim that occasional patients respond to high-dose antibiotics even if no underlying infection can be detected, but personal experience suggests little or no benefit.

Cold urticaria: a clinico-therapeutic study in 30 patients, with special emphasis on cold desensitization

Henquet JM, Martens BPM, van Volten WA. Eur J Dermatol 1992; 2: 75–7.

Cold desensitization in four patients with severely disabling cold urticaria resulted in symptom-free follow-up ranging from 4 to 14 years. Induction of cold tolerance took 1 to 2 weeks.

Patients had to take cold showers (around 15°C) for 5 minutes twice a day to maintain the tolerance, so this approach is not for the faint-hearted. Cold tolerance is now outdated.

Cold urticaria: tolerance induction with cold baths

Von Mackensen YA, Sticherling M. Br J Dermatol 2007; 157: 799–846.

Nine of 23 patients desensitized with cold water immersions 15 years earlier responded to a questionnaire survey. Only one of them was able to continue the cold baths for 6 months, two for 3 months, and the others stopped almost immediately.

This report introduces a little realism concerning the likelihood of cold desensitization being an effective and well-tolerated long-term therapy for cold-contact urticaria.

Heat urticaria: a revision of published cases with an update on

classification and management

Pezzolo E, Peroni A, Gisondi P, Girolomoni G. Br J Dermatol 2016; 175: 473–8.

A comprehensive review of this rare subtype of inducible urticaria.

Rapid response to omalizumab in 3 cases of delayed pressure urticaria

Quintero OP, Arrondo AP, Veleiro B. J Allergy Clin Immunol Pract 2017; 5: 179–80.

Effective treatment of different phenotypes of chronic urticaria with omalizumab: case reports and review of literature

Kasperska-Zajac A, Jarzab J, Żerdzińska A, Bąk K, Grzanka A. Int J Immunopathol Pharmacol 2016; 29: 320–8.

Omalizumab is increasingly being reported as a successful treatment of delayed pressure urticaria. It is also effective for patients with chronic spontaneous urticaria and delayed pressure urticaria.

Efficacy of montelukast, in combination with loratadine, in the treatment of delayed pressure urticaria

Nettis E, Pannafino A, Cavallo E, Ferrannini A, Tursi A. J Allergy Clin Immunol 2003; 112: 212–3.

In a small randomized study, objective pressure rechallenge after 15 days showed that montelukast 10 mg once daily with loratadine 10 mg once daily was more effective than either drug alone.

Desloratadine in combination with montelukast suppresses the dermographometer challenge test papule, and is effective in the treatment of delayed pressure urticaria: a randomized, double-blind, placebo-controlled study

Nettis E, Colanardi MC, Soccio AL, Ferrannini A, Vacca A. Br J Dermatol 2006; 155: 1279–82.

Although this study suggests that pressure urticaria can be controlled without steroids, clinical experience with montelukast in delayed pressure urticaria is usually disappointing.

Delayed pressure urticaria: response to treatment with sulfasalazine in a case series of seventeen patients

Swerlick RA, Puar N. Dermatol Ther 2015; 28: 318–22.

This open study supports the use of sulfasalazine in delayed

pressure urticaria.

Potential side effects include bone marrow depression and hypersensitivity reactions, so patients need careful monitoring. Sulfasalazine should only be considered in patients who are not sensitive to aspirin and other nonsteroidal drugs.

Delayed pressure urticaria—dapsonе heading for first-line therapy

Grundmann SA, Kiefer S, Luger TA, Brehler R. J Dstch Dermatol Ges 2011; 9: 908–12.

Seventy-four percent of 31 patients with pressure urticaria treated with dapsonе over a 6-year period surveyed retrospectively showed a good or very good response.

Dapsonе can also be a useful and inexpensive treatment of delayed pressure urticaria.

Narrowband ultraviolet B phototherapy is a suitable treatment option for solar urticaria

Calzavara-Pinton P, Zane C, Rossi M, Sala R, Venturini M. J Am Acad Dermatol 2012; 67: e5–9.

Patients without an urticarial response to phototesting with NB-UVB were given an alternate-day exposure for 4 weeks. Those with an urticarial response to phototesting with NB-UVB were treated three times a day for 5 days in the first week and then subsequently the same as the first group for 3 weeks. Thirty-nine patients completed the study and reported good tolerance to the sun afterward.

Solar urticaria: long-term rush hardening by inhibition spectrum narrow-band UVB 311 nm

Wolf R, Herzinger T, Grahovac M, Prinz JC. Clin Exp Dermatol. 2013; 38: 446–7.

UVA rush hardening for the treatment of solar urticaria

Beissert S, Ständer H, Schwarz T. J Am Acad Dermatol 2000; 42: 1030–2.

Protection was achieved within 3 days of exposing three patients to multiple incremental UVA irradiations at 1-hour intervals. Rush hardening with UVA did not cause sunburn reactions and provided protection against visible light and UVB-induced urticaria in two of

the three patients.

UV-induced tolerance should be considered for patients who need more than antihistamines.

Successful and long-lasting treatment of solar urticaria with UVA rush hardening therapy

Masuoka E, Fukunga A, Kishigami K, Jimbo H, Nishioka M, Uchimura Y, et al. *Br J Dermatol* 2012; 167: 198–201.

Two patients with solar urticaria who reacted to intradermal injection of their own serum that had been preirradiated with visible light were treated with multiple UVA incremental exposures at 1-hour intervals for 2 to 3 days and became symptom free, and their postirradiation skin tests became negative. Maintenance UVA exposures were performed every 1 or 2 weeks for 4 months in one patient and 5 months in the other. The first patient remained clear off treatment for 6 months.

Successful treatment with UVA rush hardening in a case of solar urticaria

Mori N, Makino T, Matsui K, Takegami Y, Murayama S, Shimizu T. *Eur J Dermatol* 2014; 24: 117–9.

A direct comparison between NB-UVB, PUVA, and UVA hardening for solar urticaria has not been performed to date.

Omalizumab in patients with severe and refractory solar urticaria: a phase II multicentric study

Aubin F, Avenel-Audran M, Jeanmougin M, Adamski H, Peyron JL, Marguery MC, et al. *J Am Acad Dermatol* 2016; 74: 574–5.

Failure of omalizumab in the treatment of solar urticaria

Müller S, Schempp CM, Jakob T. *J Eur Acad Dermatol Venereol* 2016; 30: 524–5.

As in all types of urticaria, omalizumab does not work for every patient.

Third-Line Therapies

• Intravenous immunoglobulins	D
• Ciclosporin	E
• Plasmapheresis	E
• Etanercept	E

Effect of high-dose intravenous immunoglobulin in delayed pressure urticaria

Dawn G, Urcelay M, Ah-Weng A, O'Neill SM, Douglas WS. Br J Dermatol 2003; 149: 836–40.

Three of eight patients went into remission after one or more infusions of intravenous immunoglobulin (IVIG) at 2 g/kg and two improved, but confirmation of pressure-induced wheals by objective testing was not done, and all patients had spontaneous chronic urticaria. It was not clear whether the benefit of treatment was mainly on the pressure urticaria or the spontaneous urticaria.

Cold urticaria responding to systemic cyclosporine

Marsland AM, Beck MH. Br J Dermatol 2003; 149: 214.

One patient with acquired cold-contact urticaria of over 1 year's duration and unresponsive to antihistamines improved within a week of starting ciclosporin at 3 mg/kg daily, and the improvement was maintained at 1.7 mg/kg/day. It was not stated what happened on stopping treatment.

There is currently no good evidence that acquired cold-contact urticaria is an autoimmune disease, so the use of immunomodulating drugs should be regarded as speculative and of unproven benefit. The benefit seen in some patients probably relates to partial inhibition of histamine release. H₁ antihistamines should be given concurrently.

Cyclosporin A therapy for severe solar urticaria

Edström DW, Ros AM. Photodermatol Photoimmunol Photomed 1997; 13: 61–3.

A clinically useful reduction in sensitivity to visible or UV light

occurred while taking ciclosporin at 4.5 mg/kg daily, but the symptoms recurred within 1 to 2 weeks of stopping treatment. The authors suggest that this treatment might be appropriate for severe disease when other treatments have failed, especially in countries where treatment is necessary only for a few months during summer.

Solar urticaria—effective treatment by plasmapheresis

Duschet P, Leyen P, Schwarz T, Höcker P, Greiter J, Gschnait F. Clin Exp Dermatol 1987; 12: 185–8.

A refractory period of at least 12 months followed a single treatment with 3 L plasmapheresis.

Successful treatment of delayed pressure urticaria with anti-TNF- α

Magerl M, Philipp S, Manasterski M, Friedrich M, Maurer M. J Allergy Clin Immunol 2007; 119: 752–4.

Single case report of a complete response of pressure urticaria symptoms within a week of starting etanercept for concurrent psoriasis.

Successful treatment of systemic cold contact urticaria with etanercept in a patient with psoriasis

Gualdi G, Monari P, Rossi MT, Crotti S, Calzavara-Pinton PG. Br J Dermatol 2012; 166: 1373–4.

A patient with long-standing cold-contact urticaria and psoriasis treated with etanercept underwent resolution of both conditions within weeks of starting treatment, relapse on withdrawal, and improvement on reintroduction.

Aquagenic pruritus

Aquagenic pruritus is diagnosed when itching, prickling, burning, buzzing, or other skin discomfort, which may be intense, is provoked by contact with water. There are no visible skin changes. The sensation is associated with feelings of anger, irritability, or depression in approximately half of patients. The symptoms are provoked at any water temperature and degree of salinity. They occur within minutes rather than hours and start either during a bath or shower or soon afterward. The discomfort may be present for

between 10 minutes and 2 hours. Any part of the body may be affected. Patients may also itch when the ambient temperature changes. Spontaneous remission is rare. The pathogenesis of the condition is not clear.

Management Strategy

Other chronic skin diseases must be ruled out by taking a full history and by clinical examination (particularly aquagenic pruritus of the elderly manifesting as xerosis and other inducible urticarias). Direct questioning is necessary regarding cold-induced symptoms and whealing; water-induced whealing or syncope; exercise-, heat-, or emotion-induced symptoms and whealing; and friction-induced itching and whealing. The well-recognized “bath itch” that occurs in approximately 40% of patients with polycythemia rubra vera must be ruled out before aquagenic pruritus is diagnosed. Rarely, other hematologic abnormalities have also been associated. Occasionally, antimalarial drugs have induced an aquagenic pruritus–like picture in patients with lupus erythematosus. When the diagnosis is reached, it is important to explain that aquagenic pruritus is a recognized skin condition, which, although very unpleasant and difficult to manage, has no immediate implications with regard to the patient’s general health. Therapy is usually based on the use of *antihistamines*, *adding sodium bicarbonate to the water*, and *phototherapy*.

Specific Investigations

- Complete blood count (repeated yearly)
- Water induction

First-Line Therapies

• Explanation	E
• Minimally sedating antihistamine	C
• Sodium bicarbonate added to bath water	D

Antihistamines are used by these authors in the management of aquagenic pruritus. There is no consensus regarding the first-line treatment, as the response of each patient is individual and no single treatment is effective in all cases; however, it would seem reasonable to start by advising a minimally sedating antihistamine 2 hours before the bath or shower on a regular basis. Patients may have a good response to antihistamines. Not all patients respond to antihistamine treatment, however, and, of those who do, the response may consist of a diminution rather than an abolition of symptoms.

Aquagenic pruritus

Greaves MW, Black AK, Eady RAJ, Coutts A. *Lancet* 1981; 282: 2008–11.

Aquagenic pruritus

Steinman HK, Greaves MW. *J Am Acad Dermatol* 1985; 13: 91–6.

Aquagenic pruritus: pharmacological findings and treatment

Greaves MW, Handfield-Jones SE. *Eur J Dermatol* 1992; 2: 482–4.

Aquagenic pruritus may respond to the addition of sodium bicarbonate to the bath water. Advice about the amount of sodium bicarbonate to be added varies. In those who have responded, 200 g, 100 g, and 25 g have been added. The most practical approach might be to start with approximately 200 g per bath, and if there is a satisfactory response, to reduce gradually to a level that continues to suppress the itching. In a series of 25 patients, 25% improved with this treatment; however, in some cases the response may be temporary. Large quantities of sodium bicarbonate may be purchased economically at bakers' wholesalers.

Baking soda baths for aquagenic pruritus

Bayoumi AHM, Highet AS. *Lancet* 1986; 11: 464.

Aquagenic pruritus treatment with sodium bicarbonate and evidence for a seasonal form

Bircher AJ. *J Am Acad Dermatol* 1989; 21: 817.

Second-Line Therapies

• UVB	C
• Narrowband UVB	E
• Combined UVA/narrowband UVB therapy	E

Due to the necessity for hospital attendance, UVB should be considered a second-line treatment for aquagenic pruritus. A response usually occurs between 2 and 4 weeks of treatment, but relapse normally occurs within months of stopping treatment, which may then be repeated as necessary or maintenance therapy instituted as the condition is ongoing.

A good response to NB-UVB is described in two patients to whom it was administered three times per week. The improvement occurred at about 2 months of treatment and was maintained on weekly treatment in the ensuing months. In one of the patients desloratadine was added during the maintenance period. NB-UVB may prove to be an effective form of phototherapy.

Combined UVA and UVB treatment was used to treat one patient with good response.

Ultraviolet phototherapy for pruritus

Rivard J, Lim HW. *Dermatol Ther* 2005; 18: 344–54.

Narrow band ultraviolet B in aquagenic pruritus

Xifra A, Carrascosa JM, Ferrandiz C. *Br J Dermatol* 2005; 158: 1233.

Aquagenic pruritus responding to combined ultraviolet A/narrowband UVB therapy

Jean M, Koh A, Chong WS. *Photodermatol Photoimmunol Photomedicine* 2009; 25: 169.

Third-Line Therapies

• Bath oil	E
• Emulsifying ointment in the bath water	E
• PUVA	E
• Propranolol	E, C
• Transdermal nitroglycerin	E
• Naltrexone	E

PUVA treatment has been effective in the bath itch of polycythemia vera and has been used successfully both in a series of five patients and in individual patients, although either maintenance or repeated courses of therapy are necessary to maintain control of the condition. PUVA with oral psoralens may be regarded as a third-line treatment for practical reasons.

Aquagenic pruritus responding to intermittent photochemotherapy

Holme SA, Anstey AV. Clin Exp Dermatol 2001; 26: 40–1.

Repeated PUVA treatment of aquagenic pruritus

Goodkin R, Bernhard JD. Clin Exp Dermatol 2002; 27: 164–5.

Aquagenic pruritus responds to propranolol

Thomsen K. J Am Acad Dermatol 1990; 22: 697.

Treatment with propranolol of six patients with idiopathic aquagenic pruritus

Nosbaum A, Pecquet C, Bayrow O, Amsler E, Nicholas JF, Berard F, et al. J Allergy Clin Immunol 2011; 28: 113.

After a report of successful treatment of two patients with propranolol, six patients were treated with propranolol 10 to 40 mg/day for 3 months depending on their tolerance of the drug. Either relief or elimination of symptoms occurred in five after 7 days. Relapse took place after stopping, and one patient needed retreatment, which was effective.

Aquagenic pruritus response to the exogenous nitric oxide donor, transdermal nitroglycerin

Goihan Yahr M. *Int J Dermatol* 1994; 33: 752.

Transdermal nitroglycerin has been used effectively in one patient.

Efficacy and safety of naltrexone, an oral opiate receptor antagonist, in the treatment of pruritus and dermatological diseases

Metze D, Reinmann S, Beissert S, Luger T. *J Am Acad Dermatol* 1999; 41: 533–9.

Successful treatment of refractory aquagenic pruritus with naltrexone

Ingber S, Cohen PD. *J Cutan Med Surg* 2005; 9: 215–6.

Naltrexone at a dose of 50 mg daily controlled the condition in two patients with aquagenic pruritus to whom it was given.

Cholinergic pruritus

Cholinergic pruritus occurs when patients itch, sting, or prickle after a rise in body temperature. The provoking stimuli are exercise (walking, running, dancing, going to the gym), including housework (ironing, vacuuming), heat (hot room, hot food, hot bath, sunny day), and emotion (excitement, stress, embarrassment) or fever. A combination of factors may cause a more pronounced itch (e.g., walking on a sunny day). The intensity, extent, and duration of the itching seem to be directly proportional to the strength of the eliciting stimulus. By definition, no whealing occurs on the skin during an attack. Although the prevalence of this condition is not known, it is the authors' impression that many people itch when they become warm, although this itching is frequently insufficiently severe or incapacitating to present at a dermatology clinic. Cholinergic pruritus can be regarded as a variant of cholinergic urticaria. There is one case report that describes a patient presenting initially with cholinergic pruritus who progressed to cholinergic urticaria. Because there are no visible skin lesions, it is important to be aware of the condition and to differentiate it from aquagenic pruritus in those who describe itching after a bath or shower.

Management Strategy

Explaining the provoking factors and stressing that the condition is not an allergy, related to diet, or related to any underlying disease is helpful. If possible, *minimizing situations in which the itching occurs* can be helpful, and cooling the skin as quickly as possible may lessen the duration of the itching. It is not possible to tell the patient how long the condition will be present before remission takes place.

Therapeutic agents typically utilized are *antihistamines*, although *danazol* has been reported to be beneficial.

Specific Investigations

- Exercise induction
- Warm bath induction (40°–41°C)

First-Line Therapies

• Explanation	E
• Second generation H ₁ antihistamines	E

An explanation is the most important part of treatment. The patient needs to understand the relationship between the itching and heat and the importance of keeping cool. Treatment with minimally sedating antihistamines generally produces an improvement, although they are unlikely to suppress the condition completely. Antihistamines should be taken regularly every morning or 2 hours before an expected stimulus in order to assess any response. If the antihistamine proves helpful, the same dose could be repeated 9 to 12 hours later if necessary.

Second-Line Therapy

• Danazol	C
-----------	---

Cholinergic pruritus, erythema, and urticaria: a disease spectrum responding to danazol

Berth-Jones J, Graham Brown RAC. Br J Dermatol 1989; 121: 235–37.

Danazol, which has been used in cholinergic urticaria, may rarely be effective in very severely affected individuals. The recommended dose is 200 mg three times daily. This dose could be continued for approximately 1 month and reduced to the minimum that controls the condition.

Irritant contact dermatitis

Nathaniel K. Wilkin

Irritant contact dermatitis (ICD) is the most common form of contact dermatitis and is defined as the reaction to an exogenous substance—the irritant—that damages the epidermis through physical or chemical mechanisms, triggering an innate immunologic

response only. Clinical manifestations of ICD vary in presentation and severity according to multiple factors: preexisting status of the skin (atopy, barrier disruption, etc.), the nature and number of irritants (corrosives or caustic), the duration and frequency of contact, and the conditions of exposure (moisture, occlusion, temperature). Acute ICD is usually attributable to a single irritant. Chronic ICD usually results from exposure to multiple irritants, often in association with endogenous factors such as atopy or stress. Chronic cumulative ICD usually involves the hands.

ICD is common, often has a poor prognosis, has a significant economic impact on society, and seriously degrades the quality of life of affected individuals beyond the ability to work.

Management Strategy

The first step in any management strategy is *prevention*. Patients should be educated about proper skin care and protection, including handwashing, the use of moisturizers and barrier creams, avoidance of common irritants, and the use of protective clothing such as gloves and aprons when handling potentially irritating substances.

Dermatologists can encourage primary prevention by counseling patients at higher risk because of endogenous factors (e.g., atopy) or exogenous factors (e.g., frequent occupational exposures, such as in hairdressing). Secondary prevention includes measures that enable patients to remain employed without interfering with the resolution of the ICD. Chronic hand dermatitis is a common presentation of ICD, and patient education can be facilitated with a handout on lifestyle management principles directed at handwashing and moisturizing, occlusive moisturizing therapy at night, special protective modalities (such as type of glove to exclude specific irritants), and specific agents to avoid.

Azathioprine, ciclosporin, oral retinoids, psoralen and UVA (PUVA), Grenz ray therapy, and superficial radiotherapy may be justified for short-term control in patients who are compliant with moisturizing, use of protective modalities (gloves), and application of topical corticosteroids and still have a severe disruption of their quality of life due to active ICD. Because the goal of these second- and third-line therapies is to reduce the severity such that first-line therapies may become sufficient, patient selection is critical.

Specific Investigations

- Patch testing to environmentally relevant allergens
- Detailed case history of patient's work, habits, and hobbies

Irritant contact dermatitis: a review

Slodownik D, Lee A, Nixon R. *Australas J Dermatol* 2008; 49: 1–11.

Treatment of ICD is based on determining all contributing factors to the patient's dermatitis and prevention of contact with the causative agents where possible.

Clues to an accurate diagnosis of contact dermatitis

Rietschel RL. *Dermatol Ther* 2004; 17: 224–30.

Patch testing with known environmentally relevant allergens that is negative and sufficiently comprehensive would point to ICD, especially in patients without atopy, dyshidrosis, or psoriasis. A careful history and documentation of specific morphologic changes on physical examination are essential when pursuing the presumptive diagnosis of ICD after negative patch testing.

Patch testing, a detailed history, and assessment of specific morphologic changes provide for an accurate diagnosis and can identify specific environmental factors the patient should avoid. Such documentation is also useful should medicolegal questions arise regarding impairment and job placement.

Allergic and irritant contact dermatitis

Nosbaum A, Vocanson M, Hennino A, Nicholas JF. *Eur J Dermatol* 2009; 19: 325–32.

ICD and allergic contact dermatitis can have similar presentations. In such cases where differentiation is difficult, immunologic assay techniques can be used to make the diagnosis.

First-Line Therapies

• Physical skin protection	C
• Emollients	C
• Barrier creams	C
• Topical corticosteroids	C
• Topical calcineurin inhibitors	C

Current concepts of irritant contact dermatitis

English JS. *Occup Environ Med* 2004; 61: 722–6.

Avoiding exposure to irritants, relying on the use of personal protective equipment, and using moisturizing creams constitute the basis of treatment of ICD.

A review of the management of ICD cases from an occupational medicine perspective, which includes an excellent guide to various gloves that provide protection for specific types of hazards.

Therapeutic options for chronic hand dermatitis

Warshaw EM. *Dermatol Ther* 2004; 17: 240–50.

A review of the therapeutic alternatives for patients with recalcitrant hand dermatitis.

Effect of glove-occlusion on human skin (II)

Ramsing DW, Agner T. *Contact Dermatitis* 1996; 34: 258–62.

Occlusive gloves worn for prolonged periods may impair skin barrier function. Wearing cotton gloves under the occlusive gloves can prevent this negative effect.

High-fat petrolatum-based moisturizers and prevention of work-related skin problems in wet-work occupations

Mygind K, Sell L, Flyvholm MA, Jepsen KF. *Contact Dermatitis* 2006; 54: 35–41.

Detailed analyses revealed that protective gloves are the overall

most effective protection and did not indicate that a high-fat moisturizer could successfully replace gloves.

Protective gloves should be used for as short a time as possible and with cotton gloves under the occlusive gloves. Gloves provide better protection than, and should not be replaced by, moisturizers or barrier creams.

A randomized comparison of an emollient containing skin-related lipids with a petrolatum-based emollient as adjunct in the treatment of chronic hand dermatitis

Kucharekova M, Van de Kerkhof PCM, Van der Valk PGM. Contact Dermatitis 2003; 48: 293–9.

The frequent use of emollients is associated with significant improvement in hand dermatitis. No significant difference in the improvement was demonstrated for the emollient containing skin-related lipids.

The frequent use of emollients is an essential component of therapy. Traditional petrolatum-based emollients are accessible, inexpensive, and just as effective as an emollient containing skin-related lipids.

Double-blind, randomized trial of scheduled use of a novel barrier cream and an oil-containing lotion for protecting the hands of health care workers

McCormick RD, Buchman TL, Maki DG. Am J Infect Control 2000; 28: 302–10.

The scheduled use of petrolatum oil-containing lotion or a barrier cream was associated with a marked improvement (69% and 52%, respectively) in chronic hand irritant dermatitis.

It is debatable whether the distinction between “skin care” and “skin protection” is real. Side effects with emollients and barrier creams are irritation and sensitization to their ingredients. A useful procedure is to include patch tests of those emollients and barrier creams anticipated to be used by the patient in the initial comprehensive patch-testing evaluation of the chronic contact dermatitis.

Clinical efficacy evaluation of a novel barrier protective cream

Slade HB, Fowler J, Draeolos ZD, Reece BT, Cargill DI. Cutis 2008; 82: 21–8.

Cor806.805 (Tetrix cream) was associated with beneficial results regarding the establishment of a barrier against common irritants

lasting at least 6 hours.

Breakdown of the skin's barrier function occurs early in the ICD disease process. Reestablishing the skin's protective barrier is a critical step in the healing process.

Do topical corticosteroids modulate skin irritation in human beings? Assessment by transepidermal water loss and visual scoring

Van der Valk PGM, Maibach HI. J Am Acad Dermatol 1989; 21: 519–22.

Neither the corticosteroid products nor the vehicle significantly influenced barrier function during repeated application of an irritant, sodium lauryl sulfate, in low concentration.

The first step must be the elimination, to the fullest extent possible, of exposure to irritants. Until proven otherwise, no therapy should be considered sufficiently potent as to overcome the effects of continuing exposure to irritants.

Short-term glucocorticoid treatment compromises both permeability barrier homeostasis and stratum corneum integrity: inhibition of epidermal lipid synthesis accounts for functional abnormalities

Kao JS, Fluhr JW, Man MQ, Fowler AJ, Hachem JP, Crimrine D, et al. J Invest Dermatol 2003; 120: 456–64.

ICD can be treated with glucocorticoids; however, there may be a secondary compromise in barrier function, which might be correctable with topical application of lipids.

An open-label pilot study to evaluate the safety and efficacy of topically applied tacrolimus ointment for the treatment of hand and/or foot eczema

Thelmo MC, Lang W, Brooke E, Osborne BE, McCarty MA, Jorizzo JL, et al. J Dermatol Treat 2003; 14: 136–40.

Pimecrolimus cream 1%: a potential new treatment for chronic hand dermatitis

Belsito DV, Fowler JF, Marks JG, Pariser DM, Hanifin J, Duarte IA, et al. Cutis 2004; 73: 31–8.

The topical calcineurin inhibitor led to improvements over baseline in the open-label study, and there was a trend toward greater

clearance than with vehicle in the pimecrolimus study.

Topical calcineurin inhibitors may have a role as an alternative to low-potency topical corticosteroids in chronic irritant dermatitis in patients with mild inflammatory changes who do not experience a burning sensation when the product is applied.

Second-Line Therapies

• Ciclosporin	C
• UVB therapy	C
• PUVA therapy	C
• Bexarotene gel	C

Novel treatment of chronic severe hand dermatitis with bexarotene gel

Hanifin JM, Stevens V, Sheth P, Breneman D. Br J Dermatol 2004; 150: 545–53.

A phase I to II open-label, randomized clinical study of bexarotene gel, alone and in combination with a low- and a midpotency steroid, was conducted in 55 patients with chronic severe hand dermatitis at two academic clinics. Patients using bexarotene gel monotherapy reached a 79% response rate for at least 50% clinical improvement and a 39% response rate for at least 90% clearance of hand dermatitis. Adverse events possibly related to treatment in all patients were stinging or burning (15%), flare of dermatitis (16%), and irritation (29%). Bexarotene gel appears to be safe and tolerated by most patients, with useful therapeutic activity in chronic severe hand

dermatitis.

Comparison of cyclosporine and topical betamethasone 17,21-dipropionate in the treatment of severe chronic hand eczema

Granlund H, Erkkö P, Eriksson E, Reitamo S. Acta Derm Venereol 1996; 76: 371–6.

Low-dose oral ciclosporin at 3 mg/kg daily was compared with topical 0.05% betamethasone dipropionate in a randomized, double-blind study of 41 patients with chronic hand dermatitis and an inadequate response to treatment with topical halogenated corticosteroids for at least 3 to 4 weeks and/or PUVA and avoidance of relevant contact allergens. Both treatment groups had similar improvement and similar relapse rates after successful treatment. Adverse events were slightly more common in patients treated with ciclosporin.

Low-dose cyclosporine may be a useful alternative treatment, although very high-potency topical corticosteroids can be effective in patients who do not have an adequate response to other mid- to high-potency topical corticosteroids.

PUVA-gel vs. PUVA-bath therapy for severe recalcitrant palmoplantar dermatoses. A randomized, single-blinded prospective study

Schiener R, Gottlöber P, Müller B, Williams S, Pillekamp H, Peter RU, et al. Photodermatol Photoimmunol Photomed 2005; 21: 62–7.

PUVA-gel therapy can be an effective therapeutic alternative to conventional PUVA-bath therapy in treating localized dermatoses of the palms and soles. The advantages of PUVA-gel therapy are simplicity of use and low cost.

Local narrowband UVB phototherapy vs. local PUVA in the treatment of chronic hand eczema

Sezer E, Etikan I. Photodermatol Photoimmunol Photomed 2007; 23: 10–4.

There was a statistically significant improvement with both treatment modalities; however, the difference in clinical response between the two was not statistically significant. Local narrowband UVB phototherapy regimen is as effective as paint-PUVA therapy in patients with chronic hand eczema of both dry and dyshidrotic types.

Given the similar improvement in chronic hand dermatitis and the

increased side effects with paint-PUVA therapy, it would be prudent to begin treatment with local narrowband UVB therapy and only use paint-PUVA therapy if the response is inadequate.

Third-Line Therapies

• Superficial radiotherapy	A
• Oral alitretinoin	A

Oral alitretinoin (9-*cis*-retinoic acid) therapy for chronic hand dermatitis in patients refractory to standard therapy: results of a randomized, double-blind, placebo-controlled, multicenter trial

Ruzicka T, Larsen FG, Galewicz D, Horváth A, Coenraads PJ, Thestrup-Pedersen K, et al. Arch Dermatol 2004; 140: 1453–9.

Alitretinoin given at well-tolerated doses induced substantial clearing of chronic hand dermatitis in patients refractory to conventional therapy.

Alitretinoin: its use in intractable hand eczema and other potential indications

Petersen B, Jemec GB. Drug Des Dev Ther 2009; 3: 51–7.

Alitretinoin has significant therapeutic potential for the treatment of chronic recalcitrant hand eczema.

Alitretinoin is not currently approved for use in the United States. Although teratogenicity might occur at any clinically relevant dose, most other side effects are dose dependent. This drug should be reserved for patients whose chronic hand dermatitis is refractory to conventional therapies and prescribed for only as long as it takes to achieve control, which can be maintained with safer therapies.

Efficacy and patient perception of Grenz ray therapy in the treatment of dermatoses refractory to other medical therapy

Schalock PC, Zug KA, Carter JC, Dhar D, MacKenzie T. Dermatitis 2008; 19: 90–4.

Many patients treated with Grenz ray therapy (GRT) for recalcitrant dermatitis reported that this was an effective therapy in reducing the discomfort and severity of their skin condition. Overall, slightly more than half of treated patients believed GRT was a worthwhile therapy that they would use again.

Grenz ray therapy in the new millennium: still a valid treatment option?

Warner JA, Cruz Jr PD. Dermatitis 2008; 19: 73–80.

Grenz ray or superficial radiotherapy is not an obvious “go to” treatment when one second-line treatment does not provide a sufficient response, but it may be tried for some additional advantage as an adjunct to intensive first-line treatment with or without low-dose ciclosporin.

Jellyfish stings

Christopher Sladden, Jamie Seymour, and Michael Sladden

Jellyfish are members of the phylum Cnidaria, which consists of five classes: Cubozoa (box jellyfish), Hydrozoa (Portuguese man-of-war), Scyphozoa (true jellyfish), Staurozoa (staromedusans), and Anthozoans (corals). They are found in every ocean and some fresh water, from the surface to the depths of the seas. They often consist of a bell-shaped body, ranging from 1 millimeter to over 2 meters in diameter, with tentacles up to 30 meters long.

Jellyfish envenomings can occur during recreational and commercial pursuits, both in the water and when encountering living or dead animals on the shore. Jellyfish sting their prey using nematocysts, stinging structures located in specialized cells called *cnidocytes*. The nematocyst is a highly coiled, hollow, harpoonlike microtubule responsible for venom injection. Contact with a jellyfish tentacle can trigger millions of nematocysts to pierce the skin and inject venom. Those providing care to sting victims should avoid being stung by adherent tentacles on the victim.

Severity of jellyfish stings depends on many factors. These include the species and age of the jellyfish involved, the geographic location, the location of the nematocysts involved (bell or tentacle), patient age and general health, the amount of skin involved, and the number of nematocysts triggered.

Most jellyfish stings are self-limiting causing localized pain and skin lesions. However, symptoms can range from local discomfort, to severe pain, through to cardiovascular collapse and death. Immediate management of jellyfish stings occurs at the beach with first aid and resuscitation, and then if needed in a hospital. Immediate cutaneous reactions include wheals, blisters, and angioedema. Dermatologists are most likely to become involved later to manage the delayed sequelae of jellyfish stings.

In this chapter we discuss the most important type of jellyfish stings, the different symptoms and management of these stings, as well as strategies for prevention of jellyfish stings.

Clinical Features

Major box jellyfish (*Chironex fleckeri*)

Chironex fleckeri is only found in northern Australian waters and is widely considered the most venomous animal in the world. However, several other species of chiropdropids (or multitentacled box jellyfish) found throughout non-Australian tropical realms are also capable of inflicting life-threatening envenomings. The toxin is dermonecrotic, cardiotoxic, and neurotoxic. Stings cause immediate and excruciating pain. Skin manifestations include large welts and whiplike purple-red plaques. Severe envenomation is rare but can cause cardiovascular collapse and death. Victims can drown before reaching shore. Many deaths occur within minutes of envenomation, at a time when the

antivenom often is unavailable.

Irukandji jellyfish (*Carukia barnesi*)

Irukandji syndrome is a poorly defined set of symptoms occurring after envenoming by certain species of box jellyfish, usually *Carukia barnesi*. The initial sting is often barely noticed with minimal skin symptoms. The symptoms of Irukandji syndrome develop after 20 to 30 minutes with victims showing three patterns of symptoms: pain, catecholamine-like effects, and cardiopulmonary decompensation. Symptoms range from headaches, through severe pain, nausea, vomiting, and pulmonary edema, to hypertension and cardiac dysfunction, sometimes resulting in death. Although the syndrome is well documented in coastal northern Australia, it appears that Irukandji syndrome is an increasing marine problem worldwide.

Bluebottles or Portuguese man-of-war (*Physalia* species)

Bluebottle stings cause immediate intense pain and a linear red eruption at the sting site but rarely systemic effects. However, the Portuguese man-of-war (*Physalia physalis*), found in the Atlantic, Pacific, and Indian oceans, deserves special attention because it is potentially lethal.

True jellyfish (Schyphozoans)

The majority of jellyfish envenomings throughout the world occur from the Schyphozoans. Symptoms may range from mild irritation through to significant welts on the envenomed victim, which may result in skin necrosis in some instances. Life-threatening complications from these envenomings are rare.

Corals and sea anemones (Anthozoans)

Sea anemone stings range from mild erythema and tingling to painful urticarial and vesiculobullous lesions. Stings from corals are usually mild. "Coral cuts" from the hard coral exoskeleton are more serious and may introduce debris, bacteria, and other infection into the wound.

Seabather's eruption

This is an acute dermatitis caused by larvae of thimble jellyfish (*Linuche unguiculate*) and sea anemone (*Edwardsiella lineata*). It has been reported in Florida, the Bahamas, Bermuda, southeast Asia, Brazil, and New York. The rash, usually confined to underneath the bathing suit, is a highly pruritic and erythematous papular eruption. Symptoms usually begin hours to 15 days after exposure.

Cutaneous Manifestations Of Jellyfish Stings

Immediate cutaneous reactions include wheals and blisters at the site of the sting. In more severe stings, partial- or full-thickness skin necrosis can occur. Delayed, persistent, or recurrent eruptions have been reported at the initial envenomation site, consisting of erythema, urticarial lesions, papules, and plaques. Delayed hypersensitivity reactions occur infrequently. Other sequelae include dermatitis, secondary infections, postinflammatory hyperpigmentation and scarring, and erythema nodosum.

Management Strategy

First-Line Therapies

Prevention of jellyfish stings

• Stinger suits worn next to the skin reduce contact with jellyfish tentacles	E
• Beach/ocean stinger nets to provide physical barrier between jellyfish and swimmers (NB: These are only effective on jellyfish that are larger than the net mesh size)	E
• Proprietary Safe Sea cream (NB: This treatment may cause the discharge of more nematocysts in some species)	A
• Removing (and washing) bathing suits and showering to reduce/prevent seabather's eruption	E

Immediate management of stings

• Sting victims should be removed from the water	E
• Those providing care to sting victims must avoid being stung by the jellyfish	E
• Immediately remove any tentacles (dermis on fingers is usually thick enough to prevent significant envenoming to the first-aider)	E
• Wash sting site with sea water (not fresh water)	E
• Identify type of jellyfish involved	E
• Cardiopulmonary resuscitation if needed (usually only necessary for box jellyfish)	E

Topical agents to provide analgesia

• Lignocaine	C
• Ice	C
• Hot water	A

Major box jellyfish (*Chironex fleckeri*) stings

• Apply liberal amounts of vinegar to sting site to inactivate any undischarged nematocysts	C
• Cardiac monitoring, supportive care, and cardiopulmonary resuscitation if required	D

All but very minor box jellyfish stings require transport to hospital for:

• Oral and parenteral analgesia	C
• Administration of intravenous antivenom	D
• Administration of intravenous magnesium	D

Irukandji jellyfish stings

• Apply liberal amounts of vinegar to sting	C
---	---

The majority of stings require hospital admission for:

• Oral and parenteral analgesia	C
• Cardiac monitoring, supportive care, and cardiopulmonary resuscitation if required	D

Bluebottle and Portuguese man-of-war stings

• Application of hot water (45°C) gives rapid and significant relief	A
--	---

Interventions for the symptoms and signs resulting from jellyfish stings

Li L, McGee RG, Isbister GK, Webster AC. Cochrane Database Sys Rev 2013; 12: CD009688.

This review located seven trials that assessed a variety of different interventions applied in different ways and in different settings. Although heat appears to be an effective treatment for *Physalia* (bluebottle) stings, this evidence is based on a single trial of low-quality evidence.

Evidence-based treatment of jellyfish stings in North America and Hawaii

Ward NT, Darracq MA, Tomaszewski C, Clark RF. Ann Emerg Med 2012; 60: 399–414.

Systematic review of the evidence supporting various treatments for envenomation by jellyfish (cnidarian) and related organisms in North America and Hawaii. Hot water and topical lidocaine seem beneficial in improving pain symptoms. If not available, remove nematocysts and wash the area with salt water. Vinegar causes pain exacerbation or nematocyst discharge in the majority of species (but is useful in box jellyfish stings).

Efficacy of a jellyfish sting inhibitor in preventing jellyfish stings in normal volunteers

Kimball AB, Arambula KZ, Stauffer AR, Levy V, Davis VW, Liu M, et al. Wilderness Environ Med 2004; 15: 102–8.

This randomized controlled trial (RCT) showed that the topical barrier cream Safe Sea reduced incidence and severity of certain jellyfish stings.

A randomised controlled trial of hot water (45 degrees C) immersion versus ice packs for pain relief in bluebottle stings

Loten C, Stokes B, Worsley D, Seymour JE, Jiang S, Isbister GK. Med J Aust 2006; 184: 329–33.

Hot water immersion was more effective than cold packs at reducing pain in nematocyst-confirmed stings. Immersion in water at 45°C for 20 minutes provides effective and practical analgesia from bluebottle stings.

Evaluation of the effects of various chemicals on discharge of and pain caused by jellyfish nematocysts

Birsa LM, Verity PG, Lee RF. Comp Biochem Physiol C Toxicol Pharmacol 2010; 151: 426–30.

Immediate relief was reported when lidocaine was sprayed on the skin of testers in contact with jellyfish tentacles. Acetic acid, ammonia, meat tenderizer, baking soda, and urea may stimulate nematocyst discharge in *Chrysaora quinquecirrha* (sea nettle), *Chiropsalmus quadrumanus* (sea wasp), and *Physalia physalis* (Portuguese man-of-war) stings.

First aid treatment of jellyfish stings in Australia. Response to a newly differentiated species

Fenner PJ, Williamson JA, Burnett JW, Rifkin J. Med J Aust 1993; 158: 498–501.

Vinegar inhibits nematocyst discharge in box jellyfish stings and is accepted first aid treatment. However, it should not be used in *Physalia* (bluebottles) because it causes discharge of nematocysts.

First aid for jellyfish stings: do we really know what we are doing?

Little M. Emerg Med Australas 2008; 20: 78–80.

First aid guidelines in Australia still suggest the use of ice, but little evidence exists to support this. There is more evidence for the use of hot water.

Is there a role for the use of pressure immobilization bandages in the treatment of jellyfish envenomation in Australia?

Little M. Emerg Med (Fremantle) 2002; 14: 171–4.

A review of the literature indicates no benefit from applying compression bandages in jellyfish stings as recommended in some other envenomations.

Antivenom efficacy or effectiveness: the Australian experience

Isbister GK. Toxicology 2010; 268: 148–54.

A number of recent studies in Australia bring into question the effectiveness of some antivenoms, including box jellyfish antivenoms. The author notes this does not prove ineffectiveness, but suggests the need for more studies.

Australian venomous jellyfish, envenomation syndromes, toxins and therapy

Tibballs J. Toxicon 2006; 48: 830–59.

Case studies suggest antivenom for the major box jellyfish may be moderately efficacious.

Second-Line Therapies

Seabather's eruption

• Topical and oral antihistamines	E
• Topical and oral corticosteroids	E

Treatment of dermatitis and hyperpigmentation due to jellyfish stings

• Oral antihistamines	E
• Topical corticosteroids	E
• The immune modulators tacrolimus and pimecrolimus	E
• Hydroquinone	E

Secondary infections and long-term treatment

Dermonecrosis is a frequent outcome of *jellyfish* stings; however, many resolve spontaneously. Treating dermonecrosis from these envenomings as a burn, with specific attention to avoiding secondary bacterial infection, significantly decreases the risk of permanent scarring.

Seabather's eruption – a case of Caribbean itch

MacSween RM, Williams HC. BMJ 1996; 312: 957–8.

Reports one case of seabather's eruption successfully treated with topical 0.05% clobetasol propionate. In addition, the second case required 2 weeks of oral steroids, which relieved the symptoms, but the rash took 4 weeks to fade and left behind some faint atrophic scars at 8 weeks, follow-up.

Clinical perspectives on seabather's eruption, also known as "sea lice."

Tomchik RS, Russell MT, Szmant AM, Black NA. JAMA 1993; 269: 1669–72.

Seabather's eruption is usually a benign clinical syndrome that resolves spontaneously. Treatment is symptomatic and involves the use of antihistamines and steroids.

Recurrent dermatitis after solitary envenomation by jellyfish partially responded to tacrolimus ointment 0.1%

Rallis E, Limas C. J Eur Acad Dermatol Venereol 2007; 21: 1287–8.

Topical tacrolimus produced improvement in symptoms in jellyfish-induced dermatitis.

Successful management of a delayed and persistent cutaneous reaction to jellyfish with pimecrolimus

Di Costanzo L, Balato N, Zagaria O, Balato A. J Dermatolog Treat 2009; 20: 179–80.

Topical pimecrolimus produced improvement in dermatitis.

Delayed cutaneous reaction to jellyfish

Veraldi S, Carrera C. Int J Dermatol 2000; 39: 28–9.

Oral hydroxyzine and topical hydrocortisone butyrate provided relief and reduced duration of a delayed dermatitis secondary to contact with an unknown jellyfish.

Granulomatous jellyfish dermatitis

Ulrich H, Landthaler M, Vogt T. J Dtsch Dermatol Ges 2007; 5: 493–5.

Topical therapy with tacrolimus 0.1% for two 2-week treatment periods led to healing of the skin changes with a slight scar in a patient with a granulomatous dermatitis.

Treatment of a pigmented lesion induced by a *Pelagia noctiluca* sting

Kokelj F, Burnett JW. Cutis 1990; 46: 62–4.

Hyperpigmentation, present 4 years after a jellyfish sting, was successfully treated within 4 days of using 1.8% hydroquinone.

Jessner lymphocytic infiltrate

Joanna E. Gach

Jessner lymphocytic infiltrate (JLI) is a chronic inflammatory condition presenting with erythematous or reddish-brown papules or annular or arciform plaques, which can expand peripherally and sometimes develop central healing. The lesions are usually seen in adults and affect the face, neck, or upper trunk. Although they are

frequently asymptomatic, some patients report itch or burning. A case report noted ectropion as a complication. The lesions can persist from weeks to years and disappear without sequelae but may recur. Additionally, JLI has been reported as a manifestation of borreliosis and an angiotensin-converting enzyme (ACE) inhibitor-induced drug eruption.

Management Strategy

JLI runs a waxing and waning course marked by intermittent improvement and subsequent exacerbations, which makes the evaluations of therapeutic effectiveness difficult. Patients demand treatment because they find the lesions disfiguring or itchy.

Potent topical steroids applied once or twice daily for 4 weeks are the first-line treatment for many dermatologists. Unfortunately, the results of treatment are variable and, most important, only short lasting. If the response is inadequate, injection of *intralesional corticosteroids* into localized lesions or the use of *potent topical steroids under occlusive dressing* may be beneficial but is associated with a greater risk of skin atrophy. *Topical tacrolimus* may be a safer alternative.

In cases where ultraviolet exposure has been reported to induce or exacerbate lesions, additional therapy with sunscreen may be needed. This group of patients may respond to *antimalarials*, in particular, hydroxychloroquine.

A variety of other therapies have been reported to be effective in the management of JLI. *Thalidomide*, *oral gold*, and *retinoids* proved to be helpful in some cases, but their use may be limited by the adverse effects, which may be difficult for the patient and physician to accept, especially as JLI is harmless.

Many other treatments, including nicotinamide, vitamin E, penicillin, chlortetracycline, minocycline, dapsone, quinacrine (mepacrine), and radiotherapy, have been tried unsuccessfully.

Specific Investigations

- Skin biopsy
- Lesional skin for direct immunofluorescence
- Antinuclear antibodies/extractable nuclear antigen

The diagnosis can be made on clinical grounds. The investigations are helpful in differentiating the condition from discoid lupus erythematosus, lupus erythematosus tumidus, and cutaneous lymphoma.

The heterogeneity of Jessner's lymphocytic infiltration of the skin. Immunohistochemical studies suggesting one form of perivascular lymphocytoma

Cerio R, Oliver GF, Jones EW, Winkelmann RK. J Am Acad Dermatol 1990; 23: 63–7.

Skin biopsy of the lesion shows normal epidermis and a moderate, dense, sleeve-like perivascular and periadnexal infiltrate in the middle dermis. This consists of normal-looking lymphocytes with the B cells grouped in close proximity to the superficial vessels and T cells at the periphery, and occasionally, plasma cells.

Could Jessner's lymphocytic infiltrate of the skin be a dermal variant of lupus erythematosus? An analysis of 210 cases

Lipsker D, Mitschler A, Grosshans E, Cribier B. Dermatology 2006; 213: 15–22.

Immunofluorescence studies of lesional skin showed a lupus band with IgG, IgM ± C3 in 9.5% of cases of JLI. Antinuclear antibodies were present in 45% of cases.

Plasmacytoid dendritic cells: an overview of their presence and distribution in different inflammatory diseases, with special emphasis on Jessner's lymphocytic infiltrate of the skin and cutaneous lupus erythematosus

Tomasini D, Mentzel T, Hantschke M, Cerri A, Paredes B, Rütten A, et al. J Cutan Pathol 2010; 37: 1132–9.

Distribution of distinct perivascular and periadnexal clusters of plasmacytoid dendritic cells in JLI and tumid lupus erythematosus is identical.

First-Line Therapies

• Potent topical/intralesional corticosteroids	C
• Topical immunomodulators	E

Jessner's lymphocytic infiltration of the skin. A clinical study of 100 patients

Toonstra J, Wildschut A, Boer J, Smeenk G, Willemze R, van der Putte SC, et al. Arch Dermatol 1989; 125: 1525–30.

A series of 100 patients with JLI assessing clinical manifestations, duration, clinical course, and treatments. Forty-three of 91 patients treated with topical steroids had an excellent ($n = 13$) or good ($n = 30$) response, with temporary regression of the lesions. Many patients had no response.

Childhood Jessner's lymphocytic infiltrate of the skin

Higgins CR, Wakeel RA, Cerio R. Br J Dermatol 1994; 131: 99–101.

A case report of an 11-year-old boy with JLI responding to intralesional corticosteroids.

Effective treatment of chronic inflammatory skin diseases. Once a week occlusion therapy with clobetasol propionate and DuoDERM

Volden G. Tidsskr Nor Laegeforen 1992; 112: 1272–4.

JLI was among other chronic skin diseases that were treated once a week with clobetasol propionate lotion left under the completely occlusive hydrocolloid dressing DuoDERM. The lesions cleared within a few weeks.

Topical calcineurin inhibitors in treating Jessner's lymphocytic infiltration of the skin: report of a case

Tzung TY, Wu JC. Br J Dermatol 2005; 152: 383–4.

Tacrolimus 0.1% ointment twice daily produced an improvement after 2 weeks but had to be withdrawn because of diffuse erythema and desquamation that occurred 2 weeks later. The same effect occurred on rechallenge and settled with a single 5-mg dose of dexamethasone administered by intramuscular injection. Subsequently, pimecrolimus 1% cream cleared the rash within 6 weeks, with no relapse 2 months later.

Second-Line Therapies

• Systemic corticosteroids	E
• Antimalarials	D
• Retinoids	E
• Photodynamic therapy	E
• Methotrexate	E
• Laser therapy	E
• Proquazone	C

Jessner's lymphocytic infiltrate treated with auranofin

Farrell AM, McGregor JM, Staughton RC, Bunker CB. Clin Exp Dermatol 1999; 24: 500.

Intramuscular injection of 40 mg Kenalog led to temporary improvement in this patient before oral gold was used successfully.

Jessner's lymphocytic infiltration of the skin. A clinical study of 100 patients

Toonstra J, Wildschut A, Boer J, Smeenk G, Willemze R, van der Putte SC, et al. Arch Dermatol 1989; 125: 1525–30.

Antimalarial drugs (chloroquine sulfate and hydroxychloroquine sulfate) were used in 15 patients, with a good response in 6. There were no details given regarding doses or treatment regimens.

Hydroxychloroquine 200 mg once or twice a day or chloroquine 200 mg daily was used in other case reports.

Satisfactory resolution of Jessner's lymphocytic infiltration of the skin following treatment with etretinate

Morgan J, Adams J. Br J Dermatol 1990; 122: 570.

One case of JLI was treated with etretinate 50 mg daily for 3 months and 25 mg daily for another 3 months. The rash subsided within 4 weeks of treatment and did not recur for 9 months after stopping treatment.

Isotretinoin 20 mg daily was used in other case reports but was not helpful.

Photodynamic therapy: new treatment for refractory lymphocytic infiltration of the skin

Park KY, Kim HK, Li K, Kim BJ, Seo SJ, Kim MN, et al. Clin Exp Dermatol 2012; 3: 235–7.

Remission was observed after two sessions of methyl 5-aminolevulinic acid cream photodynamic therapy with Aktilite 1 lamp, 630 nm.

Successful treatment of Jessner's lymphocytic infiltration of the skin with methotrexate

Laurinaviciene R, Clemmensen O, Bygum A. Acta Derm Venereol 2009; 89: 542–3.

Oral methotrexate 15 mg weekly for 6 months produced clearance. No recurrence 2 years after withdrawal of the drug.

Pulsed-dye laser treatment of Jessner lymphocytic infiltration of the skin

Borges da Costa J, Boixeda P, Moreno C. J Eur Acad Dermatol Venereol 2009; 23: 595–6.

Single treatment with 595-nm pulsed-dye laser cleared all lesions. New lesions were treated 2 months later.

Proquazone: a treatment for lymphocytic infiltration of the skin. Comparative study with 2 other nonsteroid antiinflammatory drugs

Johansson EA. Dermatologica 1987; 174: 117–21.

Eight of the 15 patients treated with proquazone (1-isopropyl-4-phenyl-7-methyl-2[1H]) 600 mg daily healed completely after 1 to 2 months of treatment. Recurrence of the rash in two cases responded to 600 mg daily for 3 to 4 days, on alternate months. Two further

patients from among the initial responders showed a partial remission. Indomethacin (50–75 mg daily) and ibuprofen (1200 mg daily) were tried, without effect.

Third-Line Therapies

• Auranofin	E
• Thalidomide	A

Jessner's lymphocytic infiltrate treated with auranofin

Farrell AM, McGregor JM, Staughton RC, Bunker CB. Clin Exp Dermatol 1999; 24: 500.

A marked improvement within 3 weeks of starting auranofin 3 mg orally twice daily. This case was unresponsive to chloroquine, hydroxychloroquine, minocycline, dapsone, and isotretinoin. Monitoring of the therapy includes monthly full blood count for thrombocytopenia and urinalysis to detect nephritis.

Crossover study of thalidomide vs. placebo in Jessner's lymphocytic infiltration of the skin

Guillaume JC, Moulin G, Dieng MT, Poli F, Morel P, Souteyrand P, et al. Arch Dermatol 1995; 131: 1032–5.

Twenty of 27 patients achieved complete remission after 2 months of therapy with thalidomide 100 mg daily. Sixteen (59%) patients were in complete remission 1 month after stopping therapy. Side effects included sleepiness, constipation, dry mouth, and sensorimotor neuropathy in two patients.

Juvenile plantar dermatosis

Stephen K. Jones

Courtesy of Joseph Bikowski, MD.

Juvenile plantar dermatosis (JPD) is a specific condition comprising

symmetric erythema (with a polished “billiard ball” appearance), scaling, and fissuring, primarily of the pressure areas of the foot. Vesiculation is never found. The most common sites involved are the plantar aspects of the great toe, forefoot, heel, and rarely the fingertips and palms. The instep and interdigital skin are rarely affected. The condition occurs almost exclusively in children and clears around puberty.

Management Strategy

JPD usually presents between 4 and 7 years of age. Most series suggest that it is a “disease of school years,” with clearing in most by puberty. It is uncommon in adults. Spontaneous resolution occurs in the majority of patients.

The main etiologic factor is thought to be the occlusive effect of “trainer” sports shoes and manmade fibers in hosiery, resulting in hyperhidrosis. This, some suggest, washes away surface lipids, which are already reduced because of the relative lack of sebaceous glands on the plantar surface of the foot. This hyperhidrosis is, therefore, followed by rapid dehydration of the skin on removal of footwear. It is proposed that this maceration/dehydration renders the skin susceptible to trauma (e.g., from sport). Avoidance of vigorous exercise may therefore be helpful in these patients.

The role of atopy is debated. Some series have found an increased incidence of atopy in patients and families, and, indeed, this condition was first referred to as “atopic winter feet.” It has been argued that the atopic diathesis predisposes the skin of the foot to the traumatic effects of sport and vigorous activity and the effects of alternating hyperhidrosis and dehydration. Other series, however, have found no increased incidence of atopy.

Investigations are unlikely to be helpful, but positive patch tests have been found in between 10% and 29% of cases. Even when these are to footwear-related allergens, however, there is debate as to whether allergen avoidance affects clinical outcome. Increased numbers of bacteria have been suggested to cause inflammation of the sweat ducts and thereby inhibit sweat secretion, but this has not been a consistent finding.

Changing to nonocclusive footwear along with cotton socks or open footwear has been proposed as a therapeutic maneuver. *Emollients*, both to reduce fissuring and to reduce the dehydration occurring on

removing occlusive footwear, are reported to be helpful. *Topical corticosteroids* may be beneficial if there is an inflammatory component. *Occlusive bandages* containing zinc ointment, ichthammol, or tar may help if hyperkeratosis and fissuring are a prominent feature. All these often only help temporarily, and regular rotation of emollients may be required.

It is the impression of most dermatologists that this condition has become less common in recent years, possibly related to changes in teenage fashion and footwear materials.

Specific Investigation

- Patch tests

Juvenile plantar dermatosis: a new entity

Mackie RM, Hussain SL. Clin Exp Dermatol 1976; 1: 253–60.

Thirteen of 102 patients showed a positive patch test. Eight were reactions to footwear constituents, but subsequent changes in footwear did not affect the clinical outcome.

Common pediatric foot dermatoses

Guenst BJ. J Pediatr Health Care 1999; 13: 68–71.

A practical review differentiating the various forms of tinea pedis and shoe dermatitis from JPD.

Sole dermatitis in children: patch testing revisited

Darling MI, Horn HM, McCormack SK, Schofield OM. Pediatr Dermatol 2011; 29: 254–7.

Of 14 children with JPD, 29% had clinically relevant reactions.

First-Line Therapy

- Await spontaneous resolution

C

Juvenile plantar dermatosis – an 8 year follow-up of 102 patients

Jones SK, English JSC, Forsyth A, Mackie RM. Clin Exp Dermatol 1987; 12: 5–7.

Of 50 patients traced, the condition had resolved in 38. The mean age of remission was 14 years.

Second-Line Therapies

• Change to nonocclusive footwear	C
• Sport avoidance	C
• Emollients	C
• Topical corticosteroids	C
• Rotation of topical agents	C
• Topical tacrolimus	C

Juvenile plantar dermatosis. Can sweat cause foot rash and peeling?

Gibbs NF. Postgrad Med 2004; 115: 73–5.

A review of the disease, its etiology, and its treatment.

Juvenile plantar dermatosis

Graham RM, Verbov JL, Vickers CFH. Br J Dermatol 1987; 12: 468–70.

Although there was no association with any particular sport, intensive exercise causing skin cracking, soreness, and bleeding was a common complaint; 75% of parents said that a change in footwear had not been helpful.

In contrast to Jones et al. earlier, only 30% of cases in this series had resolved (mean age 11.8 years), though the ages of the remaining 70% were not stated.

Juvenile plantar dermatosis responding to topical tacrolimus

Shipley DR, Kennedy CTC. Clin Exp Dermatol 2005; 31: 453–4.

Topical 0.1% tacrolimus twice daily in conjunction with a regular emollient produced improvement within 4 weeks, with the feet appearing almost normal after 2 months. Intermittent tacrolimus was useful for relapses.

Third-Line Therapies

• Zinc oxide/impregnated bandages	C
• Bed rest/footwear avoidance	E

Juvenile plantar dermatosis

Graham RM, Verbov JL, Vickers CFH. Br J Dermatol 1987; 12: 468–70.

Occlusion with zinc paste or ichthammol-impregnated bandages was among the most beneficial of treatments.

The etiology of juvenile plantar dermatosis

Shrank AB. Br J Dermatol 1979; 100: 641–8.

Bed rest or avoidance of shoes/hosiery for 3 weeks resulted in disease clearance (thought to be related to the time taken for the sweat duct apparatus in the foot to regrow).

Juvenile xanthogranuloma

Megan Mowbray, and Lynsey Taylor

Juvenile xanthogranuloma (JXG) is a benign disorder characterized by solitary or multiple yellow-red nodules in the skin and, occasionally, in other organs. Lesions usually regress spontaneously by age 6 months to 3 years. JXG is most common in infancy and early childhood, but adults may be affected. Treatment is only recommended for systemic lesions if their location interferes with

organ function.

Management Strategy

The diagnosis of JXG is usually made clinically, but a biopsy is required for atypical clinical variants (giant, plaque-like, paired, clustered, infiltrative, lichenoid, linear, subcutaneous, and intramuscular) and if multiple lesions are present. JXG is classified as a “non-Langerhans cell histiocytosis” and characterized histologically by an accumulation of foamy histiocytes lacking Birbeck granules (non-Langerhans cells) and multinucleated Touton-type giant cells. Immunohistochemical staining of lesions shows expression of factor XIIIa, cluster of differentiation (CD68), CD163, fascin, Human leukocyte antigen-antigen D related (HLA-DR), and CD14 but not S100 or CD1a. This pattern of expression suggests that the cell of origin of JXG is the dermal dendrocyte. The histogenesis of this group of conditions is unclear, but the relationship to Langerhans cell histiocytosis (LCH) is thought to be divergent differentiation from a common precursor CD34+ myeloid cell. Cases of the two conditions reported in the same individual suggest that this divergent maturation is not irreversible. B-Raf proto-oncogene (BRAF) Valine (V) substituted by glutamic acid (E) at codon 600 (V600E) mutations have been found in high frequency in LCH and Erdheim–Chester disease (ECD), suggesting a common origin of these diseases, but not, however, in any of the other histiocytoses.

The JXG family can be divided into three groups:

- Cutaneous – JXG, benign cephalic histiocytosis, generalized eruptive histiocytosis, adult xanthogranuloma, progressive nodular histiocytosis
- Cutaneous with a major systemic component – xanthoma disseminatum
- Systemic – ECD, rarely seen in children

In the most common solitary type of JXG (60%–89% of all cases), there is a male-to-female preponderance of 1.5:1. The usual affected sites are the head, neck, and upper trunk. In young infants with multiple lesions the male:female ratio increases to 12:1. In the majority of cases no further investigation is required, with lesions regressing spontaneously within months or years without the need for follow-up. Because involvement of other organs can occasionally occur in the cutaneous group, a review of systems and general examination is

recommended to exclude extracutaneous involvement and to examine for café au lait macules (see later).

Eye involvement

The eye is the most commonly affected extracutaneous site of JXG. Uveal lesions are the most frequently reported, but lesions affecting the eyelid, orbit, conjunctiva, cornea, and optic nerve have also been described. Ocular symptoms and signs include unilateral redness and tearing, hyphema (hemorrhage into the anterior chamber), retinal detachment, and/or visible lesions of the corneal limbus, eyelids, optic nerve, or papilla. Iris lesions may lead to hyphema and glaucoma. The incidence of eye involvement in cutaneous JXG is only 0.2% to 0.4%, but ocular JXG can occur without cutaneous disease and can be locally aggressive.

Systemic JXG

Systemic JXG is classically defined as involvement of two or more visceral organs in addition to multiple cutaneous and subcutaneous lesions. However, there are many reports of extracutaneous involvement occurring both with and without cutaneous lesions. After the eye, the subcutis, central nervous system (CNS), lung, liver, and spleen are the most common sites, but there are reports of every organ system in the body being affected (testes, spine, tongue, and heart, among others). *Given the differential diagnosis is usually neoplasia, it is imperative to determine an accurate diagnosis.* As with the skin, extracutaneous lesions regress spontaneously, and treatment is therefore *only indicated in cases where organ function is compromised.*

Triple association of JXG, NF-1, and JMML

It is likely that there is an association of JXG with NF-1 (neurofibromatosis-1). Children with NF-1 have a 200- to 500-fold greater risk of developing juvenile myelomonocytic leukemia (JMML), and the triple association of JXG, NF-1, and JMML has also been reported. JMML is an aggressive myeloproliferative disorder of childhood that has an annual incidence of 1.2 per million, and although the absolute incidence is not known, it is possible that in a population of children with NF-1, the incidence of JMML could be

between 1/2000 and 1/5000. An awareness of the increased risk of JMML in NF-1 and in cases with both JXG and NF-1 is important to ensure early diagnosis. Furthermore, the high frequency of JXG in NF-1 has been found useful diagnostically in children under 2 years with NF-1, as the seven clinical criteria required for diagnosis are of limited value before the age of 2 years. As well as JXG, naevus anemicus (NA) is found in high frequency in patients with NF-1, especially in children under 2 years with fewer than two diagnostic criteria.

Association of JXG and hematologic malignancy in adults

In adults there have been sporadic reports of xanthogranulomas preceding or arising concurrently with hematologic malignancies.

Specific Investigations

- In most cases, no specific investigations are required
- Ophthalmologic assessment in children under the age of 2 years with multiple lesions
- Full blood count and/or pediatric referral in children with JXG and café au lait macules, NF-1, or a family history of NF
- Biopsy in cases of unusual clinical variants
- Biopsy in cases with systemic manifestations to avoid unnecessary invasive diagnostic procedures

High prevalence of BRAF V600E mutations in Erdheim-Chester disease but not in other non-Langerhans cell histiocytoses

Haroche J, Charlotte F, Arnaud L, von Deimling A, Hélias-Rodzewicz Z, Hervier B. Blood 2012; 120: 2700–3.

BRAF status obtained in 93 cases. BRAF mutations were detected in 54% ECD, 38% LCH, and none of the other histiocytoses.

Radiological and clinicopathological features of orbital xanthogranuloma

Miszkiel KA, Sohaib SAS, Rose GE, Cree IA, Moseley IF. Br J Ophthalmol 2000; 84: 251–8.

Of 150 cases of intraocular JXG, none was identified on routine

screening of individuals with cutaneous JXG. Of those children with eye involvement, 92% were under the age of 2 years, and if present, cutaneous lesions tended to be multiple.

Juvenile xanthogranuloma

Hernandez-Martin A, Baselga E, Drolet BA, Esterley NB. *J Am Acad Dermatol* 1997; 36: 355–67.

Recommendations are made in this review article following assessment of previously reported cutaneous and extracutaneous cases. In general, an awareness of the possibility of extracutaneous involvement is important.

The risk of intraocular juvenile xanthogranuloma: survey of current practices and assessment of risk

Wu Chang M, Frieden IJ, Good W. *J Am Acad Dermatol* 1996; 34: 445–9.

A postal survey of pediatric dermatologists (27% response rate) and ophthalmologists (44% response rate) revealed the difference in incidence of ocular xanthogranuloma presenting to both groups. Children under the age of 2 years with multiple skin lesions have the highest risk of intraocular involvement and should be screened by an ophthalmologist.

Juvenile xanthogranuloma associated with neurofibromatosis-1: 14 patients without evidence of hematologic malignancies

Cambhiangi SD, Restano L, Caputo R. *Pediatr Dermatol* 2004; 21: 97–101.

A retrospective review of 14 individuals affected by JXG and NF-1. The onset of JXG was within the first 2 years of life in 13 patients. Mean follow-up was for 4.3 years (range 1–10 years) in 11 patients, and none of these children developed hematologic malignancy during this period.

JXG, NF-1 and JMML: alphabet soup or a clinical issue?

Burgdorf WH, Zelger B. *Pediatr Dermatol* 2004; 21: 174–6.

An editorial comment and review on this triple association, which concludes that there is no evidence to support an increased risk of JMML in children with the combination of JXG and NF-1 compared with those children with NF-1 alone.

Juvenile xanthogranuloma in a child with previously unsuspected NF1 and JMML

Raygada M, Arthur DC, Wayne AS, Rennert OM, Toretzky JA, Stratakis CA. *Pediatr Blood Cancer* 2010; 54: 173–5.

Case report of a 9-month-old male with the triple association of JXG, NF-1, and JMML.

NF-1 diagnosed in a child based on multiple JXG and JMML

Jans SR, Schomerus E, Bygum A. *Paediatr Dermatol* 2015; 31: e29–31.

Case report of a 9-month-old male with multiple JXGs and NF-1 who developed JMML at 20 months of age.

Juvenile xanthogranuloma and naevus anemicus in the diagnosis of neurofibromatosis type 1

Ferrari F, Masurel A, Olivier-Faivre L, Vabres P. *JAMA Dermatol* 2014; 150: 142–6.

Among 72 patients with NF-1, 23 had JXG or NA. Both lesions were more frequent in those younger than 2 years. None of those with JXG developed chronic myelomonocytic leukemia.

First-Line Therapies

• None	E
• Surgical resection for symptomatic cutaneous and extracutaneous lesions	D

Juvenile xanthogranuloma: forms of systemic disease and their clinical implications

Freyer DR, Kennedy R, Bostrom BC, Kohut G, Dehner LP. *J Pediatr* 1996; 129: 227–37.

Surgery can be an effective cure for symptomatic extracutaneous lesions of JXG.

Update on juvenile xanthogranuloma: unusual cutaneous and systemic variants

Wu Chang M. *Semin Cutan Med Surg* 1999; 18: 195–205.

In adults, lesions tend not to resolve spontaneously and can last up to 7 years; excision may therefore be considered appropriate.

Second-Line Therapies

• Topical and intralesional corticosteroids for ocular lesions	D
• Oral corticosteroids	E
• Ocular surgery	E
• CO ₂ laser for cutaneous lesions	E

Early treatment of juvenile xanthogranuloma of the iris with subconjunctival steroids

Casteels I, Olver J, Malone M, Taylor D. Br J Ophthalmol 1993; 77: 57–60.

Ocular lesions have been successfully treated with topical and intralesional corticosteroids.

Severe congenital systemic juvenile xanthogranuloma in monozygotic twins

Chantorn Wisuthsarewong W, Aanpreung P, Sanpakit K, Manonukul J. Pediatr Dermatol 2008; 25: 470–3.

Monozygotic twins with multiple cutaneous JXG, hepatosplenomegaly, liver failure, and bone marrow involvement. Treatment with systemic prednisolone 1 mg/kg/day with regression of lesions.

Infiltrative subcutaneous juvenile xanthogranuloma of the eyelid in a neonate

Kuruvula R, Escaravage GK Jr, Finn AJ, Dutton JJ. Ophthal Plast Reconstr Surg 2009; 25: 330–2.

Successful treatment with a combination of intralesional and oral corticosteroids.

Juvenile xanthogranuloma of the corneoscleral limbus

Lim-I-Linn Z, Li L. Cornea 2005; 24: 745–7.

Case report of successful surgical excision and grafting of a limbal juvenile xanthogranuloma in a child without cutaneous lesions.

Multiple juvenile xanthogranulomas successfully treated with

CO₂ laser

Klemcke CD, Held B, Dippel E, Goerdt S. J Deutsch Dermatol Ges 2007; 144: 481–2.

Case report describing successful treatment of cutaneous JXG with CO₂ laser, with no recurrence at 5-year follow-up.

Third-Line Therapies

• Chemotherapy, including oral corticosteroids	D
• Radiotherapy	D
• Oral methotrexate	E
• Pulsed methylprednisolone	E
• Vemurafenib	E

Use of radiation in treatment of CNS JXG

Vijapura CA, Fulbright JM. Paediatr Hematol Oncol 2012; 29: 440–5.

Case report of a 13-year-old successfully treated with adjuvant radiotherapy for intracranial and leptomeningeal JXG. Literature review to identify all previous CNS JXG cases utilizing radiation, with six of eight patients demonstrating temporary or long-term improvement of neurologic disease.

Treatment of JXG

Stover DG, Alapati S, Regueira O, Turner C, Whitlock JA. Pediatr Blood Cancer 2008; 51: 130–3.

Two case reports of multisystem JXG. Treatment with LCH-based chemotherapy regimens resulted in prompt resolution of symptoms. This paper includes a literature review of all reported multisystem JXG cases treated with chemotherapy. Ten prior studies describe 15 cases (29 chemotherapeutic regimens of multisystem JXG). Twelve of the 15 patients received some form of corticosteroid; 9 of the 12 receiving corticosteroid had stable disease (SD), partial response (PR), or complete resolution (CR). Regimens that included corticosteroids

and a vinca alkaloid had the highest and those without corticosteroids the lowest rates of CR, PR, or SD, respectively.

Pediatric lymphomas and histiocytic disorders of childhood

Allen CE, Kelly KM, Bollard CM. *Pediatr Clin North Am* 2015; 62: 139–65.

A comprehensive review of the current science and treatment strategies for all pediatric patients with lymphoma and histiocytic disorders. Cladribine and clofarabine have been reported as effective in patients with refractory or recurrent JXG. Therapies for ECD have included interferon (IFN- α) and recently vemurafenib.

Cladribine is highly effective in the treatment of Langerhans cell histiocytosis and rare histiocytic disorders of the juvenile xanthogranuloma group

Adam Z, Szturz P, Pour L, Krejčí M, Zahradová L, Tomáška M, et al. *Vnitr Lek* 2012; 58: 455–65.

This paper presents a survey of published experience with cladribine (2-CdA) in patients with LCH and JXG. Seven publications describe therapy response in certain JXG variants (ECD, disseminated JXG, and localized form of plain xanthoma type) to cladribine.

Juvenile xanthogranulomatosis with bilateral and multifocal ocular lesions of the iris, cornealscleral limbus, and choroid

Longmuir S, Dumitrescu A, Kwon Y, Boldt HC, Hong S. *JAAPOS* 2011; 15: 598–600.

Case report of 14-month-old boy with JXG skin lesions presenting with increased intraocular pressure, hyphema, anterior uveitis, iris mass, and subconjunctival limbal mass of the right eye with subsequent development of subretinal mass in the left eye. Ophthalmic disease responded to periocular injections of triamcinolone, topical prednisolone, oral prednisolone, and methotrexate. First published case using methotrexate as adjunctive treatment of JXG in a child.

Kaposi sarcoma

Niraj Butala, Sandra Pena, and Steven M. Manders

Kaposi sarcoma (KS) is a distinct, often multifocal, endothelial neoplasm etiologically linked to Kaposi sarcoma herpesvirus (KSHV) or human herpesvirus 8 (HHV8), predominantly transmitted via saliva but also by solid organ transplantation. In the United States, epidemic or acquired immunodeficiency syndrome (AIDS)-associated KS is the most common presentation; however, transplant or iatrogenic immunosuppression-related KS is on the increase. In clinical practice, classic and endemic KSs are also encountered. Therapy is similar for each type.

Management Strategy

Generally, the goals of therapy target cosmetic improvement, palliation, or cessation of progression. For treatment purposes, patients can be divided into several groups. Dermatologists most often encounter limited cutaneous KS, defined as fewer than 10 skin lesions, a lack of oral or visceral involvement, and the absence of tumor-associated lymphedema. Treatment options include *cryotherapy*, *intralesional vinblastine*, *radiotherapy*, and *alitretinoin gel*. Because treatment is essentially for cosmesis, side effects such as pigmentary changes and pain become important in therapeutic decisions.

For patients with resistant limited disease, extensive cutaneous involvement, systemic KS, or tumor-associated lymphedema, treatment modalities include liposomal anthracyclines (pegylated liposomal doxorubicin or liposomal daunorubicin), taxanes (paclitaxel), and interferon- α . For epidemic KS, effective antiretroviral therapy (ART) can by itself be sufficient to halt disease progression and has been found to have a synergistic effect with the *liposomal anthracyclines*, *paclitaxel*, and *interferon- α* . However, several cases of worsening of KS with the initiation of ART have been reported as part of an immune reconstitution syndrome. Iatrogenic immunosuppression-associated KS can respond to a reduction in treatment doses or a change in the immunosuppressive regimen to *sirolimus*. *Radiotherapy* remains an alternative treatment option for this group of patients.

Treatment of oral lesions is problematic because of inaccessibility to cryotherapy and radiation-induced mucositis. Options include *intralesional vinblastine*, sclerosing agents such as *sodium tetradecyl sulfate*, or systemic treatments.

An increasing number of investigational therapeutics have been explored for the treatment and prevention of KS, including antiangiogenic agents, antiviral agents, orally active matrix metalloproteinase inhibitors, tyrosine kinase inhibitors, and agents targeting interleukin (IL)-12.

Specific Investigations

- Serology for human immunodeficiency virus (HIV), CD4+ T-lymphocyte counts, viral load (if HIV positive)

- Complete blood count, renal and hepatic function
- Chest radiograph
- Stool for occult blood
